ABSTRACT

Background

P2X7R is a nucleotide receptor that binds extracellular ATP and is present on the cytoplasmic membrane of numerous cell types, including all inflammatory and immune cells. P2X7R plays a key role in inflammation, mediating activation of the NLRP3 inflammasome and release of cytokines such as IL-1 β , and in regulating several cell death mechanisms. Expression of P2X7R was found in both the bulb and the ocular adnexa. Furthermore, on the ocular surface P2X7R is activated by chemical or mechanical sources of exogenous stress, leading to inflammation, apoptosis and cell proliferation. At the retinal level, abnormalities in P2X7R function have been linked to neuronal loss in glaucoma and neuroinflammatory processes in age-related macular degeneration and diabetic retinopathy. Based on a careful analysis of the recent literature on the involvement of P2X7R in the pathogenesis of various ocular diseases, this observational interventional study was conducted, aiming to:

- assess the presence of the soluble form of the purinergic P2X7 receptor (sP2X7R) in aqueous humour and vitreous humour;
- compare sP2X7R levels in healthy conditions and in the presence of various ocular or systemic pathological conditions with ocular involvement, underlying an inflammatory pathogenesis, such as: glaucoma, Fuchs endothelial dystrophy, pseudoexfoliation, age-related macular degeneration, diabetes mellitus and retinal detachment;
- compare sP2X7R levels in aqueous humour and vitreous humour with those in serum.

Methods

The patients enrolled in the study are represented by subjects undergoing eye surgery at the Ophthalmic Clinic Unit of the Sant'Anna Hospital of Ferrara. In the group of pathological subjects there are aqueous humour and serum samples taken from patients with different ocular pathologies who underwent planned cataract extraction surgery and vitreous humour and serum samples from patients with retinal detachment who underwent vitrectomy surgery. The control group included aqueous humour and serum samples from patients undergoing cataract extraction surgery in the absence of other eye disease and vitreous and serum samples taken from patients undergoing vitrectomy for macular hole or macular pucker.

Results

In this study, the presence of a soluble form of the P2X7 receptor (sP2X7R) was assessed, which was found to be detectable in aqueous humour and vitreous humour using a specific ELISA kit. The concentrations of sP2X7R in aqueous humour control group are in the range of 3.89-93.87 pg/ml and in pathologic group the concentration range from 3.55 to 277.4 pg/ml. In vitreous humour the range is 4.21-76.92 pg/ml in the control group, whilst in pathological condition the range was 28.52 to 284.57 pg/ml.

The Kruskal-Wallis Chi-squared on the equality of the medians of the groups, both control and pathology groups of the aqueous samples, (Kruskal-Wallis chi-squared = 18.254, df = 10, p-value = 0.05082) estimates a p-value slightly above the test reliability limit (p=0.05), confirming that the median value of the sP2X7r concentration measured in the pathology groups, when all the data are considered together, is significantly different from the control group. Despite the finding of high maximum concentrations of P2X7r in its soluble form in the disease groups, analysing each pathology group compared to the control group, statistical analysis using Dunn's Test to perform the pairwise comparison of the groups with the Bonferroni's correction factor, failed to confirm a statistically significant difference.

The non-parametric hypothesis test performed with the Kruskal-Wallis Test on the equality of the median of the groups in Figure 20 (Kruskal-Wallis chi-squared = 4.6481, df = 3, p-value = 0.1995) does not allow the initial hypothesis to be rejected with probability p-value = 0.1999 (Talbe 17). The test result therefore does not allow the assertion that there is a significant difference between the P2X7r content in the vitreous of healthy patients and patients with the studied eye diseases

Conclusions

In this study the presence of the soluble form of the P2X7 receptor in aqueous humour and vitreous humour was tested for the first time, and the ELISA kit used proved to be a reliable tool. In the global examination of pathologic groups it can be stated that sP2X7R is a marker of ocular inflammatory status in, but the stratification analysis failed to prove a significant correlation with the single pathology.

Those data reflect a local and time-limited reality, but could lay the groundwork for further investigation.

CHAPTER 1: THE P2X7 RECEPTOR

Generalities on the P2X7 receptor

The P2X7 receptor (P2X7R) is a member of the P2X receptor subfamily (P2XR), which is part of the P2 nucleotide receptor (P2R) family. The P2X7R, which is present on the cytoplasmic membrane, binds extracellular ATP and, depending on the agonist concentration and time of stimulation, can behave either as a selective cation channel or as a non-selective membrane pore capable of allowing the passage of molecules with masses up to 900 Da [1] [2].

The receptor is widely distributed in human tissues and expressed in numerous cell types including neurons, dendritic cells, fibroblasts and endothelial cells. In addition, P2X7R is expressed by all inflammatory and immune cells, belonging to both innate and adaptive immunity. Its activity has been best characterised in the monocyte-macrophage lineage, including dendritic cells, microglia and osteoclasts, but it is also present in T lymphocytes, B lymphocytes and their precursors [3] [4].

The P2X7 receptor has been extensively demonstrated to play a key role in both inflammation and immunomodulation under both septic and sterile conditions [5] [6], including the inflammatory response developed in allergic reactions [7]. In addition, P2X7R mediates the activation of the NLRP3 inflammasome, the release of cytokines, such as IL-1 β and IL-18, chemokines and oxygen free radicals [5], promotes the proliferation and differentiation of T lymphocytes [8] and the activation of several transcription factors. In addition, depending on cell type and agonist binding, P2X7R can act as a cytotoxic receptor regulating various cell death mechanisms such as apoptosis, pyroptosis and necrosis [9] [10]. Its function in neoplastic cell growth processes and tumour progression has been documented. This makes P2X7R a potential target for anti-inflammatory and anti-tumour therapies [11] [12].

Although the function of the receptor has been well characterised under pathological conditions, in which high concentrations of ATP in the extracellular environment trigger multiple inflammatory processes, accumulating evidence suggests that P2X7R also has a basal level of tonic activation in healthy cells and tissues, supported by physiological amounts of endogenously released ATP, where it probably regulates cellular ion balance, supports mitochondrial metabolism and thus ATP synthesis, promotes motility and supports cell proliferation and differentiation [13] [14].

Inflammation and DAMPs

Inflammation is an essential defence mechanism involving components of innate immunity and is a key homeostatic response to protect the body from exogenous or endogenous sources of tissue or cellular damage. The main targets of the inflammatory response are:

- localising and eliminating the initial cause of the injury, such as pathogenic micro-organisms or toxins, and the products of that injury (e.g. damaged cells and necrotic tissues)
- initiate reparative processes, promoting healing.

It develops through reactions that take place at various levels: vascular responses; responses based on the coordinated activity of specialised cells of the lymphoid and myeloid lines, which are responsible for the innate and adaptive immune response; responses linked to the intervention of plasma proteins of inflammation.

Inflammation may be acute or chronic, depending on the nature of the stimulus, the duration of the reaction and the result achieved in terms of elimination of the noxious agent and damaged tissue. Usually when the acute inflammation, which mainly involves neutrophil granulocytes, succeeds in eliminating the noxious stimulus, the reaction is extinguished. However, if the target is missed, a chronic response may occur. Chronic inflammation, which may follow acute inflammation or have a slow and insidious onset, lasts longer and is associated with the presence of macrophages and lymphocytes, the formation of new blood vessels, fibrosis and tissue destruction.

However, inflammation can become a source of damage or disease because the same inflammatory mechanisms have the capacity to damage healthy tissues as well, where conditions arise in which inflammatory reactions are inappropriately directed towards host tissues or, because they are not adequately controlled, damage healthy cells and tissues. Inflammatory reactions are at the basis of many types of diseases and therefore many research efforts are aimed at identifying mediators and biomarkers that allow early recognition of the inflammatory process or factors that may be potential therapeutic targets to prevent or treat the resulting damage [15].

A crucial role in triggering the inflammatory process is played by PRRs (**Primitive Pattern Recognition Receptors**), receptors present on the surface of innate immunity

cells such as monocytes, macrophages, dendritic cells and neutrophils, which are able to recognise and bind two classes of molecular patterns: PAMPs, Pathogen-associated molecular patterns, expressed or released by pathogenic microorganisms, and DAMPs, Damage-associated molecular patterns, expressed or released by host cells during damage or cell death. The acronym DAMPs refers to different classes of molecules that are normally sequestered intracellularly and released after cellular damage; once in the extracellular space, DAMPs activate the immune system by interacting with specific receptors to trigger protective and regenerative responses [16]. One of the oldest and most conserved DAMPs is extracellular ATP, which performs this role by binding to purinergic P2X receptors, of which P2X7R is one of the most relevant.

The role of ATP in inflammation

Adenosine-5'triphosphate (ATP) is a ribonucleotide consisting of a nitrogenous base, adenine, a pentose sugar, ribose, and three phosphate groups. The hydrolysis of the two pyrophosphate bonds, which bind the three phosphate groups to each other, allows a considerable amount of energy to be released. For this reason, it is universally recognised that ATP plays a central role in maintaining the energy homeostasis of cells: While it is the main product of reactions such as oxidative phosphorylation, cellular respiration and fermentation, it can also be regarded as an energy donor in most endoergonic processes, i.e. a series of reactions in which energy from the hydrolysis of pyrophosphate bonds is used to support cell survival and to enable cell proliferation and motility [17]. Mammalian cells contain intracellular ATP concentrations of between 5-10 mmol, and even higher levels of ATP are stored within special storage structures such as synaptic vesicles. At non-adrenergic and non-cholinergic nerve endings in the central and peripheral nervous systems, ATP acts as a neurotransmitter by binding to purinergic receptors, while at the level of dense platelet granules, once released it amplifies ongoing platelet activation through an autocrine and paracrine mechanism [18] [19].

Signalling by extracellular ATP

In complex multicellular organisms, cells communicate through different types of molecules, which are used in a variety of ways: they can diffuse in intercellular space, they can be transferred through intercellular channels shared between one cell and another, or they can be released into extracellular space via the vesicular system. Theoretically, all living cells are able to release variable amounts of this nucleotide into

the extracellular environment to exchange information between cells of the same kingdom (eukaryote-eukaryote or prokaryote-prokaryote cell), but also across different kingdoms (prokaryote-eukaryote) [20]. Although it is generally accepted that purine nucleotides appeared among the primordial mediators of cell-cell communication, it is only in recent decades that the role of ATP as a ubiquitous extracellular messenger and in particular its character as an inflammatory mediator of the immune system has been highlighted.

In recent years, the mechanism of signalling via extracellular ATP has received extensive experimental support, especially after the development of techniques that allow direct measurement of ATP concentration in different pathophysiological contexts such as the tumour microenvironment (TME), the inflammatory microenvironment (IME), at ischaemic sites and in regions of tissue injury [21] [22].

The most important and recent advance in this field has been the introduction of the pmeLUC (plasma membrane luciferase) probe, a chimeric protein that, being sensitive to ATP concentrations in the micro-millimolar (μmol - mmol) range and insensitive to other nucleotides, allows the semi-quantitative measurement of extracellular ATP levels in living organisms [23]. As a result of this groundbreaking research work, the role of extracellular ATP in inflammation and immunity has been supported by direct *in vivo* demonstration that inflammatory sites contain high concentrations (hundreds of $\mu\text{mol/L}$) of ATP, as opposed to the interstitium of healthy tissues where the concentration is below the nanomolar (nmol) range [24].

There are several stimuli and mechanisms by which ATP is released into the extracellular environment to perform its mediating function. ATP can be released from damaged or dead cells through damage to the cytoplasmic membrane, which is why it is considered one of the first and most important DAMPs. Given that ATP from the cellular processes of glycolysis or oxidative phosphorylation is normally present at very high physiological intracellular concentrations (mmol/L) and higher than in the physiological extracellular environment, where it is found in minimal quantities, it can be deduced that this difference in concentrations across the negatively charged plasma membrane generates a strong gradient towards the extracellular environment. This gradient is both chemical and electrical because at physiological concentrations of Mg^{2+} and Ca^{2+} , one ATP molecule carries two negative charges. Given these premises, it can be deduced that any breach in the integrity of the plasma membrane will cause a timely outflow of large quantities of ATP which, being soluble in an aqueous environment, will quickly diffuse into the extracellular environment due to its low molecular weight and electrical charge [25]. In

the extracellular space, ATP undergoes rapid enzymatic degradation by ectonucleotidases, soluble or plasma membrane-associated enzymes that not only control the half-life of ATP as a receptor agonist, in order to avoid over-stimulation or desensitisation of the purinergic receptor, but also generate its metabolites such as ADP or adenosine, which are also ligands of specific purinergic receptors [26]. The main metabolite of ATP is adenosine, which is a potent immunosuppressive agent capable of attenuating the inflammatory reaction and can be considered as a component of a negative feedback signalling system, an additional control factor of most homeostatic systems [27]. In addition to efflux in passive mode, ATP can also be released from intact cells through active mechanisms involving different pathways that can be dependent on vesicular transport, as in constitutive or regulated exocytosis, or using transmembrane channels and proteins, such as pannexin-1 and connexin-43, the CALHM (Calcium homeostasis modulator) ion channel and the P2X7 receptor (P2X7R) [28] [29]. Several pro-inflammatory stimuli have been found to trigger the extracellular release of ATP, although the signalling pathways involved in many cases have not been identified or fully characterised. Immune cells are able to release ATP in response to bacterial PAMPs such as endotoxins (e.g. LPS, lipopolysaccharide) to signal the presence of microorganisms, but at the same time bacterial colonies are able to release ATP to shape the mucosal immune response and establish a controlled tolerance between commensal microorganisms [30]. It has been shown that the accumulation of LPS in the cytosol of human macrophages triggers the release of ATP through the activation of pannexin1 [31] [10]. No less important is the fact that infections by intracellular bacteria and protozoa trigger the release of high amounts of ATP, which on the one hand promotes the propagation of damage and on the other hand triggers an immune response [32]. It is worth mentioning that reactive oxygen species (ROS) are involved in multiple intracellular signalling pathways [33], just as hypoxia, a condition commonly found at inflammatory sites, is another well-known factor in promoting ATP release [34]. From the above considerations, it can be understood that the high intraextracellular gradient of ATP, its release into the intercellular environment in response to different stimuli, its high solubility in water, its rapid degradation by membrane nucleotidases that regulate its extracellular concentration, and the presence of specific purinergic receptors, make ATP a true extracellular messenger, a ubiquitous mediator involved in septic and sterile inflammation. This signalling system has a high signal-to-noise ratio (SNR), so the release

of even small amounts of ATP from the cell generates a very strong signal because it leads to a high increase in extracellular fractional concentrations [11].

Purinergic receptors

Generalities

Purines and pyrimidines, the building blocks of all living organisms, are the main constituents of nucleotides and nucleosides, ubiquitous molecules that perform a variety of functions as basic building blocks of nucleic acids, coenzymes, allosteric modulators, energy intermediates, intracellular and extracellular messengers [35]. During evolution, complex multicellular organisms, from plants to higher mammals, have developed a signalling system that exploits the release of ATP as an extracellular messenger; interestingly, although in plants and animals they evolved from different proteins by gene recombination [36], receptors for extracellular ATP are widely expressed in all *phyla*, where they regulate similar protective responses for cell survival and tissue homeostasis. A radical change has occurred in recent years where a large body of scientific evidence has shown that nucleotide signalling governs some of the most essential immune responses; In particular, it has been observed that ATP accumulation in IME and TME produces multiple effects and supports various processes such as inflammatory cell migration, specifically macrophage and neutrophil chemotaxis, antigen-driven proliferation of T lymphocytes, cell differentiation to Th1 or Th2, and killing of intracellular pathogens, activation of NADPH-oxidase [37], maturation and activation of the NLRP3 inflammasome and release of IL-1 β and IL-18, and can also facilitate the release of cytokines, chemokines and growth factors, production of ROS and nitrogen radicals, stimulation of stromal or tumour cell growth and even possess direct toxicity effects [38] [39].

Classification

Purinergic receptors are divided into two families: P1 receptors, selective for adenosine, comprising four subtypes, A1, A2A, A2B and A3, and P2 receptors, selective for purine nucleotides, comprising two subfamilies with distinct pharmacological profiles: metabotropic G-protein-associated P2YRs and ionotropic P2XRs. Eight members of the P2YR subfamily (P2Y1, 2, 4, 6, 11-14) and seven members of the P2XR subfamily (P2X1-, 2, 4, 6, 11-14) were identified.

7).

P2Y receptors (P2YR) show a higher affinity for ADP, UDP, UTP, UDP-glucose, or UDP-galactose, except for P2Y11R which is the only ATP-selective one. In contrast, the P2XRs have ATP as their preferred physiological agonist, whereas they are inactive for other nucleotides [40].

P2XRs are ionotropic receptors whose subunits associate to form ion channels for the transit of monovalent (Na^+ , K^+) and bivalent (Ca^{2+}) cations. The subunits (P2X1-7) can combine to form homo-multimers or hetero-multimers. When three ATP molecules bind to the extracellular portion of a P2X receptor, a conformational change takes place that generates a rapid opening, in the millisecond range, of a channel that makes the plasma membrane permeable to positively charged ions, causing an increase in intracellular Ca^{2+} and Na^+ and a simultaneous decrease in the intracellular K^+ concentration. Opening of the channel leads to depolarisation of the cell membrane and initiation of ^{2+}Ca -dependent signalling events downstream. Only the P2X7R has the peculiarity of forming a non-selective membrane pore when exposed for longer to higher concentrations of the agonist. P2X receptors are widely expressed in different human and animal tissues: at pre- and post-synaptic endings of the nervous system, or in various types of muscle cells, such as those of cardiac muscle, skeletal muscle and smooth muscle fibrocells of the bladder and vas deferens, but also in epithelial cells, endothelium and platelets [41] [42]. Little is known about the functions of P2X5R and P2X6R in the immune system, with the exception of the up-regulation of P2X5R in CD34+ leukaemic myeloid cell subpopulations and T lymphocytes [43] [44]. In contrast, the role of P2X1, P2X4 and P2X7 receptors has been better characterised in human immune cells. P2X1R has been associated with the regulation of metabolism, T-lymphocyte proliferation and neutrophil overflow. P2X4R has been implicated in the activation of the transcription factor NFAT and the modulation of T-lymphocyte responses [45]. In this panorama, the P2X7 receptor stands out as the only member of the family

P2XR with a firmly established role in multiple inflammatory and immune responses. Nevertheless, P2Y receptors are also variously implicated in several inflammation-related, ATP-associated responses, such as chemotaxis, release of proinflammatory cytokines and stimulation of platelet granule component release. Incidentally, the different selectivity of P2YRs suggests that other nucleotides could also act as DAMPs [46] [47].

Table 1. Classification of P2 receptors (Di Virgilio et al., 2017)

Receptor	Preferred agonist	Coupled mechanisms	Transduction mechanism	Intracellular signalling
P2YRs				
P2Y1	ATP, ADP	Gq/G	PLC activation and IP3 production	Ca ²⁺ increase
P2Y2	ATP, UTP			
P2Y4	UTP			
P2Y6	UDP			
P2Y11	ATP	G/G-Gs _{q11}	PLC activation and IP3 production Stimulation of adenylate cyclase	Increase in Ca ²⁺ /cAMP
P2Y12	ADP	I _o	Inhibition of adenylate cyclase	Decrease in cAMP
P2Y13	ADP			
P2Y14	UDP-glucose UDP-galactose			
Receptor	Preferred agonist	Assembled subunits	Mechanism of transduction	Intracellular signalling
P2XRs				
P2X1	ATP	P2X1, P2X2, P2X4, P2X5	Cation-selective ion channel	Increase in Ca ²⁺ and Na ⁺
P2X2		P2X2, P2X3, P2X6		
P2X3		P2X3, P2X2		
P2X4		P2X4, P2X6		
P2X5		P2X5, P2X1		
P2X6		P2X6, P2X2, P2X4		
P2X7		P2X7	Ion selective channel for cations, Membrane pore non-selective	Increase in Ca ²⁺ and Na ⁺ , Decrease in K ⁺

Genetics, protein structure and function of the P2X7 receptor

The P2X7R is an ATP-dependent homotrimeric membrane ion channel, i.e. formed by the assembly of three identical P2X7 subunits. Rapid stimulation with low concentrations of physiological (ATP) or synthetic agonist Bz-ATP [2',3'-O-(4-benzoylbenzoyl)-ATP], generates the opening of a cation channel 0.7-0.8 nm in diameter that allows the influx of Na⁺ and Ca²⁺ and the efflux of K⁺, leading to a large increase in intracellular Na⁺ concentration and depolarisation of the plasma membrane. Ca influx²⁺ increases the intracellular Ca²⁺ concentration, thereby activating calcium-dependent signalling pathways, while K⁺ efflux, by lowering the cytosolic Ca concentration, promotes the activation of additional processes such as assembly and activation of the NLRP3 inflammasome. Prolonged stimulation with high concentrations of ATP (0.5-1 mmol) causes the opening of a non-selective pore with a larger diameter (4nm) that is permeable to hydrophilic solutes of molecular weight up to 900 Da, which are normally not diffusible through the membrane, such as choline, methylglucamine, ethidium bromide, YO-PRO-1 or lucifer yellow. This also causes the efflux of low molecular weight cytoplasmic solutes, including ATP itself. The purinergic P2X7 receptor does not undergo desensitisation, so the pore formed by ATP stimulation remains open as long as the agonist is present in the extracellular environment, and closes after its removal. Macropore formation, which requires the presence of the intracellular C-terminal tail of P2X7, has been associated with NLRP3 inflammasome activation and P2X7R-mediated cytotoxicity [48] [49] [50].

In fact, recent work shows, through detailed electrophysiological analysis of the human and murine P2X7R, that the increase in conductance through the macro-pore, rather than occurring only after prolonged stimulation by the agonist, occurs without delay after P2X7R 'gating' allowing both large (e.g. YOPRO-1) and small cationic fluxes to pass simultaneously [51] [52]. YOPRO-1) and small cation fluxes and that permeability to organic solutes is an early and intrinsic property of the channel itself that does not require progressive dilation of the channel [51] [52].

The gene encoding for P2X7R is located in humans at the level of the long arm of chromosome 12, at 12q24.3, centromeric and close to the gene for P2X4R (12q24.32). The sequence homology between P2X7 and P2X4 monomers is 41%. A number of single nucleotide polymorphisms (SNPs) have been identified and some of these genetic variants, present in the coding region, result in gain-of-function or loss-of-function

versions of the receptor, some of which are associated with different disease conditions. The selection of mutated alleles may in fact be due to selective environmental pressure exerted by infectious agents or chronic inflammatory conditions [53] [54].

Nine different human isoforms of P2X7 subunits resulting from alternative splicing processes were identified and the full-length canonical form was named isoform A (P2X7A). The human truncated B variant is probably the isoform that has been best characterised in terms of its pathophysiological role and has been associated with cell growth, mesenchymal cell differentiation and tumour progression. Truncated variants are mostly non-functional, but it has been seen that some of them can behave as positive or negative modulators of the canonical A isoform [55] [56] [57].

Each P2X7 monomer is a protein of 595 amino acids that assembles into a trimeric complex to form the three-dimensional functional form of P2X7R. The P2X7 monomer has a short intracellular N-terminal residue (26 aa), an extended extracellular loop (282 aa), two transmembrane helices TM1 and TM2 (approximately 24 aa each) and a long cytoplasmic carboxy-terminal tail (239 aa). The extracellular loop contains pockets for binding to agonists and antagonists. In the C-terminal tail, there is a sequence homology site for the TNF receptor (TNFR1) and an LPS binding site homologous to that found on serum LPS binding proteins in the acute phase. The carboxy-terminal tail is crucial for the formation of the membrane pore that gives P2X7R its high conductance, and the presence of extra amino acids in this portion distinguishes it from other P2XR receptors [50]. Without this tail, the P2X7B splicing variant forms a receptor lacking the ability to form the macropore, while retaining ion channel activity [57].

Information on the tertiary structure and general architecture of the P2XR receptor family in both the closed (apo) and open (ATP-bound) forms was obtained by homology from the resolution of the crystallised structure of P2X4R in zebrafish, of the human P2X3R and the P2X7R in the panda (*Ailuropoda melanoleuca*) and this allowed us to specify the three-dimensional structure of the P2X7R, the ATP binding site, the interaction between the subunits and the mechanism of membrane pore opening [58] [59] [60].

The three-dimensional structure of the P2X3, P2X4 and P2X7 monomers was assimilated to the shape of a dolphin and the various subunit domains were made to correspond to the anatomical parts of the dolphin: the two transmembrane helices (TM) form the tail and the segments of the extracellular region form the various body sections i.e. head, side fins and dorsal fin. (Figure 1). Dolphin anatomy is now generally adopted to identify specific

regions in the tertiary structure of P2X7 subunits and also to describe the architecture of the P2X7R.

The ATP binding sites are located on the extracellular domains, at the interface between two adjacent subunits, between the dorsal fin of one subunit and the tail and left fin of the adjacent subunit, while the ion channel is formed by the TM2 helix of each subunit [58]. Comparison of the apo and ATP-linked crystallised structure suggests the mechanism of "gating and channel opening:

Binding to ATP triggers a major conformational rearrangement whereby the monomers change their orientation towards each other, thus behaving like rigid bodies without altering their configuration. During this process, the head domain of the monomers approaches the dorsal fin of the adjacent units, while the TM domains change their orientation towards each other, thus generating a pore formed by lateral fenestrations lined by the TM2s of each monomer. The process of channel formation allows for the rapid flow of Na⁺ and Ca²⁺ inwards and the flow of K⁺ outwards. Both inward and outward ion fluxes are critical in the implementation of P2X7R-activated responses. The onset of the current is followed by a phase of inactivation, called desensitisation, and recovery. In the other receptors of the family, prolonged exposure to the agonist would cause inactivation of the receptor, but a peculiar feature of the human P2X7R (and also possible in P2X2R and P2X4R) is the absence of desensitisation under continuous agonist stimulation, which instead promotes further rearrangement with reorientation of the three monomers that allows transmembrane flow to hydrophilic molecules. This progressive increase in activity is a property called facilitation [61] [62].

Homology models based on the structure of P2X3R explain that ATP binding of P2X7R causes a reorientation of the three monomers and the formation of a so-called 'cytoplasmic cap' consisting of the N- and C-terminal segments and partially covering the end of the transmembrane pore. Another interesting property of the increased conductance of P2X7R is its reversibility upon ATP removal. This property has been exploited to trap normally non-permeable low molecular weight aqueous solutes such as nucleotide analogues, fluorescent probes and anticancer drugs in the cytoplasm of different cell types [63] [5].

Architecture of human P2X7R reconstructed using homology models based on the crystallised structure of human P2X3R. The role of the P2X7 receptor in inflammation

The P2X7R receptor is unanimously recognised as the main ATP sensor during inflammation and the most potent stimulus for NLRP3 inflammasome activation and thus mediates the maturation and secretion of Interleukin-1 β (IL-1 β) of the early phase of the immune response [64]. Synthesis of pro-IL-1 β , a 31 kDa immature protein, begins with activation of the nuclear transcription factor NF- κ B. Maturation into the bioactive 17 kDa form requires cleavage by caspase-1, which in turn is activated from pro-caspase-1 through formation of the inflammasome. Without this conversion, pro-IL-1 β is rapidly degraded by the proteasome [65] [66]. The NLRP3 inflammasome is a multi-protein intracellular complex formed by the assembly of four components that create a heterotetramer consisting of a central NLRP3 protein, which is a structural, scaffold protein, to which other proteins are associated when the immune cell is activated: an adaptor protein ASC, pro-caspase-1 and the sensor protein Nima-kinase 7 (NEK7). The NLRP3 inflammasome is activated by ATP but can also assemble in response to PAMPs from infectious agents, other DAMPs or chemical and physical agents that cause cellular damage [67]. When the NLRP3 component is activated, the adaptor protein ASC is recruited, which brings NLRP3 into contact with pro-caspase-1. Activation of caspase-1 is an autocatalytic phenomenon. By bringing several caspase-1 elements next to each other, as these are proteolytic enzymes, they are self-activated by self-proteolysis releasing the activated caspase-1, which can act on pro-IL-1 and produce mature IL-1. This assumes that since the formation of the initial heterotetramer, for proteolytic activation by self-proteolysis to occur, several heterotetramers must come into contact with each other, bringing into contact several pro-caspase-1 molecules. In fact, the mature inflammasome is a penta- or heptameric structure composed of the aggregation of 5 or 7 heterotetramers that form a cytoplasmic superstructure [68].

Membrane pore function is a prerequisite for NLRP3 activation, suggesting that a major reduction in intracellular K⁺ is required to trigger the process, although the underlying molecular mechanism has not yet been elucidated [69]. Recent evidence suggests that localised modification of the intracellular ionic microenvironment directs the recruitment of inflammasome components and facilitates their assembly in the vicinity of the P2X7R itself, and that decreased intracellular K⁺ enhances the interaction of NLRP3 with the NEK7 protein, a sensor of the ionic concentration of the microenvironment in which the inflammasome is located. NEK7 is required for P2X7R-driven inflammasome assembly

and evidence of this is the fact that ATP-stimulated NLRP3 activation is abrogated in NEK7-deficient bone marrow-derived macrophages [70].

In addition, P2X7R is a strong stimulus for the externalisation of active IL-1 β as it is the main driver of multiple release mechanisms, such as passive release following cell death or secretion through lysosomes, exosomes or plasma membrane-derived microvesicles [71] [72].

Following the results of some recent evidence, an alternative model of P2X7R activation in inflammation has been formulated according to which the binding of PAMPs to membrane receptors or sensors in the cytoplasm triggers the controlled release of ATP and autocrine/paracrine stimulation of P2X7R. This leads to the inference that stimulation of P2X7R activates intracellular effector systems (e.g. the NLRP3 inflammasome) and further amplifies the effect of other pro-inflammatory agents by releasing ATP, which in turn acts as an inflammatory stimulus [73].

P2X7R also promotes inflammation through the activation of different intracellular pathways

which may also be associated with inflammasome formation. One example is the activation of the transcription factor NF- κ B, probably through an adaptor protein that interacts with the C-terminal domain of P2X7R, to enable the expression of genes encoding for several components of the inflammatory chain including IL-1, TNF- α and cyclooxygenase (COX) enzymes [74]. Expression of COX-2 and activation of COX-1 by P2X7R has been associated with the occurrence of fever and inflammatory pain, which is why it could be considered a potential target for new drugs, alternative to non-steroidal anti-inflammatory drugs (NSAIDs), such as aspirin [75] [76]. Other signalling pathways associated with P2X7R are Ca-dependent²⁺ activation and translocation into the NFAT core to promote lymphocyte and osteoblast proliferation, a process that can also promote tumour cell multiplication [77] [78]. Other pro-inflammatory cytokines secreted upon P2X7R activation include IL-6 and IL-1 α , albeit through inflammasome-independent pathways, and other inflammatory mediators such as prostaglandin E2, leukotriene B4 and thromboxane A2. Furthermore, stimulation of macrophages via P2X7R leads to the release of VEGF (vascular endothelial growth factor) suggesting its involvement in regeneration and neoangiogenesis processes [79] [80].

Inflammatory signalling pathways activated by P2X7R: activation of NLRP3 inflammasome, synthesis and release of IL-1β and IL-18; activation of NF-κB via MyD88 and promotion of IL-1β gene expression; NFAT²⁺ factor-dependent activation leading to IL-2 synthesis, lymphocyte proliferation and down-regulation of GSK3β factor. In addition, stimulation of P2X7R promotes activation of HIF-1α and subsequent VEGF release.

(Adinolfi et al., 2018)

The role of the P2X7 receptor in cell death

The P2X7 receptor is considered a cytotoxic receptor and a potent activator of cell death, which can occur by different mechanisms depending on cell type, agonist concentration and duration of binding. In the absence of bacterial-derived products, as is the case in sterile inflammation, the most common type of cell death triggered by P2X7R is necrosis [5]. P2X7R is not only linked to cell necrosis, but its stimulation in mouse lymphocytes has been observed to lead to oedema and cell lysis. It has also been shown that the P2X7 receptor, activated by binding to ATP, allosteric modulators or pathogens, promotes pyroptosis in mononuclear cells, a type of caspase-1-dependent inflammatory cell death [81]. In human cells, pyroptosis can be triggered by caspases-1, -4 and -5 [82]. Stimulation of the receptor by ATP can lead to the release of cytochrome-C from the mitochondria and the cleavage of caspases-3, -8 and -9, which are directly linked to the mechanism of apoptosis [83].

Soluble form of P2X7 receptor

Research recently conducted at the University of Ferrara has led to evidence that a soluble form of the full-length P2X7R receptor (sP2X7R) is released into the blood under both healthy and pathological conditions. Specifically, sP2X7R was found to be present in both plasma and serum regardless of storage mode. In contrast to the low concentrations found in healthy control subjects, levels of the soluble form are much higher in different pathological conditions including infectious diseases, ischaemia, cancer and other conditions such as autoimmune diseases and trauma. By measuring levels of C-reactive protein (CRP), considered a systemic inflammatory marker, it was observed that sP2X7R levels correlated with CRP levels. Furthermore, taking into account a PCR cut-off of 3mg/dL, considered to indicate a systemic inflammatory state, a significant increase in sP2X7R concentration was found in subjects with PCR > 3 mg/dL. These results indicate that the measurement of plasma sP2X7R could complement the assessment of PCR and other markers currently used to investigate a subject's inflammatory status. Possible sources of the plasma soluble form of the receptor include peripheral blood mononuclear cells (PBMCs) isolated from peripheral blood. PBMCs isolated from healthy subjects release sP2X7R into the culture medium after stimulation with BzATP [2',3'-O-(4-benzoylbenzoyl)-ATP], an ATP analogue, and to a greater extent after pre-stimulation with LPS, simulating an inflammatory condition on an infectious basis in vitro. Finally, the study showed that plasma sP2X7R is present to a large extent associated with

microvesicles/microparticles (MVs/MPs), i.e. heterogeneous populations of particles of different sizes and cellular origin [84].

CHAPTER 2: P2X7R AND EYE DISEASES

P2X7R locations and functions in the eye

Purinergic receptors are abundantly distributed in the various ocular segments and perform many functions in the physiological field, but dysregulation of the biomolecular processes involving them can also contribute to the development of ocular pathologies.

The P2X7R receptor is expressed both in the eyeball and in the ocular adnexa. On the ocular surface, this receptor is activated by chemical or mechanical sources of exogenous stress, such as by contact with ophthalmic solutions containing preservatives or surfactants, or by corneal abrasion, leading to inflammation apoptosis and cell proliferation. In the case of corneal injury, the P2X7R receptor acts, in coordination with P2Y2R, to ensure appropriate tissue repair by promoting epithelial cell adhesion to the basement membrane, coordinating Ca^{2+} mobilisation, rearrangement of the cytoskeleton and formation of a normal stromal collagen structure. At the retinal level, the P2X7R receptor and abnormalities in its function have been potentially linked to neuronal loss occurring in glaucoma and hereditary retinal degeneration, as well as contributing to neuroinflammatory processes occurring in age-related macular degeneration and diabetic retinopathy [85].

Table 2. Expression of the P2X7R receptor in the eye structures of different species. (Dutot et al.,2017)

Fabric	Cells	m-RNA		Protein	Species
Cornea	Corneal epithelial cells				Human
	Section of cornea		+		Mouse
	Corneo-limbal epithelial cells	+	+		Human
Conjunctive	Conjunctival epithelial cells		+		Human
	Calico cells		+		Rat
Crystalline	Lenticular fibres	+	+		Rat
	Epithelial cells		+		Human
Retina	Müller cells	+	+		Human
	Section of retina	+	+		Rat
	Retinal Ganglion Cells	+			Rat
	Retinal pigment epithelium cells (ARPE-19 cell line)		+		Human
	Retinal pigment epithelium cells (primary culture)	+	+		Human
	Retinal pigment epithelium cells	+	+		Mouse
	Photoreceptors	+	+		Rat
Ciliary body	Epithelial cells	+			Bovine

P2X7R as a therapeutic target

The P2X7 receptor has recently attracted particular interest as a potential therapeutic target due to its wide involvement in ocular diseases. Several highly selective P2X7R inhibitors are currently available, some of which are in phase 1 and 2 clinical trials for the treatment of certain chronic inflammatory diseases [86] [87] [88] [89]. Understanding the exact functioning of the molecular mechanisms associated with the P2X7R receptor in the context of ocular diseases would be important in order to adopt new therapeutic strategies to prevent the onset of visual symptoms or slow down the progression of disease processes towards more advanced stages and thus limit their impact in terms of visual disability.

Topical administration of medication, in most cases in the form of eye drops, is usually used to treat diseases of the anterior segment of the eye, particularly the cornea and conjunctiva. In this regard, hyaluronic acid or sodium hyaluronate (HA) is considered to be a potent modulator of the P2X7 receptor, and pre-treatment with this molecule is able to reduce P2X7R-mediated oxidative and apoptotic damage induced by sodium lauryl sulphate, an anionic surfactant with irritating power, and benzalkonium chloride, a quaternary ammonium salt that is widely used as an antimicrobial preservative [90] [91].

Although oral administration is not a very efficient way of delivering a therapeutic molecule to the eye, the administration of omega-3-rich fatty acids, such as docosahexaenoic acid DHA and eicosapentanoic acid EPA, combined with Brilliant Blue G, a potent selective P2X7 receptor antagonist, has been shown to prevent the neurocytotoxic effect of amyloid β in age-related macular degeneration (AMD) [92].

To date, no P2X7R inhibitors are commercially available for the treatment of retinal diseases, but several antagonists of this receptor, which attenuate IL-1 β production, have been found to cross the blood-brain barrier. The NJ55308942 molecule reduces Ca²⁺ conductance through P2X7R and IL-1 β release from blood monocytes and cultured microglia. In addition, in experimental animal models, following oral administration at increasing doses of this compound, there is an increase in the number of P2X7 receptors occupied by microglia, suggesting that it is able to cross the blood-brain barrier. Consistently, treatment with JNJ55308942 in mouse models of chronic stress reduced inflammation and the subsequent clinical signs associated with it [93]. Given the similarities in the structure of the blood-brain barrier with the blood-retinal barrier, it is likely that several brain-permeable receptor antagonists, including JNJ-55308942 or JNJ-5417446, could be effective in the treatment of P2X7R-associated retinal disease [94].

Recently, dimeric nanoparticles have been developed that are able to reduce or increase P2X7R conductance, inhibit membrane pore formation and IL-1 β release in macrophages and T cells, and in experimental in vivo models of allergic contact dermatitis and glomerulonephritis have been shown to be effective in attenuating the inflammatory process [95].

Against this background, further studies are needed to analyse the potential of various P2X7R antagonists and inhibitors in ophthalmological diseases.

The following is a review of the most recent knowledge concerning a potential involvement of the P2X7R receptor in the pathogenesis of several ocular diseases.

Diabetic eye diseases

Diabetes mellitus is one of the most prevalent metabolic diseases in the world. The potentially fatal condition affects more than 422 million people worldwide and its prevalence is expected to grow to 592 million by 2035 [96] [97].

Diabetes mellitus develops when the endocrine pancreas is no longer able to synthesise insulin and/or when the body becomes resistant to it due to persistently high blood glucose

levels. The 3 main types of diabetes are Diabetes Mellitus type 1, Diabetes Mellitus type 2 and Diabetes Mellitus type 3.

Diabetes Mellitus Type 2 and gestational diabetes. Chronic hyperglycaemia and failure to control the condition leads to various microangiopathic complications at the tissue level, the most common of which in the visual system are diabetic keratopathy and diabetic retinopathy [98].

Diabetic keratopathy

Diabetic keratopathy or diabetic corneal epitheliopathy is a degenerative corneal disease. Some of the clinical features present at the corneal level in a patient with diabetes are: delayed corneal re-epithelialisation with impaired wound healing, reduced corneal sensitivity (hypo-anesthesia), neurotrophic ulcers and corneal oedema. These features are mainly caused by the fact that local hyperglycaemic conditions lead to multiple effects on corneal tissue, including: changes in corneal epithelial basement membrane composition, deposition of advanced glycation products (AGEs), damage to corneal nerve endings, reduced tear secretion and oxidative stress.

It is also known that the hyperglycaemic environment leads to abnormalities at the stromal level and at the level of endothelial cells, whose morphological changes and altered cell density are some of the factors that lead to neovascularisation and increased corneal thickness [99]. Furthermore, during the initial phase of diabetes, morphological changes are observed in the nerve fibres, which become thicker and degenerate due to the accumulation of advanced glycation end products (AGEs).

In addition to chronic hyperglycaemia, the cornea is also subject to high levels of inflammation and oxidative stress, hallmarks of diabetes in all tissues. The interaction between AGEs and their receptors (RAGE) causes the formation of oxygen free radicals and the release of pro-inflammatory cytokines. In the human eye, AGEs have been detected in the corneal stroma, Descemet's membrane, the basement membrane of the corneal epithelium, the lens and the lamina cribrosa. In a study in mouse models of diabetes induced by streptozotocin injections, AGEs immunoreactivity levels in the cornea were higher than in non-diabetic controls, and were localised to the epithelium, corneal stroma and endothelium, as reflected in the expression of the oxidative DNA damage marker 8-OHdG. Furthermore, treatment with the AGEs inhibitor aminoguanidine prevented the development of diabetic corneal structural abnormalities, such as degeneration of intracellular organelles, formation of cytoplasmic vacuoles and

oedema in the corneal stroma. In Western blot analysis, caspase-3 protein expression was significantly increased in diabetic corneas compared to non-diabetic controls, indicating that corneal cells also undergo apoptosis. In addition, the activation of NF- κ B and its elevated presence in diabetic corneas suggest that the AGE/RAGE interaction leads to NF- κ B activation, which promotes increased oxidative stress and transcription of pro-apoptotic cytokines, thereby mediating corneal tissue damage in diabetes [100].

Mankus et al. found that P2X7 receptor expression is increased in corneal epithelium samples from diabetic donors compared to age-matched controls [101].

Using a mouse model of pre-diabetes type 2 with diet-induced obesity (DIO), changes in corneal sensory nerves and P2X7R expression were characterised under diabetic conditions. A significant reduction in sub-basal nerve plexus density associated with increased tortuosity and decreased diameter was observed. In addition, P2X7 mRNA expression was significantly higher in the corneal epithelium of DIO mice and, after abrasion, the increase in transcription was more intense in the central regions of the abraded area, where the cells migrated after injury, and in the peripheral areas surrounding the abrasion. The re-epithelialisation process was slower and incomplete in DIO mice compared to controls, suggesting that dysregulation of P2X7R expression may be associated with the altered healing process in diabetic corneas. While in non-diabetic controls P2X7R is more highly expressed at the main wound margin, it is less specifically distributed in DIO mice. This feature allows us to hypothesise that normally the purinergic receptor may play a role in promoting protein migration and cytoskeletal rearrangements at the healing margin of a corneal wound, whereas in diabetic conditions this activity is dysregulated [102].

Diabetic retinopathy

Diabetic retinopathy is the most frequent microvascular complication of diabetes mellitus and includes all the pathological and functional changes observed in the retina as a result of chronic exposure to hyperglycaemia. It affects approximately one third of patients with type 1 and type 2 diabetes, with the risk increasing in proportion to the duration of the disease and the levels of glycosylated haemoglobin HbA1c. Diabetic retinopathy is the leading cause of visual impairment in the working-age population, accounting for 15-17% of cases of blindness [103].

Development of diabetic retinopathy

The progressive development of diabetic retinopathy follows different clinical stages that are set out in the International Classification or Severity Scale of Diabetic Retinopathy and Diabetic Macular Oedema drawn up in 2003 [104].

Table 3. Diabetic retinopathy (DR.) severity scale (Wilkinson et al., 2003)

Clinical stage	Retinal injuries
Non RD	No injuries
Mild non-proliferative RD	Microaneurysms only
Moderate non-proliferating RD	Any or all of the following signs: microaneurysms, retinal haemorrhages, hard exudates, cottony nodules; not associated with other lesions of severe non-proliferative RD
Severe non-proliferating RD	Any of the following signs and no signs of proliferative retinopathy: more than 20 intraretinal haemorrhages in all 4 quadrants; significant venous <i>beading</i> in 2 or more quadrants; IRMA (intraretinal microvascular abnormalities) prominent in 1 or more quadrants
Very severe non-proliferating RD	Two or more criteria for severe non-proliferating RD
Proliferating RD	One or more of the following: neovascularisation vitreous/pre-retinal haemorrhages
High-risk proliferating RD	One or more of the following: neovases on the disc greater than or equal to 1/3 of the disc area retinal neovases at least ½ the size of the haemovitreous disc area

Table 4. International diabetic macular oedema (EMD) severity scale. (Wilkinson et al., 2003)

Level of severity of macular oedema	Ophthalmoscopic signs
Mild EMD	Retinal thickening or hard exudates at the level of the posterior pole, but distant from the centre of the macula
Moderate EMD	Retinal thickening or hard exudates approaching the centre of the macula, but not involving the centre
Severe EMD	Retinal thickening or hard exudates involving the centre of the macula

Pathogenesis of diabetic retinopathy: the role of inflammation

During diabetic disease, various systemic metabolic changes develop, such as dyslipidaemia and hyperglycaemia, which are the starting points in the pathogenesis of the complications of this disease. In the eye, chronic exposure to high levels of glycaemia leads to the activation of various biochemical mechanisms such as the polyol and hexamine pathways, the activation of protein kinase C isoforms and the non-enzymatic glycation of proteins, which are the molecular basis for the initiation of pathological processes characteristic of diabetic retinopathy such as retinal microangiopathy, inflammation and neurodegeneration, causing structural and functional changes in the retina leading to irreversible impairment of visual function.

OXIDATIVE STRESS AND MITOCHONDRIAL DYSFUNCTION

Hyperglycaemia induces disruption of the electron transport chain at the level of the inner membrane of the mitochondria leading to the production of oxygen free radicals (ROS), such as superoxide anion. ROS are harmful to the mitochondria themselves by inducing oxidative damage at the level of the mitochondrial DNA leading to a dysfunction of the respiratory chain and thus to increased production of ROS and the auto-oxidation of glucose. Over time, ROS production saturates the capacity of antioxidant systems and leads to exposure of retinal cells to oxidative stress. Intracellular oxidative modifications of lipids, proteins and DNA promote further mitochondrial damage, inflammation, apoptosis and subsequent tissue effects. ROS-induced mitochondrial dysfunction also causes a reduction in ATP production and an increase in mitochondrial membrane

permeability, which leads to the release of apoptotic factors such as cytochrome c within the cell cytoplasm, inducing apoptosis in pericytes and endothelial cells. In parallel, hyperglycaemia promotes non-enzymatic glycation of serum, cellular and tissue proteins, leading to the formation of AGEs, the end products of advanced glycation. AGEs are able to bind to specific receptors called RAGE and activate the transcription factors NF- κ B, STAT (signal transducer and activator of transcription), AP-1 (activator protein 1) that trigger inflammatory processes, neurodegeneration and loss of pericytes at the retinal level, components of the retinal vascular walls [105] [106].

NEUROVASCULAR ALTERATIONS

Oxidative stress together with the inflammatory process induces neurotoxicity leading to apoptosis of **retinal** ganglion cells (RGCs) and hyperactivation of glial cells, in a process called neuroinflammation. Retinal ganglion cell damage is the result of oxidative stress, inflammation and hypoxia and emerges early, before the onset of obvious vascular lesions and before pericyte apoptosis [107] [108].

Neuronal death or dysfunction of retinal neuronal cells promotes the process of **reactive gliosis** indicated by the up-regulation of glial fibrillary acidic protein (GFAP) in astrocytes and Müller cells. Reactive gliosis is associated with increased activation of immune-related signalling pathways leading to increased production of pro-inflammatory factors and growth factors, contributing to vascular injury [109]. An elevated level of GFAP has been detected in the aqueous humour of diabetic patients without clinical signs of diabetic retinopathy or in patients with non-proliferative diabetic retinopathy.

The first vascular changes observed are the loss of pericytes and thickening of the basal membrane [110]. The loss of the pericytes of the retinal capillary wall, which normally line the outside of the capillary endothelium, guaranteeing greater mechanical resistance, would appear to be responsible for the breakdown of the blood-retinal barrier and the loss of vascular tone. This causes a progressive deformation and widening of the vessels, an increase in permeability and proliferation of endothelial cells due to the deficit of TGF- β , which was produced by the pericytes. These changes lead to the formation of microaneurysms and intraretinal haemorrhages, two of the first clinical features observable ophthalmoscopically in RDNP. In addition, thickening of the basement membrane and disjunction of the *tight junctions* are the factors determining *leakage* from the retinal capillaries with passage of the intravascular contents, mainly represented by lipids, proteins and inflammatory mediators, into the interstitial space.

Figure 3. (a) Fundus ocularis photograph, (b) Fluorangiography and (c) SD-OCT of a patient with Non-Proliferative Diabetic Retinopathy (RDNP) and Diabetic Macular Edema (EMD). In (a) hard exudates (arrows), microaneurysms and retinal haemorrhages (asterisks) can be observed. In (b) we observe multiple spots of hyperfluorescence prevailing in the areas where aneurysmal lesions and vascular leakage are present. In (c) we observe an SD-OCT where multiple intraretinal cysts (asterisk) and subfoveal neuroretinal detachment (arrow) are present. (Mesquida et al., 2019)

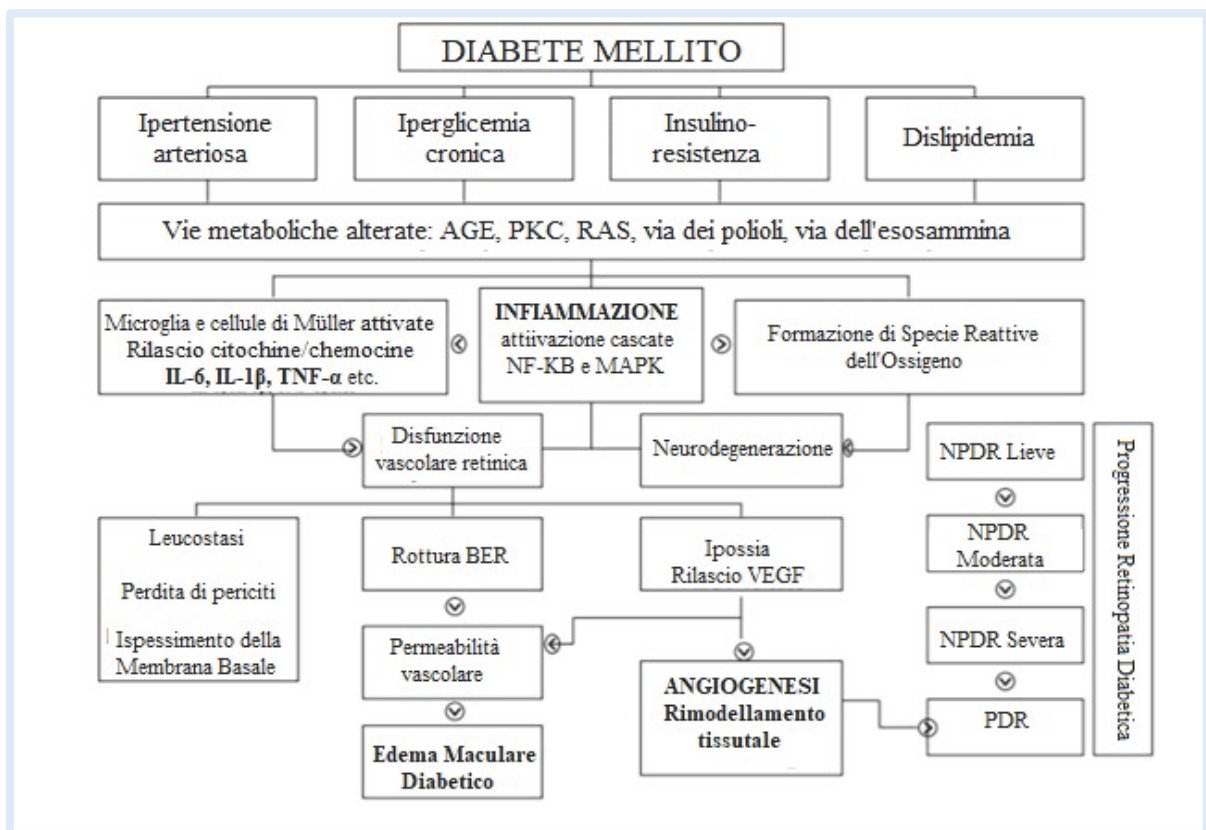

On the other hand, retinal glial cells, i.e. Müller cells and microglia, EPR, and macrophages lead to the secretion of vascular growth factors such as VEGF-A and pro-inflammatory cytokines, such as IL-1 β , TNF- α , IL-6, IL-8, MCP-1(monocyte chemoattractant protein 1), contributing to vascular dysfunction. Persistent secretion of inflammatory mediators can lead to the establishment of a state of chronic inflammation, which has two main effects on the retina: the breakdown of the blood-retinal barrier and leukostasis.

An alteration in the blood-retinal barrier results in an increase in vascular permeability, which has as its clinical consequence the appearance of hard exudates, due to the leakage of plasma constituents, especially lipids and proteins. As a result, fluids accumulate in the macula, leading to diabetic macular oedema, which, if left untreated, has the potential to impair visual function [111].

Pro-inflammatory factors lead to increased expression of adhesion factors on the surface of endothelial cells, in particular ICAM-1 (intercellular adhesion molecule 1) and VCAM-1 (vascular cell adhesion molecule 1), where activated leukocytes adhere, triggering a process called leukostasis.

Leukostasis is the determinant of retinal capillary occlusion and activation of the thrombogenesis process. The resulting ischaemia is one of the most severe complications of this pathological process and determines a progression of retinopathy towards an advanced form of proliferative type, where new vessels develop within the retina or optic disc. Indeed, hypoxia is able to activate the production of HIF-1 α (hypoxia inducible factor) in endothelial and glial cells, which feeds the process of angiogenesis by increasing the production of VEGF-A in endothelial cells, glial cells, astrocytes and EPR cells, the secretion of which is also favoured by ROS, hyperglycaemia itself, AGEs and inflammatory cytokines such as IL-1 β and IL-6 [112].

The importance of inflammation in this phenomenon has been demonstrated by the fact that blocking inflammation reduces neovascularisation. In mouse models of choroidal neovascularisation, elimination of the factor MCP-1, which is responsible for recruiting monocytes to hypoperfused areas, and elimination of ICAM-1 or CD18 leads to a significant reduction in the process of neoangiogenesis. Similarly, inhibition of cyclooxygenase-2 (COX-2), which normally produces prostanoids, reduces VEGF production and the resulting vascular *leakage* in animal models of diabetic retinopathy and reduces neovascularisation in mouse models of proliferative ischaemic retinopathy [113].

Schematic representation of the pathogenesis of damage and its progression in diabetic retinopathy. (Mesquida et al.,2019)

MICROGLIA AND NEUROINFLAMMATION

'Neuroinflammation' is a process that plays a major role in the pathogenesis of diabetic retinopathy. The fundamental mechanism by which the process of neuroinflammation begins in response to tissue nerve disturbances caused by the metabolic dysregulations of diabetes is microglial activation. Under normal conditions microglia cells are represented by dormant macrophages located in the inner layers of the retina.

In response to hyperglycaemia, dyslipidaemia, AGEs and oxidative stress, these cells become activated, retract their dendrites and assume an amoeboid phenotype whereby they infiltrate the deeper layers of the retina where they initially take on an anti-inflammatory role mediated by M2 cells to delay disease progression. However, persistent exposure to diabetic conditions leads to the decline of the M2 response with the respective emergence of M1 cells that assume a pro-inflammatory role and, by activating the NF- κ B and ERK pathways, contribute to neuronal damage by releasing neurotoxic factors such as glutamate, iNOS, caspases and TNF- α , IL-6, IL-1 β and VEGF [114] [115].

CYTOKINES AND ANGIOGENESIS

In support of the role of inflammation in the pathogenesis of diabetic retinopathy, several studies have shown a specific expression profile of various cytokines and proinflammatory factors in serum, aqueous humour and vitreous humour using *protein array* analysis techniques. Local pro-inflammatory biomarkers in ocular fluids, whose main source of production is retinal glial cells, correlate more precisely with the various stages of diabetic retinopathy and diabetic macular oedema than do their corresponding serum levels. These comparisons showed that:

- IFN- γ , IL-1 α , IL-3 and MCP-2 are higher in diabetic patients without clinical signs of DR than in non-diabetic controls.
- Factors IL-1 β , IL-3, IFN- γ , IFN- γ induced protein 10 (IP-10) and monocyte chemoattractant protein 2 (MCP-2) are significantly increased in diabetic patients compared to controls;
- Granulocyte-Macrophage Colony Stimulating Factor (GM-CSF), IFN- γ , IL-10, IP-10, Regulated And Normal T cells Expressed and Secreted (RANTES) and Soluble Tumour Necrosis Factor Receptor (sTNF-R) II are highly elevated in diabetics with mild DR compared to control cases;
- Macrophage Inflammatory Protein (MIP-1b), GM-CSF, RANTES and sTNF-RII increase more in diabetics with mild DR than in diabetics without DR. In more advanced stages of diabetic macular oedema and proliferative diabetic retinopathy, increased concentrations of IL-6, VEGF, IL-12, IL-8, IP-10, MCP-1, platelet-derived growth factor (PDGF) and ICAM-1 are reported in the aqueous humour, while IL-6, IL-8, TNF- α , IL-1 β , VEGF, ICAM-1, MCP-1 and complement factors are increased in the vitreous humour [116].

In addition to participating in the processes of neurodegeneration and apoptosis, the increased expression of pro-inflammatory cytokines in the diabetic environment promotes the creation of new vessels through the recruitment of endothelial cells, which are in turn induced to produce pro-angiogenic factors. Endothelial cells are extremely susceptible to cytokines, in particular IL-1 β , TNF- α , and IFN- γ , which induce the production of IL-8, MCP-1, and Regulated and normal T cells Expressed and Secreted (RANTES) in them. In vitro studies have shown that endothelial cells respond more to cytokines than to elevated glucose levels, suggesting that diabetes-induced retinal vascular injury is primarily due to cytokine release from neighbouring cells rather than the direct effect of hyperglycaemia on endothelial cells themselves [117].

P2X7R in the pathogenesis of diabetic retinopathy

P2X7R has been described at the level of ganglion cells, photoreceptors, amacrine cells, EPR and Müller cells and many studies in recent decades have linked P2X7R-related functions to the pathogenesis of diabetes.

In a recent study in mouse models, in which diabetes was induced by streptozotocin (STZ) injections, a significant increase in P2X7R expression was observed approximately one month after the onset of induced diabetes and simultaneously the percentage of P2X7R-positive peripheral blood mononuclear cells (PBMCs) was increased compared to controls [118].

The inflammatory microenvironment contains high concentrations of extracellular ATP, sufficient to trigger the opening of P2X7R and the release of the cytokines IL-1 β and IL-6, membrane metalloproteases and the production of ROS. In this regard, in mouse models of diabetes it has been observed that genetic deletion of P2X7R or its pharmacological inhibition protects against CD-40-induced release of TNF- α , IL-1 β , ICAM, and NOS-2 over-expression in Müller cells [119]. Moreover, P2X7R activation represents a powerful trigger for VEGF release. Indeed, the expression of the NLRP3 inflammasome, which can be activated by P2X7R stimulation, is increased in the vitreous fibrovascular membrane of patients with diabetic retinopathy and dysregulation of NLRP3 in hyperglycaemic transgenic mice leads to vascular *leakage* and retinal neovascularisation [120].

In a recent study in animal models of type 1 diabetes, it was found that hyperglycaemia induces increased P2X7R expression in the retina and that selective P2X7R antagonism reverses some of the diabetes-induced inflammatory effects in the retina, such as increased microvascular permeability and neovascularisation. This protective effect is accompanied in parallel by a strong inhibition of VEGF release and a normalisation of retinal IL-6 levels, thus supporting the hypothesis that P2X7R-related signalling plays a key role in promoting the inflammatory process and oxidative stress in the development and progression of diabetic retinopathy. [121]. Exposure of pericytes to high concentrations of glucose induces the activation of a P2X7R-mediated signalling pathway that promotes the acquisition by these cells of an inflammatory phenotype, as evidenced by the secretion of TNF- α and IL-1 β . In the same study that demonstrated this phenomenon, it was also found that hyperglycaemia-induced damage in retinal pericytes leads to cell lysis, accompanied by the release of ATP into the extracellular environment, which in turn binds P2X7R on neighbouring cells, activating the inflammasome and

taking on the function of an inflammatory damage signalling device through an autocrine-paracrine mechanism [122]. It was found that P2X7R ligand concentrations are not sufficient to induce apoptosis in controls, while they are able to induce cell death in retinal capillaries extracted from diabetic mice, suggesting that hyperglycaemia is able to increase the vulnerability of retinal vascular cells to P2X7R activation [123]. The ability of P2X7R to induce apoptosis in endothelial cells and retinal capillary pericytes, termed purinergic vaso-toxicity, is mediated by transmembrane pore formation, typically resulting from sustained stimulation of this receptor, and appears to play a crucial role in the development of microaneurysms, exudates and diabetic macular oedema due to disruption of the blood-retinal barrier [124].

A new investigation has shown that Lamivudine, a recently discovered nucleoside reverse transcriptase inhibitor of P2X7R, is able to attenuate the progression of vascular and neurodegenerative lesions of diabetic retinopathy in mouse models, in which, compared to non-diabetic controls, administration of this molecule inhibits the formation of acellular capillaries and simultaneously allows maintenance of neuroglial function [118].

Using drugs that target P2X7R could be an interesting prospect for the treatment of diabetic retinopathy in the future. Diabetic macular oedema is currently treated with intravitreal injections of biological drugs that antagonise VEGF, such as Bevacizumab, Ranibizumab and Aflibercept, or intravitreal implants of devices containing corticosteroids, such as Dexamethasone. These therapies are highly effective, but also impractical and invasive for patients who have to undergo monthly eye injections, so therapies based on small molecules that can be administered via minimally invasive routes, such as oral therapies or eye drops, would be desirable. Several pharmaceutical companies have developed highly selective P2X7R inhibitors, some of which are in phase 1 and 2 clinical trials for the treatment of certain chronic inflammatory diseases. Some of these molecules are permeable across the blood-retinal barrier and may be available in the future for the treatment of diabetic retinopathy.

Age-related macular degeneration

Age-related macular degeneration is a degenerative disorder affecting the central area of the retina, known as the macula, responsible for high-resolution colour vision, and is the major cause of severe and irreversible visual decline in people over 65 years of age in industrialised countries. This maculopathy affects about 10% of the population over 65 and more than 25% of people over 75.

The retinal pigment epithelium (EPR) is made up of a layer of pigmented cells located on the outside of the neurosensory retina and has multiple functions that are essential for maintaining homeostasis at the level of the photoreceptors, such as protecting the retina from excessive exposure to light, forming the blood-retinal barrier together with the vascular endothelium, and also playing an immune defence role at the level of the macula. The EPR undergoes numerous changes with age, which become clinically detectable on ophthalmoscopic examination when **there are** focal extracellular deposits of yellowish polymorphous material at the interface between the retinal pigment epithelium and the inner collagenous zone of Bruch's membrane. Drusen are made up of several potentially harmful molecules including: lipofuscin, a pigment composed mainly of lipids with esterified and non-esterified cholesterol, more than 120 different proteins such as amyloid- β , apolipoprotein E (APOE), clusterin, TIMP-3 (tissue metalloproteinase inhibitor 3) protein, proteins involved in complement regulation, immunoglobulins, acute phase proteins such as vitronectin and fibrinogen, together with zinc and iron ions. With ageing there is a progressive accumulation within the EPR cells of intracellular bodies containing lipofuscin that should normally be eliminated by the choriocapillaries [125].

Classification

There are several classification systems for AMD, used for clinical or research purposes, including:

- **conventional** classification, dictated by clinical and evolutionary characteristics [126]:

- Dry' form. The most common form, found in 90% of AWD diagnoses. It has a gradual progression with bilateral asymmetrical eye involvement and in 10% of cases it progresses to the wet form.

The presence of **soft drusen** and areas of focal hypo- and hyperpigmentation is characteristic. Soft drusen appear on **ophthalmoscopic examination** as yellowish-white subretinal deposits with generally ill-defined borders and a tendency to confluence.

The advanced stage is called **geographic atrophy (AG)** or areolar atrophy and is characterised by a progressive reduction in neuroepithelial thickness with defined-edge chorioretinal atrophy affecting the retinal pigment epithelium,

choriocapillaris and photoreceptors. There are no signs of macular scar thickening (disciform scar) nor of oedema, haemorrhage or exudation.

On **fluroangiography**, atrophic areas appear hyperfluorescent and associated with hypofluorescent areas. Focal pigment accumulations may vary in shape: punctiform, reticular or linear and appear as hypofluorescent areas on fluorangiography.

The loss of central vision occurs slowly over the years. In very early stages symptoms are modest and reading difficulties may occur due to blurred vision or altered size of some letters (micro- or macropsies); in more advanced stages positive scotoma, an area of vision loss in the centre of the visual field, and metamorphopsies, in which straight lines may appear distorted or broken in places, may appear.

- Wet' form. This is less common, affecting around 10% of cases. It has a more rapid course, leading to a significant reduction in vision within days weeks, and symptoms are often unilateral due to the tendency to affect one eye at a time.

The clinical picture at onset is characterised by a sudden reduction in visual acuity and the appearance of metamorphoses, positive central scotoma and blurred central vision. Peripheral vision and colour vision are generally unaffected. However, the patient may become legally blind in the affected eye (visual acuity < 20/200 in the better eye with corrective lenses), especially if treatment is not given.

The main pathophysiological alteration is **choroidal neovascularisation (NVC)**, caused by an imbalance between angiogenetic and antiangiogenetic factors. It is characterised by the proliferation of abnormal blood vessels that originate in the choroid, penetrate through Bruch's membrane and spread below the EPR and/or below the neuroretina and, in association with the proliferation of fibroblasts, form a fibrovascular complex that alters the normal architecture of the choriocapillaris, Bruch's membrane, EPR and photoreceptors, leading to the formation of subretinal scars.

Characteristic is the presence of retinal and subretinal macular oedema, grey-green dyschromia under the macula, haemorrhage in the retina, subretina or below the EPR, retinal or subretinal lipid exudation. Focal macular oedema or haemorrhage may lead to the elevation of a macular area or localised detachment

of the retinal pigment epithelium. Finally, untreated neovascularisation results in submacular disciform scarring and subretinal fibrosis.

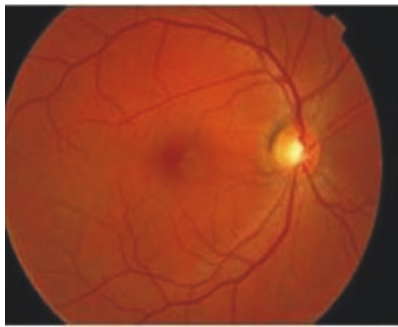

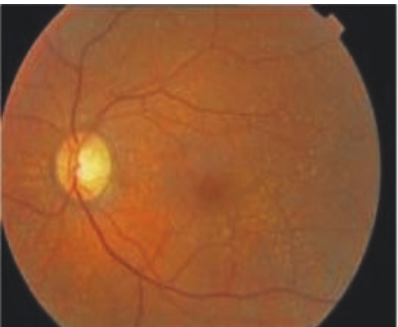

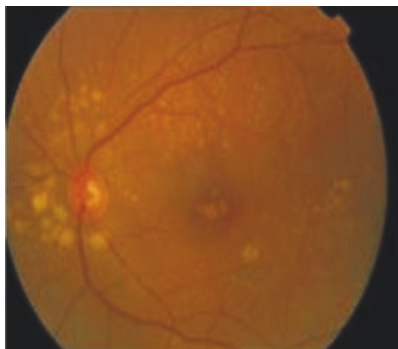

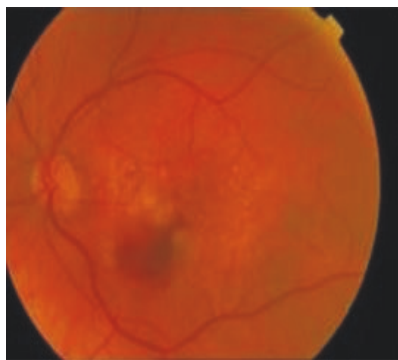

Based on **fluorangiographic** appearance, NVC can be divided into two subgroups:

Classical NVC: in early stages a delimited area of hyperfluorescence is visible and in late stages shows dye leakage; Occult NVC: characterised by the presence of late hyperfluorescence of undetermined origin or by detachment of the fibrovascular EPR.

- **Histological** classification divides NCV into 3 categories:
 - **Type 1** (or 'occult'), when the neovascularisation is localised below the EPR. Characterised by occult leakage to the FAG.
 - **Type 2** (or 'classic'), when the neovascularisation is localised above the EPR, in the subretinal space.
 - **Type 3** defined as retinal angiomatous proliferations (RAP), in which the neovascularisation develops in the context of the retinal layers and then progressively develops towards the subretinal space, creating a shunt with the choroidal circulation.

- **AREDS** classification, Age-Related Eyes Disease Study, used in clinical practice and in clinical and epidemiological studies [127]. (Table 5)

Table 5. Classification scheme of Age-Related Macular Degeneration according to AREDS (Age-Related Eye Disease Studies). (Al-Zamil et al., 2017)

Classification Category	Clinical signs
NO DMLE	 <p data-bbox="1007 510 1422 544">0-5 small drusen (<63µm in diameter)</p>
DMLE iniziale	 <p data-bbox="1007 763 1461 931">Multiple small drusen or a few drusen of intermediate size (63-124µm in diameter) or pigmentary abnormalities of the macula</p>
Intermediate DMLE	 <p data-bbox="975 1256 1437 1424">Diffuse intermediate drusen or at least one large drusen (≥125 µm) or Geographical atrophy not involving the central fovea</p>
Advanced DMLE	 <p data-bbox="975 1637 1453 1872">Geographical atrophy involving the central fovea or any signs of neovascularisation choroidal: subretinal haemorrhages, serous retinal detachment or detachment of pigment epithelium retinal, lipid exudates or fibrovascular scars.</p>

Aetiopathogenesis of Age-Related Macular Degeneration

The multifactorial pathogenesis of AMD consists of multiple activated molecular processes that have as their common denominator the dysregulation of the immune-inflammatory system.

Advancing age is accompanied, on the systemic side, by the emergence of a chronic low-level inflammatory state, known as 'Inflammaging', which can be seen as an increase in serum levels of pro-inflammatory cytokines. As we age, various oxidative insults increase and accumulate, and the controlled mechanism of para-inflammation also increases. Systemic para-inflammation concerns the immune response

Local ocular para-inflammation is the response of the eyes to insults occurring at the macular level, through which homeostasis is maintained at the level of the macula during the normal ageing process. The para-inflammatory response can become dysregulated as a result of multiple factors such as genetic predisposition, epigenetic changes or the intervention of environmental factors. The resulting chronic inflammation results in the loss of the immune privileged position possessed by the retina: there is activation of retinal immune cells, in particular microglia and dendritic cells, activation of the complement cascade and the inflammasome, with production of various pro-inflammatory cytokines that then damage the EPR and photoreceptors and lead to the development of AMD. Chronic sustained inflammation at the macular level can also lead to scar formation resulting in loss of central vision.

While ageing is the risk factor with the greatest impact, environmental factors that increase oxidative stress such as cigarette smoking, low antioxidant diets and phototoxicity from UV exposure also contribute significantly to the increased risk of onset and progression of AMD, along with the presence of various gene polymorphisms [128] [129].

IMMUNOGENTICS AND COMPLEMENT

Using wide-screening genomic techniques, some 52 genetic variants on different chromosomes related to AMD have been identified, many of which encode proteins involved in the regulation of the inflammatory and complement cascade in the immune system, but also proteins involved in mitochondrial function, collagen production, extracellular matrix production and angiogenesis.

The most important genetic risk factor associated with approximately 50% of cases of AMD is the Y402H polymorphism of the CFH gene on the 1q32 locus whose function is

to downregulate the alternative complement pathway. Thus, the presence of this gene variant leads to reduced complement factor H activity with activation of the complement cascade and triggering of the inflammatory process at the subretinal level [130]. Smoking can also lower CFH levels, which means that smokers have an increased risk of developing AMD [131]. Dysregulation of the immune system and complement is in fact one of the fundamental pathophysiological alterations in the development of maculopathy and also plays a major role in the mechanism of parainflammation of the retina undergoing ageing. Certain activation products of the complement cascade, such as C3a, C5a have been identified in the drusen of eyes affected by AMD and are also elevated in the serum of patients with AMD, compared to controls in the same age group. In some studies, exposure of choriocapillary endothelial cells to C5a in vitro has been shown to upregulate ICAM-1, an adhesion molecule that binds leukocytes, and C5a has also been shown to promote IL-22 and IL-17A secretion in human CD4⁺ T cells isolated from patients with exudative AMD. Indeed, IL-17A in vitro induces angiogenesis in choroidal endothelial cells and induces apoptosis and pyroptosis in ARPE-19 cells, which are part of a cell line derived from the retinal pigment epithelium. With the results of this research, it is possible to explain how cytokines derived from complement activation can induce neovascularisation and cell death at the macular level, two characteristics of neovascular AMD [132] [133] [134].

OXIDATIVE STRESS

Due to their high metabolic activity combined with high oxygen consumption and their polyunsaturated fatty acid content, EPR cells are usually prone to produce ROS, but daily exposure to sunlight and cigarette smoke contribute to making the EPR particularly sensitive to oxidative stress. A major function of EPR is heterophagy, a homeostatic mechanism aimed at autophagic degradation of materials from photoreceptor outer segments (POS) damaged by oxidative stress. Exposure to environmental factors, combined with a genetic predisposition for dysregulation of protective mechanisms, results in the continuous phagocytosis of this waste material by the cells of the retinal pigment epithelium, which are, moreover, aged and undividable. This leads to the accumulation in lysosomes of a non-degradable and self-fluorescent metabolite called lipofuscin, which inhibits the autophagy process by blocking the function of lysosomal enzymes and, in combination with oxidative stress, leads to the initiation of retinal inflammation. Lipofuscin is one of the key components of drusen and therefore it has

been hypothesised that it is these typical lesions that trigger the pathogenic inflammatory reactions that allow AMD to progress [135].

Studies have shown increased serum levels of oxidative markers such as malondialdehyde (MDA), and 8-hydroxy-2-deoxyguanosine (8-OHdG) in subjects with AMD compared to controls. In addition, cultured retinal pigment epithelium cells from eyes with AMD showed increased levels of ROS, AGEs and markers of oxidative damage in nuclear and mitochondrial DNA [136].

The EPR also possesses antioxidant systems that protect cells and photoreceptors from oxidative damage. Among these, the NRF2 (nuclear factor-erythroid 2-related factor 2) transcription factor-mediated signalling system, which is involved in maintaining mitochondrial metabolism by regulating several Krebs cycle enzymes, has been found to be altered and associated with retinal pigment epithelium degeneration in patients with AMD who are chronically exposed to cigarette smoke [137]. In addition, in vitro studies have shown that the antioxidant lutein can minimise the immune-inflammatory processes induced by oxidative stress in the retina by suppressing the activation of the NF- κ B factor and inhibiting the expression of enzymes such as iNOS and COX-2, the main sources of free radicals [138].

MICROGLIA, MACROPHAGES AND IMMUNOSENESCENCE

Retinal microglia cells together with dendritic cells and choroid macrophages are among the immune cells that play an essential role in counteracting retinal malfunctions and allowing the maintenance of retinal homeostasis during ageing. In the neuroretinal structures, the para-inflammatory response mechanism, characterised by the breakdown of the blood-retinal barrier, is activated by a series of subclinical damages that lead to the production of endogenous molecules called "Allarmine", which, at ocular level lead to the activation of microglia and their migration to the subretinal level, while at choroid level the proliferation of macrophage cells occurs accompanied by the activation of the complement at the EPR-basal membrane interface [139]. Several studies have identified the presence of two different macrophage lines on pathological analysis of eyes with AMD: M1 macrophages, which are proinflammatory, have been associated with geographical atrophy while M2 macrophages, found at the level of NVC formations, express the proangiogenic protein VEGF, suggesting their involvement in the development of these neovascular lesions [140]. With ageing, adaptive immunity cells, such as T lymphocytes, also undergo changes known as immunosenescence, and it has

been shown that there is *downregulation* of CD28, a co-inflammatory molecule involved in the formation of antigen-specific responses, and *upregulation* of markers typically found in natural killer (NK) cells, such as CD56, which have a non-specific reactivity. An increased number of CD56⁺ T cells was detected in the serum of patients with AMD compared to controls. Furthermore, CD4⁺ T cells play a combined role with complement in establishing an inflammatory reaction underlying pathogenesis [141].

CYTOKINES AND INFLAMMASOME

High concentrations of multiple pro-inflammatory cytokines have been found in both ocular tissues and fluids and in the serum of subjects with AMD compared to age-matched controls, suggesting that the level of 'inflammaging', i.e. the low-grade systemic inflammatory response related to the ageing process, is more severe in patients with AMD. At the systemic level, IL-1 β , TNF- α and IL-17 are elevated, where the production of the latter appears to be related to the increase in complement factor C5a [142].

Increased systemic concentrations of IL-6, IL-18 and TNF- α correlate with CFH gene haplotypes and IL-6 levels correlate with both the onset and progression of maculopathy. In addition, IL-6, which has pro-inflammatory and pro-angiogenic properties, is increased in aqueous humour from eyes of patients with neovascular AMD. The cytokines IL-22 and IL-17A, produced by the Th17 type of CD4-helper⁺ T lymphocytes, are elevated in the serum of patients with exudative AMD and were found in disease-typical lesions and not in normal macular tissue. In vitro, IL-22 induces apoptosis of human EPR cells, while IL-17A increases the production of proinflammatory cytokines produced by ARPE-19 cells, such as IL-6, IL-8 and CCL2, and induces angiogenesis in human choroidal endothelial cells [143].

A typical example of an age-related inflammatory response in the EPR is the activation of the NLRP3 inflammasome, which has been correlated with the pathogenesis of AMD because it is found in epithelial cells in lesions of both advanced forms of AMD. Several intra- or extracellular stimuli that are present in the eye during ageing can activate the NLRP3 inflammasome, such as AluRNA, β - substance, β - and β -substance.

amyloid, A2E (a chromophore retinoid contained in lipofuscin and aldehyde derivative of vitamin A involved in retinal ROS production and subsequent mitochondrial damage), lipofuscin and oxidised lipoproteins. Depending on the stimulus NLRP3 is able to produce IL-18, IL-1 β or both [144] [145] [146] [147] [148].

In a recent study, it was found that in vitro exposure of EPR cells to UVB induces ROS production and DNA damage. This contributes to IL-1 β production via a signalling pathway involving the NLRP3 inflammasome, activated by K⁺ efflux triggered by extracellular ATP, whose production is increased by UVB exposure. IL-18 production in the same cells is stimulated by UVB and ROS but through cellular pathways independent of the inflammasome [149].

A study group of patients with geographic atrophy showed higher concentrations of a non-coding RNA sequence called AluRNA in EPR cells and lower concentrations of DICER1 RNAase, an enzyme capable of cleaving and inactivating Alu-RNA. Alu-RNA is able to activate the NLRP3 inflammasome leading to the production of IL-8, which activates, via MyD88, caspase 8 responsible for apoptosis of EPR cells.

[150]. As shown in a study conducted in mouse models of EPR, activation of NLRP3 by Alu-RNA does not occur via Toll-like receptors (TLRs), although these are present in the retina, but via P2X7R [151].

Another study conducted in vivo in mouse models also found that activation of NLRP3 by β -amyloid, a component of drusen, is linked to activation of pathways leading to apoptosis of EPR cells and pyroptosis of choroid cells [152]. Furthermore, research has shown that amyloid- β induces apoptosis of Müller glial cells via a P2X7R receptor-mediated signalling pathway and that this cytotoxic effect is inhibited by incubating retinal cells with lipid solutions containing high levels of omega-3, such as docosahexanoic acid DHA and eicosapentanoic acid EPA, combined with Brilliant Blue G, a potent selective P2X7 receptor antagonist, protecting them from neurodegeneration [92].

Another study showed that in EPR cells and ARPE-19 cells, in which inflammasome activation had been induced with different types of stimuli such as lysosomal membrane permeabilisation, hydrogen peroxide-induced oxidative damage lipofuscin-mediated phototoxicity and activation of the P2X7 receptor by BnzATP, demonstrated that the application of selective NLRP3 inhibitors inactivates the inflammasome regardless of the stimulus applied to activate it [153].

The role of P2X7R in the pathogenesis of AMD

Based on in vitro studies, a study group has proposed a model of a P2X7R-dependent signalling pathway involved in the mechanisms of senescence and apoptosis of the retinal

pigment epithelium and in the pathogenesis of the two typical forms of AMD. Endogenous and exogenous tissue insults such as trauma, infection, oxidative stress and inflammation lead to ATP production and promote tissue expression of P2X7R. Extracellular ATP-activated P2X7R promotes ROS production, accelerating the process of EPR senescence and amplifying the inflammatory process underlying the early stages of maculopathy. Activated P2X7R induces apoptosis in EPR cells through a mechanism mediated by the influx of extracellular Ca^{2+} and the formation of the membrane pore pannexin-1 and also leads to dysfunction of the lysosome-phagosome system, which triggers an altered autophagy mechanism. Indeed, P2X7R has been observed to lead to ROS production by macrophages, induce lysosome alkalisation, lipid oxidation and reduce phagosome clearance in ARPE-19 cells [154] [155]. ATP binding to the receptor also triggers K^+ efflux which induces activation of the NLRP3 inflammasome leading to IL-18 secretion. All these pathways are involved in the mechanism of EPR degeneration and the genesis of the dry form of AMD. On the other hand, P2X7R can lead to the activation of p38 which in turn mediates the secretion of IL-8, Monocyte Chemoattractant Protein-1 (MCP1) and Vascular Endothelial Growth Factor (VEGF). IL-8 and VEGF are pro-angiogenic factors that promote the growth of neovases leading to the wet form of AMD. MCP-1 is a chemokine capable of attracting activated mononuclear phagocytes that on the one hand kill the cells

EPR contributing to the dry form and on the other hand induce vascular growth, participating in the neoangiogenesis of the wet form [156]. Subsequent research conducted in vivo, including the use of knockout animal models for P2X7R or pharmacological inhibitors of the receptor, has confirmed this model, demonstrating that P2X7R is a key protein in the macular degenerative process that characterises AMD. Among these studies, we would like to mention the one mentioned above in which, in a mouse model of a non-neovascular form of AMD, Alu-RNA indicates the activation of NLRP3 via P2X7, leading to degeneration of pigment epithelium cells. In addition, the same research group, again using mouse models, demonstrated that the application of the nucleoside reverse transcriptase inhibitor NRTIs, a drug commonly used against HIV, inhibits the P2X7R-NLRP3 inflammasome complex in dry Alu-RNA-induced forms of AMD and improves the outcome of the laser-induced neovascular form [157] [158].

Schematic representation of P2X7 receptor-mediated signalling pathways involved in the pathogenesis of AMD. (Yang & Chen, 2014)

Increased levels of ATP were found in aqueous humour samples from exudative AMD patients with subretinal haemorrhages and in corresponding mouse models, application of the P2X7 receptor antagonist Brilliant Blue G (BBG) prevented photoreceptor apoptosis, suggesting that ATP-mediated P2X7 activation may contribute to the development of these lesions in subjects with advanced exudative AMD [159].

In P2X7R/SOD-1 double knockout mice, the absence of P2X7R can be shown to prevent the accumulation of microparticles within the EPR and the choroid and block the action of oxidative stress in the retina [160].

Furthermore, oxysterols, oxidised derivatives of cholesterol, have been shown to accumulate in drusen during AMD and P2X7 receptor activation plays a key role in oxysterol-induced retinal degeneration in human pigment epithelium cells [161].

Finally, underlining the importance of P2X7R in the pathogenesis of AMD, genetic investigations have shown that a haplotype containing two rare genetic variants of P2X7R and P2X4R is associated with an increased susceptibility to the onset of AMD [162].

Based on this information and using a 'P2X7 null' mouse model in which a loss of P2X7R function was induced, a recent study suggested that the P2X7 receptor normally acts as a scavenger in retinal macrophages and microglia and that in the absence of P2X7R, altered

phagocytosis by these cells leads to the accumulation of photoreceptor-derived debris at Bruch's membrane and age-related loss of EPR cells and photoreceptors [163].

Glaucoma

The term glaucoma refers to a heterogeneous group of optic neuropathies characterised by the progressive degeneration of retinal ganglion cells (RGCs) and their axons, which make up the optic nerve, due to altered fluid dynamics in the anterior and vitreous chambers of the eye. Glaucoma is considered the leading cause of blindness in the world and it is predicted that more than 76 million people will be affected by 2020. Early diagnosis is made difficult by the fact that symptoms often appear late in the course of the disease, so that therapeutic measures are applied when irreversible loss of retinal neurons has already begun. In general, the decline in visual function becomes detectable when more than 30% of RGCs have been lost, although it has been observed that symptoms, i.e. gradual loss of peripheral vision followed by progressive loss of central vision, are reported by patients even later [164].

Types of glaucoma

In the past, increased intraocular pressure (IOP) was considered the primary marker for the diagnosis of glaucoma, but it has been observed that many individuals with elevated IOP do not show clinical signs of glaucoma and optic nerve damage, and up to 50% of glaucoma patients have IOP within normal ranges.

Primary glaucoma is related to anatomic-functional alterations of the eye that compromise ocular hydrodynamics and can be distinguished into three types [165]:

- Primary open angle glaucoma (**POAG**)

It is the most common form of glaucoma and accounts for more than 80% of cases in the Western Hemisphere. Risk factors for primary open-angle glaucoma include: older age, positive family history, African ethnicity, thinner central corneal thickness, systemic hypertension, diabetes and myopia. Clinically, POAG is diagnosed when the following are present: open angle, IOP > 21 mmHg and visual field loss associated with degeneration of ganglion cell axons (optic neuropathy). The corneal iris angle, i.e. the anatomical angle formed between the iris and the cornea, is open in POAG as it is in the normal eye, but

the aqueous humour drainage mechanism at the level of the trabecular meshwork is altered, while production at the level of the ciliary body is usually normal.

- **Normal pressure glaucoma (NTG)**

It is present in about 30% of patients with POAG. Intraocular pressure is within the normal range, 10-21 mmHg, but optic nerve damage and visual field deficits typical of glaucoma are present, following an "hourglass pattern". Risk factors include female sex, race (more common in Japanese than Caucasians), vascular dysregulation and low blood pressure. Normal tension glaucoma evolves very slowly, but progression can be continuous even with very low blood pressure. The presence of haemorrhages in the optic papilla is often characteristic of disease progression [166]. Patients are likely to express *gain-of-function* mutations in genes involved in sensitivity to mechanical stimuli, which would make them hyper-sensitive to modest increases in IOP.

- **Primary closed angle glaucoma (PCAG)** The disease is caused by disturbances of the iris, crystalline lens and retro-lenticular structures that prevent the drainage of aqueous humour by narrowing the corneal iris angle. It is more common in Asian populations, women and people with high hypermetropia due to reduced anterior chamber depth. In about one third of patients with angle-closure glaucoma, an abrupt increase in IOP (often above 30 mm Hg) causes acute symptoms: violent eye pain, nausea and vomiting, conjunctival hyperemia, corneal oedema, pupillary mydriasis requiring immediate medical attention. An acute glaucoma attack, if not treated promptly, can lead to blindness in a short time.

Secondary glaucoma reflects pathological mechanisms that elevate IOP above the normal range due to pathological increased aqueous humour production at the ciliary body and/or reduced drainage at the trabecular level. Variants include pseudoexfoliative glaucoma, neovascular glaucoma, pigmentary glaucoma and steroid-induced glaucoma. Other types of glaucoma are associated with cataract formation, some ocular tumours, uveitis, myopia and early-onset glaucoma (juvenile glaucoma). In inflammatory or uveitic glaucoma, glaucoma may result from obstruction of the drainage structures in the anterior segment as a secondary consequence of ocular inflammation [167].

Figure 6. Schematic representation of open angle glaucoma (left) and closed angle glaucoma (right). In PCAG, dislocation of the lens and iris obstructs the outflow of aqueous humour at the level of the trabecular system. (Wiggs & Pasquale, 2017).

Glaucoma pathogenesis: the role of inflammation

The mechanisms underlying the pathogenesis of glaucoma have for decades been identified as abnormalities in the regulation of intraocular pressure (IOP) and/or altered mechanical sensitivity of the eye cells. Although the contribution of IOP is responsible for a significant proportion of glaucoma cases, approximately 30-70%, it has been observed that at any level of ocular pressure, even normal, lesions typical of the disease can be observed, and that, despite careful therapeutic control of IOP, 15-25% of glaucoma cases progress to more advanced optic neuropathy. For these reasons, the pathogenetic role of neuroinflammation, oxidative stress and alterations in the blood-retinal barrier is emerging in terms of increasing importance [168].

VASCULAR ALTERATIONS AND OXIDATIVE STRESS

The impact of intraocular pressure in the pathogenesis of glaucoma is generally explained through two complementary theories: the mechanical theory, in which increased IOP causes direct compression of retinal ganglion cell (RGCs) axon fibres at the lamina cribrosa, where the axons join to exit the eyeball at the level of the optic papilla.

According to the vascular theory, the increased IOP would cause compression of the capillaries resulting in reduced blood flow to the optic papilla and leading to chronic ischaemic optic nerve damage [169].

Many authors suggest that there is a multifactorial vascular insufficiency underlying glaucomatous optic neuropathy and that among the factors involved, in addition to the aforementioned mechanical vascular compression, is a reduced ability to self-regulate blood flow at the papilla level. In this regard, it has been observed that due to multifactorial predisposing causes such as genetics, ageing and lifestyle, the blood-retinal barrier and the blood-brain barrier surrounding the optic nerve are impaired in glaucomatous eyes. This leads to dysregulation of the vessel wall, resulting in the leakage of molecules that may be responsible for the establishment of the local inflammatory response, and an inability of the autoregulatory mechanism to maintain the blood supply to the papilla and optic nerve. This particular situation occurs during stressful conditions that can be generated either by an increase in IOP or by a reduction in local perfusion pressure due to low blood pressure. An impairment of the autoregulatory system then causes periods of relative ischaemia leading to reperfusion injury when flow is restored. A consequence of relative ischaemia is an increase in the concentration of endothelin-1 (ET1) in the retina, where by activating caspase 3 it may be one of the factors responsible for RGC cell death, and in the choroid where it induces capillary vasospasm intensifying the hypoxic condition due to reduced perfusion. It has been observed that ET-1 may also stimulate the enzyme NO-synthase (NOS) to produce nitric oxide, thereby increasing oxidative stress and contributing to neuronal death, as well as inducing GFAP production at glial level, stimulating astrocyte and Müller cell proliferation [170].

Under hypoxic stress conditions in the retina, HIF- α expression is induced, which on the one hand is a regulatory mechanism to protect RGCs, but on the other hand induces the production of NO, VEGF and activation of the NF- κ B signalling pathway, which correlates with the synthesis of various inflammatory mediators including TNF- α and IL-6. HIF- α also correlates with RGC death because it is accompanied by increased expression of p53 and various pro-apoptotic caspases [171].

The presence of HIF- α and hypoxia can also dysregulate the mitochondrial respiratory chain leading to increased production of reactive oxygen species (ROS), which in turn create a vicious cycle that leads to damage to various cellular components, including the mitochondria, with the release of pro-apoptotic factors. Increased levels of oxidative stress markers from DNA oxidation and lipid peroxidation have been documented in

glaucoma patients or mouse models with elevated IOP. In addition to facilitating apoptosis of RGCs, oxidative DNA damage can also occur in the cells of the trabecular system, leading to increased resistance to aqueous humour outflow and thus contributing to elevated IOP and visual impairment [172].

MICROGLIA, ASTROCYTES AND MÜLLER CELLS

When damage or pathological phenomena occur in the retina, as in the glaucomatous process or with an increase in IOP, the retinal surveillance immune system, composed of microglia, astrocytes and Müller cells, is activated to protect the neurons. In particular, studies over the last few decades have shown that the phenomenon of neuroinflammation related to the pathogenesis of glaucoma takes place at various points in the visual system including: the vitreous chamber of the eye, i.e. at the level of the retina and the optic papilla, in the optic tract and at the level of the brain tissue, in particular at the level of the superior colliculus and the lateral geniculate nucleus, and at the level of the immune system of the peripheral blood, due to the infiltration of blood lymphocytes at the level of the optic papilla and the retina [173]. The cells that suffer the most significant damage are the retinal ganglion cells (RGCs), which belong to the layer of multipolar cells of the retina whose axons form the optic nerve at the optic papilla. Their dendrites, on the other hand, enter into synapses with the amacrine cells and the bipolar cells of the inner plexiform layer, located externally, and through which they receive visual information collected by the retinal photoreceptor cells, cones and rods.

Astrocytes and Müller cells have been found to be activated under conditions of ocular hypertension. In particular, studies in animal models of chronic ocular hypertension have shown that levels of GFAP, produced by activated astrocytes, are elevated as early as 2 hours after IOP elevation, and in DBA/2J mice, traditionally used as glaucoma models, Müller cell activation was detected even before IOP elevation.

IOP. GFAP is a mediator that stimulates proliferation and infiltration of glial cells, a process known as astrogliosis [174].

One of the theories correlating astrocyte activation with neuronal death of RGCs is that neurotoxic mediators can propagate through the connexins, the main components of the *gap junctions* that connect astrocytes [175]. Ischaemia can induce astrocytes to alter axon transport and induce biomolecular changes at the level of the lamina cribrosa and the extracellular matrix. In addition, ischaemic conditions stimulate the release of potentially

toxic factors for neighbouring neurons such as NO, TNF- α , TGF- β and glutamate, contributing to glaucomatous neuropathy [176].

In the early stages of the disease process, the activation of Müller cells is intended to maintain the homeostasis and integrity of the retina, as they express several receptors related to cell growth and survival; however, when over-activated, they are able to release several damaging factors including TNF- α , IL-1 and NO, leading to the activation of receptors related to cell death and altering the homeostasis of potassium and H₂O in the retina. Müller cells usually perform the function of removing extracellular glutamate from retinal tissue to prevent its diffusion beyond synaptic spaces via GLAST, the main glutamate transporter, whose expression is reduced in glaucomatous conditions, contributing to the pathological process of excitotoxicity, neuronal death and photoreceptor degeneration [177].

Microglia, retinal immunocompetent cells that act as sensors of neuronal damage, are among the first cell lines to be activated after the first glaucomatous damage events, before retinal ganglion cell degeneration occurs. In response to a damaging stimulus, microglia proliferate at the retinal level and at the level of the optic papilla and undergo a morphological change, assuming an amoeboid inflammatory phenotype with the release of pro-inflammatory cytokines such as IL-6 and TNF- α and reactive oxygen species such as nitric oxide (NO), harmful to RGCs, and increased expression of phagocytosis-related CD68⁺ proteins and major histocompatibility membrane complexes MHC I and MHC-II. The extent of activated microglia cells correlates with the extent of axonal degeneration at the optic nerve head induced by the glaucomatous process [178] [179]. Various findings in animal models of glaucoma suggest that microglia activation occurs early and prior to elevation of intraocular pressure or signs of neuronal damage. Moreover, in experiments, inhibition of the activity of these cells by pharmacological molecules such as Minocycline or Azithromycin, an antibiotic with immunomodulatory properties, is able to stop the death of RGCs, improving their survival, modulating the local inflammatory state and preventing disease progression. In addition, in a model of acute ocular hypertension, induced by the injection of saline into the anterior chamber, it was observed that deletion of the CX3CR1 chemokine receptor reinforces neurotoxicity by modulating microglial activation [180].

Figure 7. (A) Example of phenotypic change of microglial cell from quiescent branched to reactive amoeboid. (B) Murine model of chronic glaucoma in which the number of microglia at the optic nerve head in the early stages of glaucoma correlates with the following late axonal loss. (C) Early stage glaucoma: microglia are labelled with CD11b (red), astrocytes with GFAP (blue) and both cell types show signs of hypertrophy with enlarged soma and thickened processes. (Križaj D, *What is glaucoma?*; Webvision: *The Organization of the Retina and Visual System*, 2019)

Interestingly, investigations in experimental glaucoma models have shown that increased IOP is associated with higher numbers of M1-like microglia, with a pro-inflammatory phenotype, while few M2-CD86+ microglia have been detected between ganglion cells and optic nerve fibres. In the regulation of inflammatory responses, a reciprocal dialogue is established between microglia and astroglial cells: it has recently been reported that activated M1-like cells release IL-1 α , C1q and TNF- α that induce the expression of the reactive A1 phenotype in astrocytes, which also has a neuroinflammatory function, leading to the expression of several genes, such as those involved in the complement cascade, that have destructive effects on synapses. Various components of the classical complement pathway, such as C1 and C3, are found to be increased in glaucoma mainly at the level of the optic papilla and the inner plexiform layer where they may play a protective role by coming into contact with the dendrites of retinal ganglion cells [181]. Infiltration of monocyte-macrophage cells has also been shown to occur coinciding with the onset of glaucoma in DBA/2J mice [182].

Importantly, other cell types, including neurons, astroglia and infiltrating leukocytes such as T cells, also participate in the neuroinflammatory process, and unravelling the molecular pathways that underlie the phenotype acquired by retinal cells in glaucoma

could be useful in finding better targets for treatment. To date, most of the information available in favour of the neuroinflammatory hypothesis has come from animal models and it will be important in the future to explore the biomolecular mechanisms involved in this process both in human subjects and in experimental models relevant to this disease.

PRO-INFLAMMATORY SIGNALLING PATHWAYS IN GLAUCOMA

From the point of view of the triggering of the inflammatory pathway, multiple investigations have led to the recognition of three main signalling pathways:

- **Toll-Like Receptor (TLRs)** mediated signalling pathway

Activation of innate immunity receptors TLRs in glial cells, microglia and astrocytes can occur through binding to oxidative stress products induced by glaucomatous conditions. Tenascin-C, an endogenous activator of TLR4, is a DAMP whose expression is elevated in astrocytes during glaucomatous optic neuropathy. Several studies have reported increased TLR2, TLR3 and TLR4 immunoreactivity of microglia and astrocytes in the retina and that stimulation of these receptors leads to activation of the NF- κ B and MyD88 mediated signalling pathway, which amplify the secretion of proinflammatory cytokines IL-1 and IL-6 contributing to the creation of an inflammatory environment and degeneration of RGCs [183] [184] [185].

- **Tumor necrosis factor- α (TNF- α)**-mediated signalling pathway.

The pro-inflammatory cytokine TNF- α is produced by astrocytes and microglia in the retina and optic nerve. Its release is induced by increased IOP, ischaemia and oxidative stress. Certain genetic polymorphisms have been linked to an increased risk of developing glaucoma. Several investigations have found increased levels of this mediator in the aqueous humour and serum of glaucoma patients. Intraocular injections of TNF- α in mouse models with normal eyes have been observed to induce death of oligodendrocytes and RGCs and axonal damage of the optic nerve comparable to that in glaucoma patients. TNF- α expresses its functions by binding to TNF-R1 and TNF-R2 receptors and in glaucomatous conditions has been shown to play a role in inducing neuronal death of RGCs, as genetic ablation of these receptors results in neuroprotection of retinal cells and the optic nerve in experimental glaucoma models [186] [187] [188].

- **P2X7** receptor-mediated signalling pathway

P2X7 receptor expression was found in retinal amacrine cells, retinal ganglion cells (RGCs), microglia and astrocytes from animal models of glaucoma. Increased levels of ATP and P2X7R activation have been demonstrated in in vitro and in vivo models of ocular hypertension. ATP is released from cells as a result of apoptosis and necrosis caused by elevated IOP or ischaemia during glaucoma. It has been hypothesised that the P2X7R receptor is capable of activating several molecular signalling pathways involved in microglia activation, RGCs cell death and the creation of an inflammatory environment. In a study in which injection into the eyeball of BzATP, a P2X7R agonist, was used to establish an animal model of chronic ocular hypertension, the level of Iba1, the characteristic marker of microglia, was found to be significantly increased, suggesting that stimulation of P2X7R in glaucoma could drive microglia cells into a reactive form. In this regard, pretreatment with a P2X7R receptor antagonist, Brilliant Blue G (BBG) reduces microglia activation and also provides some level of neuroprotection by preventing retinal ganglion cell death [189].

Other research in animal models of glaucoma has shown not only that P2X7R activation is linked to microglia proliferation and activation but that RGCs death occurs through a P2X7R-NLRP3 mediated pathway. Indeed, the addition of a P2X7R inhibitor called A438079 or an NLRP3 inhibitor called Mcc950 on the one hand reduces the number of microglia cells present and on the other increases the survival rate of RGCs. Furthermore, the application of the NLRP3 inhibitor alone does not reduce the presence of transcripts of certain proinflammatory cytokines, implying that microglia are able to produce TNF- α , IL-6, IL-1 β , IL-18 and IL-11 through stimulation of P2X7R, but through an independent NLRP3 pathway [190].

Pannexin-mediated mechano-sensitive ATP release stimulates P2X7Rs on RGCs and astrocytes leading to Ca²⁺ overload and caspase activation and, in addition, P2X7R stimulation due to mechanical stress on astrocytes or RGCs leads to IL-6 release [191].

In retinas from DBA/2J mice, increased P2X7R activation in RGCs correlates with *loss of function* of the ERG gene and increased expression of caspase-3, mediated by increased activation of MAPK, JNK and p38, suggesting that P2X7R is involved in a pro-apoptotic mechanism, induced by elevated intraocular pressure, leading to RGCs cell death. Recently, it has been shown that in vivo P2X7R is involved in the mechanism of NMDA-induced retinal damage leading to glaucomatous death of RGCs cells [192].

Stimulation of P2X7R in vivo has also been shown to lead to NMDA receptor activation, which is followed by a large influx of Ca^{2+} into RGCs, leading to neuronal death and retinal damage [193].

In conclusion, the results of these studies suggest that the P2X7R receptor is involved in the pathogenetic mechanisms leading to the onset and progression of glaucoma, being responsible for the processes of neurodegeneration, inflammation and gliosis, which prevent proper tissue regeneration. Inhibition of P2X7R-activated signalling pathways by specific pharmacological antagonists could therefore be an interesting therapeutic proposal for the prevention and treatment of glaucoma in the years to come.

Pseudo-exfoliative syndrome or PEX

Pseudoexfoliative syndrome, commonly abbreviated as PEX, is an age-related systemic disorder resulting from the deposition of pseudoexfoliative material (PXF) in various organs and tissues.

PEX affects around 60 million people worldwide, its incidence increases rapidly after the age of 50 and its geographical distribution is more concentrated in countries with a high incidence of PEX.

Scandinavia, Greece and parts of Africa, where several epidemiological studies have shown a higher frequency in specific ethnic groups [194].

PXF is an amyloid-like, grey-white, extracellular fibrillar material resulting from abnormal metabolism of the extracellular matrix and formed histologically from various matrix, basement membrane and elastic fibre constituents such as fibrillin-1, elastin, laminin, fibronectin, LTBP1 and LTBP2 (latent TGF- β binding proteins), clusterin and the cross-linking enzyme LOXL1 [195]. Fibrillar deposits have been found in or on the surface of all structures of the anterior chamber of the eye and appear to be produced by the epithelium of the pre-equatorial zone of the lens, corneal endothelium, endothelium of the trabecular meshwork, pigmented epithelium of the iris, and almost all cell types of the iris stroma, such as fibrocytes, melanocytes, endothelial cells, pericytes and smooth muscle cells [196].

The deposition of white-fur material on the surface of the lens is the most consistent and important diagnostic sign of PEX. The classic pattern of the advanced stage consists of three distinct zones on the anterior surface of the lens that become visible when the pupil is fully dilated: a central disc that corresponds approximately to the diameter of the pupil,

a granular and stratified peripheral zone and a free intermediate zone created by rubbing the iris against the surface of the lens during pupillary movement [197].

Figure 8. Classic presentation of lens with PEX. (Ritch & Schlötzer-Schrehardt, 2001)

PEX is the most common cause of secondary open-angle glaucoma, called pseudo-exfoliative glaucoma (PXG), which compared to primary open-angle glaucoma (POAG), has a greater increase in intraocular pressure (IOP), reduced visual function with more advanced visual field loss at diagnosis, worse prognosis and poor response to therapy [198].

Obstruction of the trabecular meshwork by pseudo-exfoliative material or accumulation of free iris pigment at the irido-corneal angle are generally considered to be the most plausible causes of increased IOP caused by blockage of the outflow of aqueous humour. The severity of glaucoma and subsequent optic nerve damage has been related to the amount of PXF material present in the iuxtacanalicular region of the trabecular system in studies of organ donor eyes. However, it is still unclear why a proportion of patients with PEX develop glaucoma, although most will probably never do so [199] [200] [201] [202]. In addition, PEX carriers are at high risk of developing various ocular pathological conditions that include angle-closure glaucoma, accelerated cataract formation, zonular weakness, droplet keratopathy or spheroidal degeneration, retinal vein occlusion and even decreased pupil dilation [203] [204].

Alterations in the vascularisation and blood-ocular barrier of the iris occurring in PEX would lead to alterations in aqueous humour composition and consequently may dysregulate the metabolism of the lens leading to cataract formation. Weakness of the zonular apparatus combined with poor pre-operative pupillary mydriasis leads to an increased risk of intraoperative complications in cataract extraction surgery [205] [206].

Systemic fibrillar deposition includes the skin, heart, vessels, lungs, bladder, kidneys and meninges, and several epidemiological studies have shown that affected individuals are at increased risk of cardiovascular disorders such as coronary artery disease, hypertension, cerebrovascular diseases, abdominal aortic aneurysm, peripheral vessel disease, renal artery stenosis, but also Alzheimer-like dementia, sensorineural hearing loss and, recently, erectile dysfunction and pelvic organ prolapse [207] [208] [209] [210] [211] [212] [213] [214].

Aetiopathogenesis of Pseudoexfoliative Syndrome

The etiopathogenesis of the syndrome is multifactorial. The variability in prevalence among populations of different ethnicities and the tendency for family aggregation in which multiple members of the same family present with different manifestations of the syndrome have extended interest in hypothesising the involvement of various heritable risk factors. Single nucleotide polymorphisms (SNPs) in the LOXL1 gene were the first to be highlighted, followed by the polymorphism in the CACNA1A gene, which encodes for the α -subunit of a 2^+ Calcium-dependent channel, whose concentrations are high in deposited material [215].

Altered expression of the enzyme LOXL1 (lysyl oxidase-like1), found in deposits in the ciliary body, lens capsule and other affected tissues, could be associated with dysregulation of elastin and collagen metabolism and lead to structural disorganisation of elastin in the lamina cribrosa of the eye [216]. Although SNPs of LOXL1 are very common in the general population, most carriers do not develop pseudoexfoliative syndrome, suggesting that other genetic, epigenetic and environmental factors may contribute to the development of the condition [166] [217].

Molecular studies have revealed multiple disrupted pathways in PEX involving TGF- β 1 signalling, the function of matrix metalloproteinases MMPs and their endogenous inhibitors TIMP, which result in aberrant synthesis on the one hand and altered degradation of the extracellular material that makes up fibrillar deposits on the other [218] [219]. High plasma and aqueous homocysteine levels and reduced folate *intake*, which contributes to hyperhomocystinemia, are additional risk factors associated with the syndrome [220]. Dysregulated molecular pathways in the development of pseudoexfoliative glaucoma also include those that regulate mitochondrial function and the autophagy phenomenon, which is important for the degradation of *misfolded* proteins,

which would contribute to the accumulation of fibrillar material and a reduced response to oxidative stress [221].

PEX is an age-related disease and therefore chronic exposure to harmful factors such as infections, UV radiation, environmental allergens and trauma alters the balance between oxidant and antioxidant factors, exposing ocular tissues to oxidative stress. Many research works have shown that a deficit in the cellular capacity to mitigate oxidative stress and exposure to a chronic inflammatory state contribute to the pathogenesis of PEX. On the one hand, reactive oxygen species (ROS) such as hydrogen peroxide ($2\text{H}_2\text{O}_2$), lipid peroxidation products and advanced glycation products are elevated in the aqueous humour and blood, on the other hand there is a concomitant reduction in the levels of proteins and antioxidant molecules such as ascorbic acid and reduced glutathione. Oxidative damage is a trigger for degeneration of the trabecular system, causing a significant increase in intraocular pressure (IOP), which underlies the pathogenesis of glaucoma and associated neuronal lesions, which are also sustained by the lack of adequate local antioxidant defences. In the presence of reactive oxygen species (ROS), nitric oxide produces toxic metabolites called peroxynitrites and the resulting oxidative stress induces a chronic inflammatory process sustained over time, which is also responsible for fibroblast cell proliferation and neurotoxicity. Lower levels of nitric oxide (NO) were found in patients with PXG than in those with PEX and this could lead to a double negative effect contributing to both the development and progression of glaucoma because on the one hand the ocular blood flow is increased due to the vasodilating effect of NO on the endothelium, but on the other hand, since it has a vasoconstricting effect on trabecular cells, a reduction in NO leads to a reduced outflow of aqueous humour [222]. In addition, oxidative stress, tissue ageing and increased IOP induce the transcription of the NF- κ B factor, which is widely involved in amplifying the inflammatory cascade. In this regard, a study conducted on daily dietary supplementation of docosahexaenoic acid (DHA), an omega-3 fatty acid, showed benefits in patients with PXG in terms of improving retinal function due to its inhibitory effect on NF- κ B activation and cytokine synthesis and its protective antioxidant effect on the retinal pigment epithelium and photoreceptors [223].

Local oxidative stress triggers a chronic state of inflammation accompanied by the production of several pro-inflammatory cytokines such as IL-6, IL-17, TNF- α . In the pathogenesis of PEX, pro-inflammatory cytokines are involved in the regulation of the immune response, in the deposition and remodelling of the extracellular matrix, in

increased vascular permeability and in stimulating the secretion of other profibrotizing cytokines. Several studies have shown increased levels of TNF- α , IL-6, IL-17 in the aqueous humour of patients with early PEX and increased serum levels of IL-6 in both early and late PEX, thus suggesting that IL-6 contributes to the maintenance of the inflammatory process both locally and systemically and to the initiation of the fibrotic process underlying the pathogenesis of PXG. The levels of IL-17 and TNF- α in the aqueous humour remain high up to the stage of glaucoma while those of IL-6 continue to maintain an upward trend even after the onset of glaucoma.

There is a reciprocal stimulation of the above cytokines in that: IL-6 activates the local synthesis of TNF- α and IL-17 by stimulating Th1 and Th17; among the most relevant effects of IL-17 are the stimulation of stromal cells to secrete IL-6, IL-8, the granulocyte growth factor GCS-F (granulocyte colony-stimulating factor), prostaglandin E2 and nitric oxide and the regulation of IL-6 and TNF- α release by macrophages; the increased levels of TNF- α during the development of PEX suggest that chronic inflammation underlies this process and further intensifies the process of fibrosis and release of fibrotic material due to inhibition of collagen phagocytosis by fibroblasts [224]. The fibrotic process, which characterises the development of PEX and contributes to the injury of the trabecular system in pseudoexfoliative glaucoma, begins when the immune inflammatory response and wound repair process develops in tissues damaged by oxidative stress. Damage to epithelial and endothelial cells is accompanied by the release of proinflammatory cytokines (IL-1, TNF- α , IL-6, IL-17) with activation of the fibrinolysis system of the coagulation cascade to repair the damaged vessel. Activated thrombin in turn activates fibroblasts, promoting their proliferation and differentiation into collagen-producing myofibroblasts. Thrombin acts in conjunction with TGF- β release to lead to clot formation and increase vascular permeability to promote extravasation and recruitment of leukocytes to the lesion. The basement membrane, which lies beneath the epithelium and endothelium, retains the recruited leukocytes and matrix metalloproteinases MMPs degrade and release some of the basement membrane constituents increasing the extravasation of inflammatory cells at the damaged site. Inflammatory cells exploiting TNF- α can lead to the local synthesis of TGF- β , which together with CTGF (connective tissue growth factor) increases the secretion of EGF and IGF and accelerates the proliferation and differentiation of fibroblasts into myofibroblasts. These physiological processes are dysregulated and abnormally increased

in the pathogenetic process leading to PEX and PXG [225] [226]. A recent study also showed that the concentration of the proinflammatory protein YKL-40 was found increased in aqueous humour, but not in serum, indicating that it may be used as a localised inflammatory marker at PEX [227]. Also worthy of mention is the role of hypoxia due to occlusion of the iris vessels with pseudo-exfoliative material and gradual degeneration of vascular cells. It has been shown that conditions of iris hypoperfusion and hypoxia in the anterior chamber can up-regulate LOXL1 expression and that high levels of vasoregulatory molecules such as endothelin-1, a potent vasoconstrictor, and proangiogenic molecules such as VEGF are present in the aqueous humour of patients with PEX [228] [229].

Fuchs endothelial corneal dystrophy

Fuchs' endothelial corneal dystrophy is the most common form of primary posterior corneal dystrophy and is the most frequent indication for corneal transplantation in the world [230]. This disease is characterised by a progressive loss via apoptosis of corneal endothelial cells and the sub-endothelial formation of extracellular matrix outgrowths, called **guttae**, at the level of Descemet's membrane.

Fuchs' dystrophy affects around 4% of the population and typically occurs in the fourth to fifth decade of life with a higher frequency in women.

Most patients in the early stages of dystrophy are not symptomatic: the presence of centrally located guttae in the cornea may be an incidental finding during a routine ophthalmological examination. Imaging detects a reduction in endothelial cell density, which should be at least 400-500 cells/mm² to allow physiological maintenance of function, with abnormalities in cell shape and size. The progression of the pathology leads to an increase in the number of guttae, which become peripheral and confluent, an increase in corneal thickness and a corresponding reduction in corneal function. The reduction in cell density triggers the loss of ion transport activity, causing the corneal endothelium to be unable to maintain an appropriate fluid balance between the stroma and the aqueous humour resulting in oedema and loss of corneal transparency [231].

At this stage, worsening stromal oedema leads to a decline in visual function with blurred vision, especially during the day, due to reduced evaporation of fluid from the corneal surface and a consequent increase in oedema during the night. In the advanced stages, epithelial and sub-epithelial blistering can be observed, the rupture of which can cause pain and tearing, and increased inflammation in the anterior chamber, which can contribute to increased sensitivity to glare. Reduced corneal innervation can lead to neurotrophic keratopathy characterised by erosions, ulcers and corneal scar formation, but this is an uncommon clinical finding in countries with advanced diagnostic, monitoring and treatment techniques [232] [233].

Figure 10. Progression of Fuchs' endothelial corneal dystrophy observed with backlight and slit lamp biomicroscopy. (Matthaei et al., 2019)

(a)(b) Early stage of corneal dystrophy in which central guttae of Descemet's membrane with clear, compact stroma are observed.

(c)(d) As the disease progresses, the appearance of guttae at the periphery and stromal oedema cause loss of transparency of the cornea.

(e)(f) Advanced stage in which epithelial bullae, stromal oedema and corneal haze are present.

Aetiopathogenesis of Fuchs' endothelial corneal dystrophy

From a pathogenetic point of view, Fuchs' dystrophy is a complex multifactorial disease in which the interaction between genetic and environmental factors leads to the activation of processes of cell apoptosis and aberrant deposition of extracellular matrix. Sixteen gene mutations and/or single nucleotide polymorphisms of sporadic or hereditary origin have been identified. The proteins encoded by these altered genes cover a wide range of cellular functions such as DNA damage repair, regulation of the apoptosis process and secretion of the extracellular matrix [234].

Oxidative stress is the major determinant in the pathogenesis of Fuchs' dystrophy and contributes, together with genetic and epigenetic factors, to the progressive degeneration of corneal endothelial cells, the loss of their hexagonal shape and the reduction in their density.

A number of exogenous factors, such as prolonged daily exposure to ultraviolet radiation and pollution, cigarette smoking and diabetes, promote an imbalance between oxidant and antioxidant factors in a genetically predisposed individual, thus increasing oxidative stress [235]. Many studies conducted in recent decades have found an increase in the corneal concentration of ROS and their cytotoxic derivatives, such as advanced glycation products (AGEs) and nitrotyrosine, and other markers of oxidative DNA damage, such as 8-hydroxy-2'-deoxyguanosine (8-OHdG). Oxidative stress leads to an accumulation of non-repairable DNA damage that blocks the proliferative capacity of cells and leads to premature senescence [236] [237].

Analyses carried out using molecular biology methods such as PCR have also demonstrated a transcriptional *down-regulation* of antioxidant factors such as Peroxiredoxin 2,-3,-5 (Prx-2,-3,-5) and Superoxide dismutase (SOD) and of the transcription factor Nrf2, which coordinates the expression of various proteins involved in defence against oxidative stress in the nucleus [238] [239].

The absence of Nrf2 induces perturbations in tissue homeostasis and activates molecular pathways involved in p53-dependent apoptosis in corneal cells [240]. An increased level of oxidatively damaged mitochondrial DNA and *misfolded* proteins found in the vicinity of guttae confirms the association between endothelial apoptosis and macromolecular damage caused by oxidative stress. ROS-induced cell apoptosis is also involved in the activation of NF- κ B-mediated proinflammatory signalling pathways [241].

In addition, the intracellular elevation of ROS leads to dysregulation of mitochondrial function and cellular synthetic capacity. Indeed, at the level of the guttae, senescent

corneal endothelial cells have been found to become metabolically active and assume a fibroblastic phenotype, caused by the production of profibrotic mediators such as TGF- β 1, which induce the endothelial-mesenchymal transition and the consequent increased subendothelial deposition of extracellular matrix. TGF- β 1 is also involved in the initiation of apoptotic processes mediated by 'unfolded protein response' (URP) because it causes an overload of matrix proteins at the endoplasmic reticulum by increasing the formation of *misfolded* proteins. The guttae in turn create a toxic microenvironment around them that propagates the oxidant/antioxidant imbalance underlying the pathogenesis of dystrophy [242] [243].

Uveitis

The term uveitis refers to an inflammatory process affecting exclusively or predominantly the uvea, the middle tunic of the eye, composed of the iris, ciliary body and choroid; in fact, during uveitis, all structures of the eye may be affected.

In industrialised countries, uveitis affects approximately 2 out of every 1,000 people, around 35 % of those affected suffer from severe visual impairment and this disease is the cause of 5 % of cases of legal blindness, mainly due to ocular hypertonia, macular oedema and retinal ischaemia [244] [245].

Classification of uveitis

On the basis of the anamnestic and objective information collected, four different classifications of uveitis have been drawn up to guide the differential diagnosis [246]:

- **Clinical** classification. Based on the time of onset of ocular disease and the clinical course, uveitis can be subdivided into acute, which identifies uveitis with an acute onset and limited duration of less than 3 months, such as HLA-B27-associated anterior uveitis; recurrent, which is characterised by repeated episodes separated by periods of remission lasting more than 3 months without treatment; and chronic, which is of persistent duration of more than 3 months or recurring in a period of less than 3 months after treatment is discontinued.
- **Anatomical** classification. Uveitis is defined as anterior when there is pathological involvement of the anterior segment of the eye and is called iritis

when it involves only the iris and iridocyclitis when it involves the iris and ciliary body; intermediate uveitis involves the posterior part of the ciliary body, the vitreous cavity and the pars plana, the most peripheral portion of the retina; posterior uveitis involves the posterior segment of the eye and depending on the initial localisation one may speak of retinitis, retinochoroiditis, chorioretinitis or neuroretinitis. Panuveitis occurs when the inflammation affects all segments of the eye simultaneously.

- **Aetiological** classification. Infectious uveitis is due to bacterial, viral, fungal and parasitic infections. Infectious agents can enter the eye from the outside (exogenous uveitis) or reach it via the blood stream (endogenous uveitis). The Non-infectious uveitis may be related to known systemic or local disease processes, mainly immune-mediated or autoimmune. The systemic diseases most frequently associated with non-infectious uveitis are: HLA-B27 associated uveitis, juvenile idiopathic arthritis, rheumatoid arthritis, inflammatory bowel disease, sarcoidosis, Behçet's disease (BD), psoriasis or tubular-interstitial nephritis (TINU). Approximately 25%-45% of uveitis in Western countries are not related to systemic diseases or to known ocular pathological entities and are therefore defined as "idiopathic".

Pathogenesis of uveitis: the role of inflammation

Uveitis is a complex and heterogeneous group from an etiopathogenetic point of view as many genetic, environmental, comorbidity-related or underlying systemic disease factors play a role in determining its final phenotype.

Under normal physiological conditions, the aqueous humour, the cornea and certain types of immune cells form a natural immune barrier to prevent the invasion of foreign pathogens.

Inflammation in these tissues occurs when trauma occurs, when pathogenic microorganisms enter the ocular structures through a local injury or through the bloodstream, or when autoimmune responses are triggered after exposure to self-antigens. During these events the immune response is stimulated leading to the activation and proliferation of autochthonous immune cells in the eye.

In the pathological process leading to uveitis, a dysregulation of adaptive immunity, which normally represents the first line of defence of the autoimmune system, may develop. In recent decades, ocular dendritic cells have acquired an increasing role in the pathogenesis of uveitis. Dendritic cells are present at the peripheral margins and iuxtapapillary areas of the retina in mouse models, and in the human eye they are normally concentrated in the central corneal and limbal epithelium, the basal lamina and the sub-basal nerve plexus. These cells possess phagocytic abilities and when activated lead to the release of pro-inflammatory cytokines such as TNF- α , IL-12, IL-6. Human and murine dendritic cells express both MHC-II/HLA surface molecules, TLR4 and the receptor complex for LPS to it [247] [248] [249].

Under pathological conditions they behave as antigen presenting cells (APC) and in a mouse model of uveitis, activated ocular dendritic cells were found at the level of the choroid, where they probably lead to the maturation of antigen-specific Th1 and Th17 cells. In addition, in animal models it was observed that many autoimmune cells such as NK cells, serum dendritic cells and CD4⁺ cells infiltrate inflamed ocular tissues and interact with dendritic cells locally, promoting their mutual maturation. Interaction of ocular dendritic cells with NK cells leads to activation and maturation of both cell types and stimulates the secretion of cytokines such as INF- γ , TNF- α , IL-12, IL-15, IL-18 [250].

Differentiation of Th17 cells is also stimulated by the presence of IL-1 β , IL-6 and TGF- β produced by APC cells. In addition to IL-17, Th17 cells express IL-22, IL-17F, IL-21, GM-CSF, IL-6 and IFN- γ , all of which play important roles in inflammatory processes and autoimmunity.

In experimental models of autoimmune uveitis (EAU), treatment with anti-IL-17 antibody is sufficient to block the development of the disease. In humans, elevated levels of IL-17 have been identified in the eyes of patients with "birthshot" chorioretinopathy (BSCR), "Vogt - Koyanagi - Harada" (VKH) uveitis, HLA-B27 uveitis and Behçet's uveitis. In addition to driving the expression of inflammatory cytokines, IL-17 stimulates the expression of metalloproteases, which are responsible for tissue damage, and chemokines, which attract leukocytes to the inflammatory site [251]. Binding of TNF- α to its receptor TNFR1 triggers the activation of a complex cascade of cellular signals mediated by the TRAF (TNF receptor associated factor) protein: downstream, translocation of NF- κ B to the cell nucleus and activation of MAPKs lead to the production of inflammatory mediators. In the

EAU, neutralisation of TNF- α suppresses the disease process and it has been shown that TNFR1-deficient mice are resistant to the development of uveitis [252].

In aqueous humour samples derived from human eyes, high levels of TNF- α in patients with HLA-B27 uveitis, idiopathic uveitis, VKH and Behçet's uveitis [251]. However, the levels of this cytokine in ocular fluids do not seem to reflect the degree of disease activity and do not correlate with the efficacy of systemic treatment with Adalimumab. Adalimumab is a humanised IgG monoclonal antibody that acts by inhibiting TNF- α and has been shown to be effective for the treatment of non-infectious intermediate, posterior and panuveitis uveitis, especially in adult patients who have had an inadequate response to corticosteroids or are intolerant to corticosteroid therapy [253] [252]. Several experimental studies in EAU models have demonstrated the importance of IL-6 in the pathogenesis of non-infectious uveitis. In an animal model of T-cell-mediated uveitis with IRBP-induced immunisation, researchers demonstrated that in IL-6-deficient mice, the absence of the cytokine resulted in a lack of stimulation of Th17 cells. On the other hand, systemic or intravitreal administration of anti-IL-6 receptor antibodies reduced the degree of inflammation in the uveitic process. This effect in EAU models appears to occur by suppressing the differentiation of both Th1 and Th17 cells, both of which are essential in the development of this animal model of uveitis [254] [255]. High levels of IL-6 are present in the aqueous humour of patients with uveitis, such as in uveitis caused by *Toxoplasma gondii*, in Fuchs' heterochromic cyclitis and in some forms of non-infectious uveitis, including Behçet's disease, VKH uveitis, sarcoidosis, idiopathic uveitis, acute retinal necrosis and HLA-B27 uveitis. In addition, IL-6 plays an important role in the development of ocular complications resulting from the uveitic process such as neovascularisation and macular oedema [256].

Area of ischaemia and retinal inflammation causing retinitis (in white) and haemorrhages (in red). (C) Uveitis in Fuchs' heterochromic cyclitis. Presence of typical keratic precipitates in the posterior portion of the cornea. (Kenneth et al., 2006)

A further study showed that VEGF and TNF- α factors, as well as IL-1 β , can contribute to blood-retinal barrier breakdown in both experimental models of autoimmune uveitis and in patients with uveitis, probably by inducing the opening of *tight junctions* and increasing vesicular transport within endothelial cells. In contrast, IL-1 β -blocking molecules inhibit the development of uveitis experimentally [257]. Many studies have linked the role of CD4⁺ T cells to the pathogenesis of autoimmune uveitis, but this is actually a rather rare occurrence because, on the one hand, the thymus normally eliminates self-reactive CD4⁺ T clones that form during cell development, while on the other hand the formation of T cells reacting against self antigens depends on the interaction of genetic predisposition factors with environmental factors. Regardless of the type of antigen they react against, whether self or external, CD4⁺ T cells involved in uveitis development are activated by antigen-presenting cells, such as ocular dendritic cells or macrophages, that possess

antigenic peptides on the outer side of the membrane as part of major histocompatibility complex type II (MHC II) molecules. Once activated, they can differentiate into Th1 and Th2 cells. Several animal models of anterior and posterior uveitis have shown a prevalence of Th1-CD4⁺ cells, which have a key role in triggering the inflammatory cascade. Their activation stimulates the secretion of IL-2 and consequently of other pro-inflammatory cytokines such as INF- γ and TNF- α , which have been found in the ocular fluids and peripheral circulation of patients with uveitis. Once these cells are active in the injured tissue, the inflammatory process is maintained through the production of chemokines and cytokines, including from local cells such as those of the retinal pigment epithelium. It has also been shown that, during inflammation, retinal pigment epithelium and choroid endothelium cells expose adhesion factors such as ICAM-1, VCAM-1 and ELAM-1, leading to adhesion and extravasation of leukocytes in the eye and subsequent immune-mediated tissue damage [258].

Macular Pucker or Epiretinal Membrane

Epiretinal membrane or macular pucker is a relatively common macular pathological condition characterised by the formation of a thin fibrocellular membrane along the surface of the inner limiting membrane of the retina. It may manifest ophthalmoscopically as a translucent membrane, which may wrinkle, leading to deformation and progressive distortion of the macula, or cell proliferation and scar tissue formation may exert traction on the retina and lead to detachment causing impairment of central vision. The visual deficit can be very variable, ranging from none to severe with a very slow period of evolution. One of the main symptoms is metamorphopias, i.e. distorted images, but blurred vision up to loss of detail may also be present.

Epiretinal membrane usually develops after the age of 50 and is more common among people aged > 75.

In most cases, epiretinal membrane develops in an eye with no history of ocular disease and is therefore termed 'idiopathic', while a smaller proportion of patients develop pucker due to ocular inflammatory disease, retinal detachments, trauma and retinal vascular disease [259] [166]. It is usually preceded by vitreoschisis and posterior vitreous detachment (DPV); by tangentially stretching the retina it can cause macular hole.

Figure 12. Fundus oculi (left) and OCT (right) of macular pucker. (O.U. Ophthalmology Clinic,

A.O.U. Sant'Anna of Ferrara, Prof. P. Perri)

Pathogenesis

For the pathogenetic mechanisms underlying the development of the idiopathic form of epiretinal membrane, a number of theories have been written concerning both the functions of multiple cell types such as glial cells, retinal pigment epithelium cells, fibroblasts and hyalocytes, and the role of cytokines and growth factors. Studies have shown that the predominant cell types in macular pucker samples are Müller cells and hyalocytes and that immunohistochemical investigations of surgically removed membrane samples show strong positivity for GFAP, CD68, CD163, vimentin and CRALBP protein, indicating the presence of glial cells and hyalocytes [260]. A study using *real time PCR* genetic analysis of vitreous samples from patients with epiretinal membranes showed increased expression of genes coding for IL-6, TGF- β 2, VEGF-A, CXCL1, GFAP, RELA and tenascin C (TNC) compared to controls [261].

RELA is a subunit of the nuclear transcription factor NF- κ B, which is activated by many stimuli including hypoxia and the pro-inflammatory cytokines IL-1 β and TNF- α . NF- κ B and the pro-angiogenic factor IL-8 are expressed in glial and endothelial cells and their expression has been associated with epiretinal membrane formation in later life [262].

TGF- β 2 is a growth factor that is elevated in the vitreous humour of patients with macular pucker and in its presence hyalocytes trans-differentiate into myofibroblasts, showing immunopositivity to the α -SMA (α -smooth muscle actin) contractile protein, suggesting a role in the contractions that the epiretinal membrane generates at the vitreoretinal interface [263].

IL-6 is a pro-inflammatory cytokine reported to be involved in the activation of Müller cells by stimulation by microglia and epiretinal membrane formation in eyes with proliferating diabetic retinopathy and vitreoretinal proliferation, while the factor CXCL-1 may be associated with the pathogenesis of macular pucker due to its role in inflammatory, angiogenic and wound repair processes [264] [265].

The hypothesis suggested by the above study is that in a TGF- β 2-rich environment, the ageing of ocular structures and the destructuring of the vitreous humour accompanied by possible posterior vitreous detachment could stimulate the expression of RELA-NF- κ B, IL-6 and CXCL1. Consequently, NF- κ B stimulates glial cells to produce VEGF-A, which together with tenascin-C, promotes endothelial growth and, via CXCL1, stimulates glial cell proliferation. The increased production by glial cells and astrocytes of GFAP leads to a process of progressive fibrosis that characterises the formation of the epiretinal membrane.

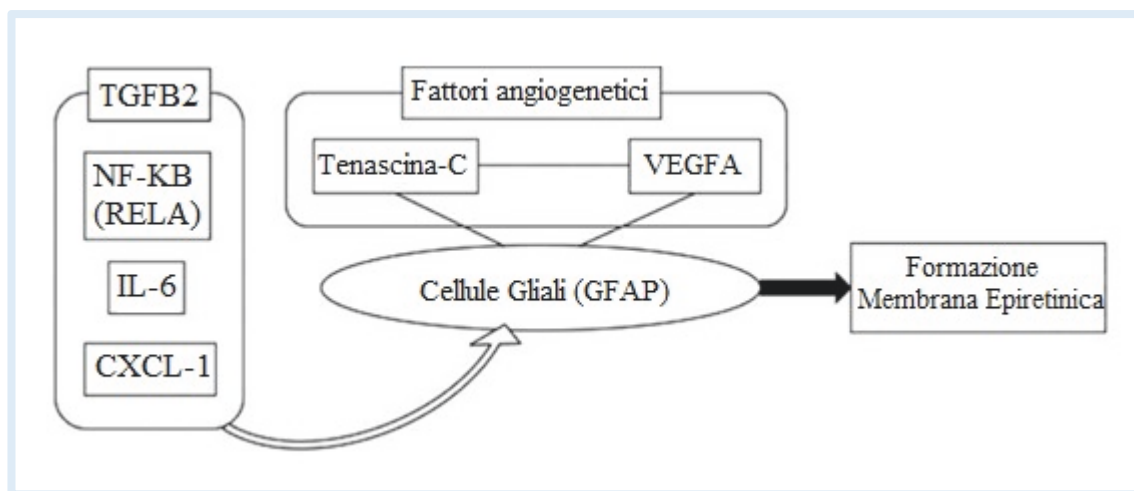

Figure 13. Illustrative diagram of the relationship between different factors whose genes have been found upregulated in eyes with idiopathic epiretinal membrane.

CHAPTER 3: PURPOSE OF THE STUDY

This interventional observational study aims to:

- Check for the presence of the soluble form of the purinergic P2X7 receptor (sP2X7R) in aqueous humour and vitreous humour.
- To compare the levels of sP2X7R in healthy conditions and in the presence of different ocular pathological conditions underlying an inflammatory pathogenesis, such as: glaucoma, uveitis, Fuchs' endothelial dystrophy, pseudoexfoliation (PEX), diabetic retinopathy, myopia, age-related macular degeneration and retinal detachment.
- Compare the levels of sP2X7R in aqueous humour and vitreous humour with those in serum.

These diseases of ophthalmological interest, which can lead to a significant reduction in visual function up to and including blindness, are determined or complicated by altered inflammatory processes. Therefore, the identification and measurement of the soluble form of this receptor in aqueous humour and vitreous humour could indicate an involvement of sP2X7R in processes leading to the development of serious eye diseases and designate sP2X7R as a marker of the ocular inflammatory state.

This evidence could be a prerequisite for targeted therapy.

Inhibition of the activity of this receptor, supported by the current availability of various pharmacological inhibitors of the P2X7 receptor.

CHAPTER 4: MATERIALS AND METHODS

Study groups

The patients involved in the study are those who underwent eye surgery at the Ophthalmic Clinic Unit of the Sant'Anna Hospital of Ferrara, from March 2019 to May 2022.

From February to September 2020, sample collection was suspended due to the shutdown of the surgical activity caused by the Sars-COV 2 pandemic.

The cohort of patients was divided into 2 groups with the following inclusion and exclusion criteria:

Group 1 - inclusion criteria:

- Patients with different eye diseases who are scheduled to undergo cataract extraction by phacoemulsification procedure
- Patients with proliferating diabetic retinopathy, trauma, vitreal haemorrhage, retinal detachment with vitreoretinal proliferation who must undergo vitrectomy procedure
- Both sexes
- Age > 18 years
- Patients giving consent for participation in the study.

Group 2 - inclusion criteria:

- Patients undergoing cataract extraction surgery in the absence of other eye diseases
- Patients undergoing vitrectomy for hole or macular pucker
- Both sexes
- Age > 18 years
- Patients giving consent for participation in the study.

Refusal to participate in the study was considered as the only exclusion criterion for both groups.

Informed consent

Candidate patients were selected based on the above-mentioned inclusion criteria, taking into account the specific ocular pathological conditions under investigation in the study at the time of the scheduled eye surgery at the Ophthalmic Clinic Unit of the Sant'Anna Hospital of Ferrara. After being informed about the procedures and the aims of the study, informed consent was collected, in accordance with the Declaration of Helsinki and the indications of the Ethics Committee for Biomedical Research (Comitato Etico di Area Vasta Emilia Centro della Regione Emilia-Romagna (CE-AVEC); ethical committee ID number: *461/2019/Oss/AOUFe*).

Sample collection and storage procedures

Collection and preparation of aqueous and vitreous humour samples at the Ophthalmic Clinic of the A.O.U. Sant'Anna of Ferrara:

- Aqueous humour samples were obtained by collection after paracentesis to access the anterior chamber of the eye during cataract extraction surgery or "closed-bulb" in the case of other procedures such as vitrectomy. This method of collection carried out early in the procedure prevents contamination of the sample with fluids and viscoelastic materials, used during surgery.

Limitation of the sampling procedure:

It is important at this point to emphasise the difficulties and limitations of the extracting procedure of the aqueous humour from the anterior chamber.

The anterior chamber is the aqueous humor-filled space inside the eye between the iris (posteriorly) and the cornea's innermost surface, the endothelium (anteriorly). The depth of the anterior chamber of the eye varies between 1.5 and 4.0 mm, averaging 3.0 mm. Its volume is about 250 microlitres (i.e. 0.25 ml) and aqueous humour is constantly produced by the ciliary bodies at a rate of approximately 2 $\mu\text{L}/\text{min}$ within the anterior cavity.

Extracting the aqueous humour from the anterior chamber logically reduces its depth, which is why the maximum amount that can be taken is around 0.1 to 0.2 ml, depending on the anatomical features and any ocular pathology present, so that the anterior chamber is not excessively deflated and the surgical procedure can then be continued safely. Most of the samples taken therefore have a volume of 0.05 ml. (min 0.05 ml, max 0.5 ml).

Of 210 patients screened for the study and who accepted and signed the informed consent to participate, 206 samples were taken during the intervention (4 samples were not sufficient for collection). Of these, 168 samples were collected in sufficient quantity for the analysis procedure to be carried out.

Minimum quantity of sample indicated per sampling: 0.05 ml.

Total number of samples collected: 206 samples

- Vitreous humour samples were obtained by sampling collected during minimally invasive 23-25 Gauge vitrectomy surgery. After placement of the 3 trocars to access the vitreous chamber, with the infusion line closed in order to avoid dilution of the sample, a 1 ml syringe was connected to the aspiration line, disconnected from the cutter to allow manual aspiration, the cutting speed was reduced to approximately 1000 cycles/min.

The vitreous chamber contains the vitreous body and the average chamber volume is between of 4 to 4.4 mm³. Therefore, vitreous humor samples of approximately 2–3 ml can be safely collected from each eye. As the volume of the vitreous chamber is larger, the amount of material that can be taken is thus higher (min 0.2 ml, max 2 ml).

The limitation to the collection of material stems from the relatively lower frequency of these pathologies (compared to cataracts), so there are fewer interventions in clinical practice.

Of 50 patients who were screened for the study and accepted and signed the informed consent to participate, 48 samples were collected during the intervention and subsequently analysed. Only 2 samples were insufficient for collection.

Minimum quantity of sample indicated per sampling: 1 ml.

Total number of samples collected: 48 samples.

- The biological fluids collected and catalogued, placed in special test tubes, were sent to the Chemical-Clinical Analysis Laboratory of the A.O.U. Sant'Anna of Ferrara and frozen at -80°C for preservation until use.

Collection and preparation of serum samples at the Ophthalmology Clinic of the A.O.U. Sant'Anna in Ferrara:

- Each of these patients was given a venous blood sample using tubes without anticoagulant before undergoing eye surgery. The venous blood sample was taken

from a peripheral venous access, which is placed in all patients attending the operating room, as a safety procedure for possible anaesthesia care during surgery.

- The test tubes were sent to the Laboratory for Chemical-Clinical Analysis of the A.O.U. Sant'Anna in Ferrara where the serum was separated by centrifugation at 300 rpm for 15 min at 4°C and divided into aliquots that were frozen at -80°C to preserve them until use.

Total number of samples collected: 210 total samples collected and analysed.

Sample analysis and measurement of sP2X7R concentration

The concentration of soluble P2X7R (sP2X7R) in vitreous humour, aqueous humour and serum samples was measured using the human P2X7 ELISA kit (Cusabio, Texas, USA) at the Experimental Medicine section of the Department of Medical Sciences, University of Ferrara.

ELISA is a quantitative enzyme immunoassay used to detect the presence of a substance using several antibodies to one of which an enzyme is bound. In the direct method, or variant

The "sandwich" wells used in this specific kit contain an antibody specific for the antigen being measured. The plasma/serum, aqueous humour or vitreous humour sample containing the antigen being tested is then added to the well, followed by a second antibody bound to a biotin molecule directed against the antigen bound to the first antibody. Next, a biotin-binding avidin solution is added, which is conjugated to a horseradish peroxidase (HRP). The peroxidase converts a specific substrate (TMB) into a coloured product that will highlight the well in which the antigen of interest is present.

The procedure began with the preparation of the **reagents**, which were brought to room temperature (18°C-25°C) before use. The tube containing the biotinylated antibody was centrifuged before opening and then serial dilution of 10 µL of 100x antibody with 990 µL of diluent was performed. The tube containing avidin-HRP reagent was centrifuged before opening and then 10 µL of 100x avidin-HRP was diluted with 990 µL of diluent. Wash buffer was prepared by bringing to room temperature and shaking the solution to dissolve any crystals present and then diluting 20 mL of 25x concentrated buffer in 480 mL distilled H_2O to obtain 500 mL of 1x wash buffer. The standard antigen solution was

prepared by centrifuging the tube at 6000-10000 rpm and the contents reconstituted with 1 ml of sample specific diluent to obtain the stock solution of 1600 pg/ml. The tube was kept in agitation for at least 15 minutes before dilutions were made. 250 μ L of diluent was inserted into each tube and 2x dilutions were made from the stock solution, taking care to mix each tube well before subsequent transfer. The undiluted standard solution acts as a high concentration standard (1600 pg/ml) while the diluent alone acts as a zero standard (0 pg/ml).

This was followed by the preparation of the **samples** for testing. Samples were brought to room temperature and centrifuged. 100 μ L of standard solution or 100 μ L of sample was added to each well of the 96-well plate. The plate was then covered with an adhesive strip and incubated at 37°C for 2 hours. At the end, the contents of the wells were removed without rinsing and 100 μ L of 1x biotinylated antibody was added to each well, the plate was covered with adhesive strip and incubated for 1 hour at 37°C. At the end of the incubation, 3 washes were performed with 200 μ L of wash buffer each. After the last wash, the plate was inverted on absorbent paper for a few minutes to remove any residual buffer. 100 μ L of 1x avidin-HRP was then added to each well, the plate was covered and left to incubate for 1 hour at 37°C. The washing procedure was then repeated 5 times. 90 μ L of TMB substrate was added to each well. The plate was then incubated for 15-30 min at 37°C in the dark. At the end of the incubation, 50 μ L of stop solution was added to each well.

Finally, the **optical density of** each individual well was determined at 450nm using a Multiskan FC spectrophotometer (Thermo Scientific), within 5 minutes of the addition of the stop solution. The tests were performed in duplicate and the antigen concentration for each well was calculated by reference to the standard curve.

Figure 15. Table with the values of the concentrations of the sP2X7R standard solution (pg/ml) and the corresponding optical densities (OD). Graph obtained from concentrations and OD of sP2X7R standard solution. In red, equation to derive the analyte concentrations knowing the OD of the sample examined.

Analysis of population characteristics and statistical analysis

The analysis of population characteristics and statistical analysis were conducted using Graph Pad for Windows and Excel.

For the numerical variables, Student's t-test was used and the chosen significance level is 0.05; for the categorical variables, Fisher's exact test was used, reporting absolute frequencies and percentages.

For the analysis of non-parametric variables, the Kruskal-Wallis test was used¹. Dunn's test is a continuation (post-hoc test) of the Kruskal-Wallis test on the comparison of ordered and ranked groups and takes into account Bonferroni's correction for multiple comparisons. For an explanation of the Dunn test and the non-parametric tests used in the report see "Alboukadel Kassambara. Package rstatix. Pipe-Friendly Framework for Basic Statistical Tests. CRAN November, 22". <https://cran.r-project.org/web/packages/rstatix/rstatix.pdf>.

All statistical analyses were performed in the R environment².

CHAPTER 5: RESULTS

Population characteristics

The analysis of the demographic characteristics of the patients enrolled has already been assessed in a preliminary analysis, subject of a dissertation discussed in the academic year 2019-2020³, in order to refine the sampling technique and preparation and the sample analysis. We therefore report those partial data in relation to demographic characteristics.

In order to analyse the characteristics of the test population, the samples collected were classified into two groups: the control group and the pathological group, consisting of all the aqueous and vitreous samples evaluated for each group.

The average age of the control group is 72.7 ± 10.8 years, while the pathological group has a mean age of 73.9 ± 12 years. The difference between the means of the groups was not statistically significant ($P > 0.74$, Student's t-test).

In the control group (17 in total) there were 9 males (52.94%) and 8 females (47.06%). In the pathological group (23 in total) there were 13 males (56.52%) and 10 females (43.48%). The difference in sex distribution between the two groups was not statistically significant ($P > 0.99$, Fischer's exact test).

With regard to laterality, the right eye was sampled in 7 cases (41.18%) in the control group and in 12 cases (52.17%) in the pathological group. While the eye affected by the sampling was the left one in 10 cases (58.82%) in the control group and in 11 cases (47.83%) in the pathological group. Also for this parameter the difference was not statistically significant ($P > 0.53$, Fischer's exact test).

Finally, the presence of systemic comorbidities in the patients of the two groups was assessed: these were found in about 11 cases in the control group (64.71%) and in 13 cases in the pathological group (56.52%). The difference was not statistically significant, with a P value of 0.74 (Fischer's exact test).

From what has been analysed, it can be seen that the two populations under consideration have homogeneous characteristics.

“Determinazione della forma solubile del recettore P2X7 in umor acqueo, umor vitreo e siero in condizioni normali e patologiche: sP2X7R come indicatore dello stato infiammatorio oculare”

Table 6. Summary of population characteristics.

	Group of controls (tot. n 17)	Pathological group (tot. n 23)	P value (<0.05)
Age (years)	72,7 ± 10,8	73,9 ± 12	P>0,74
M-F (%)	9 - 8 (52,94% - 47,06%)	13 - 10 (56,52% - 43,48%).	P> 0,99
OD-OS (%)	7 - 10 (41,18% - 58,82%)	12 - 11 (52,17% - 47,83%)	P> 0,53
Systemic Comorbidities	11 (64,71%)	13 (56,52%).	P> 0,74

Analysis of sP2X7R concentrations in aqueous humour

The datasets describing the aqueous humour and vitreous humour samples are given in Appendix A e B, each table has 16 columns and the same number of rows as the aqueous humour and vitreous humour samples taken, respectively. The measured value of the P2X7r receptor is reported in column 14 (P2X7r_pg_ml) in pg/ml. Columns 1-7 identify the subject who participated in the study with ID, date of birth, age, sex, right or left eye (OD/OS), type and date of surgery; columns 8-10 describe the sample indicating whether it was aqueous or vitreous humour, the total volume taken and the number of samples used for analysis. Columns 11-13 were reserved for the indication of the subject's primary pathology, secondary ocular pathology and any systemic pathology. Column 14 provides the measurement of the P2X7r receptor concentration in the sample taken, column 15 the results of any subsequent tests on the same sample, and column 16 the average of the values obtained.

The subjects from whom an aqueous humour sample was taken total 206 and the subjects from whom a vitreous humour sample was taken total 48.

In view of the significant difference between the subjects for whom a sample of a limiting volume for analysis (0.05 ml) was collected - especially for the aqueous humour samples - we decided to carry out a preliminary analysis to compare the distribution of P2X7r values in samples of different volumes.

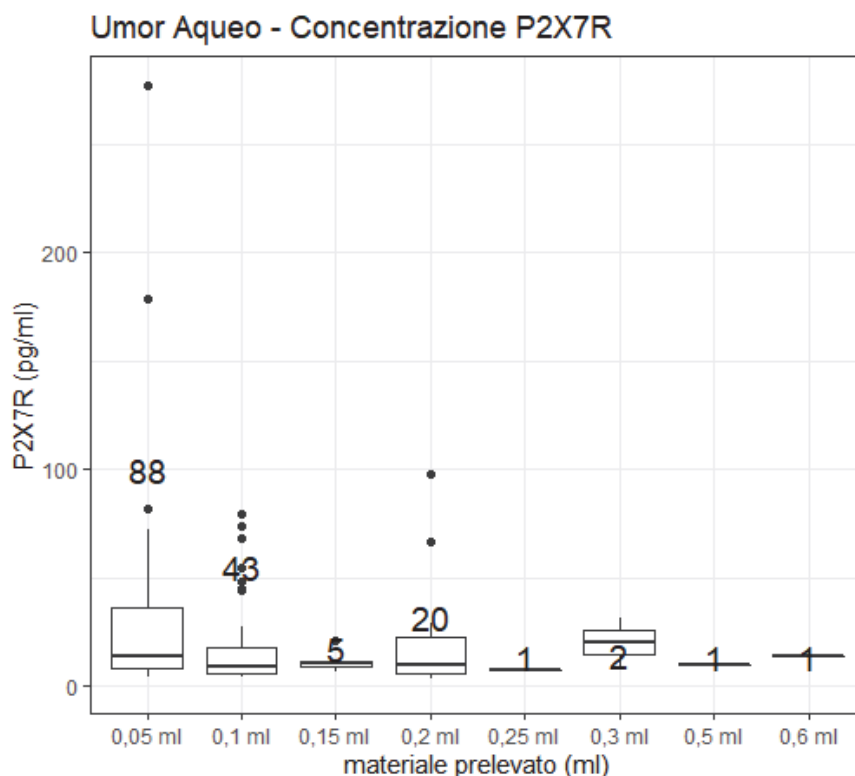

Figure 16. Box-plot of P2X7r concentration values (pg/ml) detected in aqueous humour samples

Figure 16 shows, in box-whisker plot form, the distribution of P2X7r values (pg/ml) detected in samples extracted from aqueous humour. The numbers associated with each box plot show that of the 161 values available, approximately 55% are from a sample volume of 0.05 ml and 27% and 12% respectively are samples with volumes of 0.1ml and 0.2ml; samples with volumes of 0.15ml and above 0.2ml are reduced to a few. The presence of very high outliers in the 0.05ml category makes the graph difficult to read, but it seems clear that in the most representative categories (0.05ml, 0.1ml and 0.2ml), the distribution of values is asymmetrical towards high values. As there was no reason related to the sampling technique to exclude the outliers highlighted for the 0.05 ml category, it was decided to preserve those subjects for whom a value above 100 pg/ml was observed. In the description of the sample, we will mainly refer to these three categories. On visual inspection the median value of the 0.1ml and 0.2ml groups appears to be of equal value, whereas the median value of the 0.05 group appears to be higher. For the completeness of the description we have shown in Table 7 the percentile values of each category of 'material taken' for the percentile values between the minimum value (0%) and the maximum value (100%) where next to the quartiles (25%, 50% and 75%) the percentiles 10% and 90% are taken. For the sampling categories with only one case, the percentile

values are the same and for the other categories, the median value was chosen as the representative value for the group. The 50% column of Table 7 shows that for the groups with a significant number of subjects (0.05ml, 0.1ml, 0.15 and 0.2ml) the median value is between 9 and 13 pg/ml and the Kruskal-Wallis chi-square test (chi-squared = 7.6279, df = 7, p-value = 0.3665) shows that the differences observed in do not depend on the available sample volume and the limitations of the sampling technique.

Table 7. Percentiles of the distribution of P2X7 values (pg/ml) detected in the aqueous humour samples.

Materiale Prelevato	Soggetti	Media	0%	10%	25%	50%	75%	90%	100%
0,05 ml	88	26.77	3.90	5.54	7.67	13.32	36.17	64.49	277.05
0,1 ml	43	17.57	3.90	4.29	5.93	8.68	17.31	47.18	79.24
0,15 ml	5	11.46	6.27	7.22	8.64	10.06	11.09	17.18	21.23
0,2 ml	20	18.95	3.56	4.51	5.51	9.69	22.29	32.78	97.43
0,25 ml	1	7.31	7.31	7.31	7.31	7.31	7.31	7.31	7.31
0,3 ml	2	20.23	8.98	11.23	14.61	20.23	25.85	29.22	31.47
0,5 ml	1	9.89	9.89	9.89	9.89	9.89	9.89	9.89	9.89
0,6 ml	1	13.40	13.40	13.40	13.40	13.40	13.40	13.40	13.40

The subjects for whom aqueous humour was taken were separated into healthy patients (control sample) and patients with disease (pathology samples), as depicted in Appendix B and listed in Table 8. Appendix B lists the patients for whom the appropriate attribute was assigned in the 'control/pathology' column; the number of patients belonging to the control group and the groups associated with the individual diseases is listed in Table 8, where the acronym used for the analysis is also indicated. Some non-specific pathologies causing a possible inflammatory state are indicated by the acronym MISC; these grouped pathologies account for approximately 0.018% of the sample examined. In this table not analysed samples are yet removed respect to the bulch collection.

Column M in Appendix B shows the P2X7r concentration values detected in the serum of the patients for whom an aqueous humour sample was taken. For a significant proportion of patients (approximately 60%), P2X7r could be detected in both samples, aqueous humour and plasma serum.

Table 8 Groups characteristics: description of the different groups, number of patients enrolled and sampled in each group, percentage of total.

Group definition	N of patients	%	details
CONT	69	0,411	No concomitant ocular pathology
G	17	0,101	Glaucoma
E	17	0,101	Endothelial dystrophy (Fuch's disease, guttae, low endothelial count)
M	16	0,095	Myopia
RDP	11	0,065	Proliferative diabetic retinopathy
DDRR	11	0,065	Regmatogenous retinal detachment
AMD	10	0,060	Age related macular degeneration, atrophic and/or exudative
PEX	7	0,042	Pseudoexfoliative syndrome
MP	5	0,030	Macular pucker
MISC	3	0,018	Miscellaneous (pathologies with inflammatory activation)
OVR	2	0,012	Retinal vascular occlusion
Tot	168	1	

The P2X7r values measured in the subjects belonging to the controls category (CONT) and the categories representing the pathologies listed in Table 8 are represented in the box-whisker plot in Figure 17 and are summarised in Table 9, where the mean value and percentiles between the minimum value (0%) and the maximum value (100%) are indicated; the 50% percentile or median of P2X7r is the reference value used to compare the controls and pathologies groups.

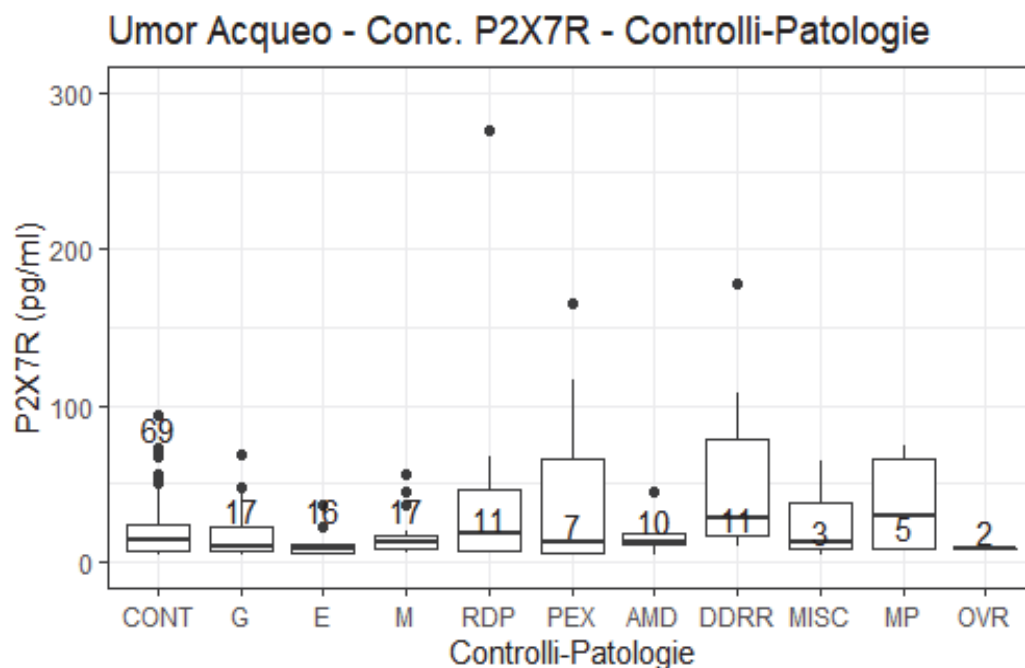

Figure 27. Box-plot of P2X7r concentration values (pg/ml) found in the Control (CONT) and disease groups in aqueous humour

OVR	2	8,07	7,31	7,46	7,69	8,07	8,45	8,83

From the graph in Figure 17, it is evident that for each group, the distribution of P2X7r values is asymmetrical towards high concentration values. In 8 of the 11 groups shown in Figure 17, outliers are evident (dots indicate the outliers). The control group (CONT) shows outliers of values approximately equal to and above the 90% percentile (53 pg/ml) shown in Table 9. The highest value outliers belong to the DDRR, PEX and RDP categories and are well above the maximum value of CONT (94 pg/ml). The graph and the values in Table 9 show that the 75 per centile of the DDRR, PEX and RDP categories have values greater than the 3rd quartile of CONT (24 pg/ml), indicating that, even with a limited number of observations, the P2X7r concentration for these diseases (108, 65 and 46 pg/ml respectively) tends to be greater than the receptor concentration values in the control group. Other pathologies such as Macular Pucker, AMD and the pathologies enclosed in the MISC category show values that are 75% higher than the control group, while other pathologies such as myopia (M) and glaucoma (G) the 3rd quartile (75%) have values similar to or lower than the control value. The Kruskal-Wallis Chi-squared on the equality of the medians of the groups listed in Figure 17 and Table 9 (Kruskal-Wallis chi-squared = 18.254, df = 10, p-value = 0.05082) estimates a p-value slightly above the test reliability limit (p=0.05), confirming that the median value of the P2X7r concentration measured in the groups listed in Table 8 is not the same.

Table 10. Kruskal-Wallis chi-squared test result

concentrazione	n	statistic	df	p-value	method	alpha
p2x7r_pg_ml	168	18,3	10	0,0508	Kruskal-Wallis	0,05

Table 11 shows the paired hypothesis testing between controls and each disease group. The Dunn-test between the paired groups allows to control the type of correction to be introduced to account for repeated testing.

We ran the test twice. Firstly, the Dunn-test was run with no correction and the test results indicate a significance ($p < 0.05$) between the P2X7r values found in the endothelial dystrophy group and the rhegmatogenous retinal detachment group compared to the control. Secondly we decided to apply the Bonferroni's correction factor to counteract the multiple comparisons problem.

Table 11. Dunn-test with no correction

Acqueous and serum analysis of sP2X7R concentrations

Of 206 patients enrolled for aqueous humour analysis, 34 serum samples were not taken or could not be analysed. Of the 170 samples taken and analysed, only 142 could be correlated with the respective aqueous samples.

Sperman's non-parametric test shows significant correlations (p-value <0.05) for sP2X7r concentration values in aqueous humour and serum in the control group, in the glaucoma and PEX group, as shown in table 13 and in Figure 18..

Figure 18. Scatter-plot representation of sP2X7r aqueous/serum correlation

Analysis of sP2X7R concentrations in vitreous humour

The dataset in which the P2X7r concentration values are collected is reproduced in the table in Appendix C. There are a total of 50 cases in this table, and the classification of the data set is the same as that used for the aqueous humour samples. The diagram in Figure 1 shows the P2X7r concentration values related to the volume of vitreous extracted for each sample (min 0.2ml – max 2ml volume samples). It was decided to represent the individual concentration values by means of a dot plot due to the small size (one or two subjects) of many samples, instead of the box-plot representation used to describe the aqueous humour sample. In the diagram in Figure 19, the segment connecting the maximum and minimum values indicates the presence of at least two values. The category NA represents two samples in which the amount of material taken was not reported in the dataset and since the samples belong to two different subjects, it was considered appropriate to exclude them from the analysis.

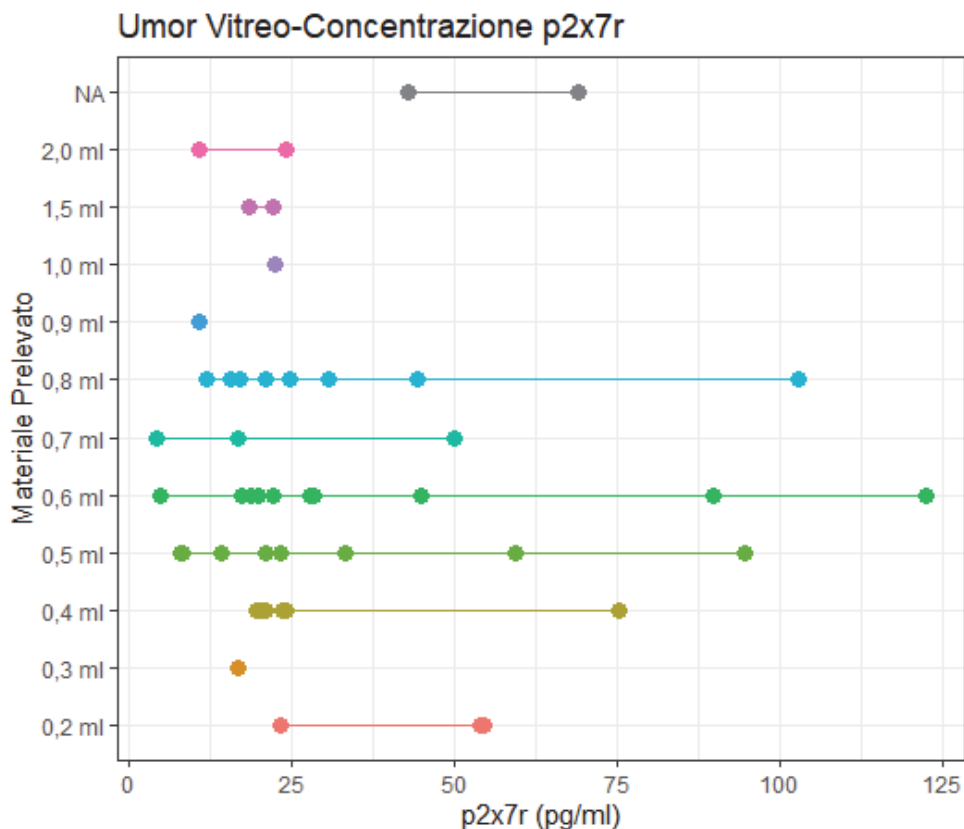

Figure 19. Dot-plot representation of sP2X7r values in vitreous humor in relation to the volume of vitreous extracted

Figure 19 also shows that for many categories of sampled material the P2X7r values are very limited in number. In order to summarise the values of the different categories it was considered appropriate to simplify the percentile representation by summarising in Table 14 the sequences of the categories of sampled material with the minimum (0%), maximum (100%), mean and median (50%) values. The hypothesis test performed for the categories with at least two observations (Kruskal-Wallis chi-squared = 7.0209, df = 10, p-value = 0.7235) supports the initial assumption of equality of the median value in the different groups.

Table 14. Percentiles of the distribution of P2X7 values (pg/ml) detected in the vitreous humour samples

tot_material_sampled	N. of patient	Media	0%	50%	100%
0,2 ml	3	43.90	23.16	54.10	54.45
0,3 ml	1	16.78	16.78	16.78	16.78
0,4 ml	7	29.68	19.71	23.51	75.32
0,5 ml	9	32.80	7.99	22.09	94.74
0,6 ml	11	37.65	4.95	22.13	122.57
0,7 ml	3	23.69	4.22	16.78	50.08
0,8 ml	8	33.51	12.03	22.82	102.76
0,9 ml	2	10.75	10.75	10.75	10.75
1,0 ml	1	22.47	22.47	22.47	22.47
1,5 ml	2	20.23	18.33	20.23	22.13
2,0 ml	2	17.47	10.92	17.47	24.03

The limited number of subjects from whom the vitreous humour sample was taken shows fewer pathologies than observed in Appendix B where aqueous humour samples are collected. Table 15 lists the number of patients in the control (no pathology) categories and the ocular pathologies found in the anamnestic-diagnostic (DDRR – rhegmatogenous retinal detachment; RDP – proliferative diabetic retinopathy; MISC- miscellaneous: subluxed IOL (intraocular lens), cortical lens residues, intraocular foreign body).

Table 15. Groups characteristics: description of the different groups, number of patients enrolled and sampled in each group, percentage of total.

Group definition	N. of samples	%	Details
CONT	19	0,396	assenza di patologie
DDRR	22	0,458	distacco di retina regmatogeno
RDP	4	0,083	retinopatia diabetica proliferante
MISC	3	0,062	miscellanea di patologie con attivazione infiammatoria
Total	48	1	

The box-plot diagram in Figure 20 shows that the distribution of receptor concentration values in the control group (CONT) have a lower median value and a limited dispersion. In Table 16 the median (50%) is 20 pg/ml and the interquartile range at IQR = 75%-25% = 21.8 pg/ml. The different pathology groups have a greater dispersion and a slightly higher median in DRRR and MISC; in the RDP group median and dispersion are much higher than in the control group.

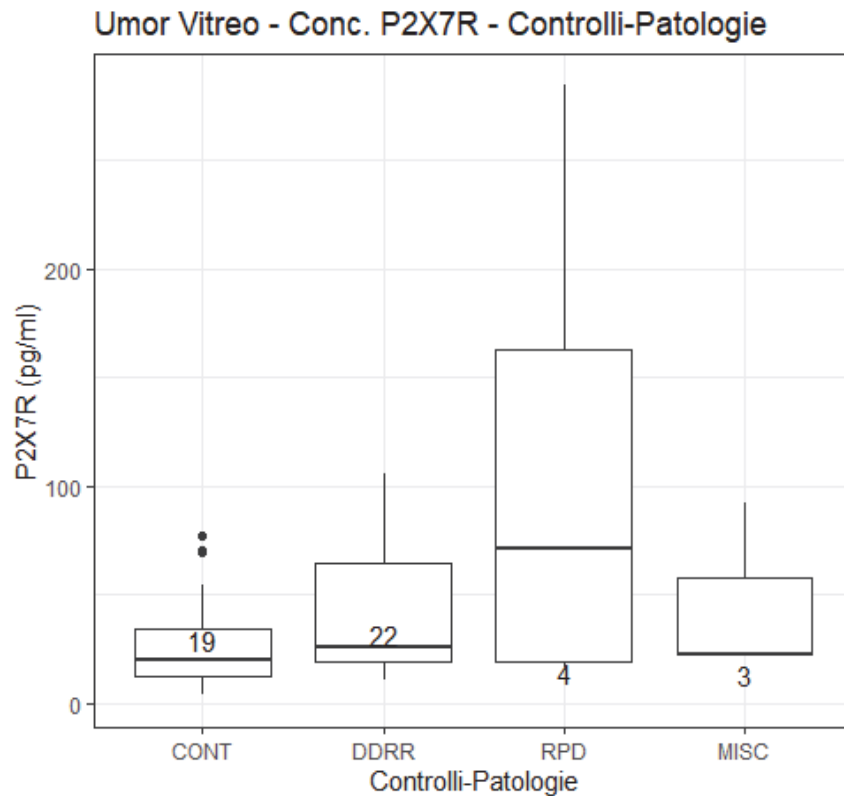

Figure 20. Box-plot of the P2X7r values distribution detected in healthy patients (CONT) and the pathology groups. Values superimposed on the box-plot indicate sample size.

Table 16. Percentiles of the distribution of P2X7r values (pg/ml) detected in vitreous humour samples

gruppo	soggetti	media	0%	10%	25%	50%	75%	100%
CONT	19	28,02	4,22	6,84	12,73	20,23	34,53	76,92
DDRR	22	42,35	10,75	17,31	19,23	25,93	64,17	105,28
RDP	4	110,91	16,95	17,73	18,91	71,07	163,07	284,57
MISC	3	45,65	22,13	22,2	22,3	22,47	57,41	92,34

The non-parametric hypothesis test performed with the Kruskal-Wallis Test on the equality of the median of the groups in Figure 20 (Kruskal-Wallis chi-squared = 4.6481, df = 3, p-value = 0.1995) does not allow the initial hypothesis to be rejected with probability p-value

= 0.1999 (Table 17). The test result therefore does not allow the assertion that there is a significant difference between the P2X7r content in the vitreous of healthy patients and patients with the studied eye diseases. The difference between the sample size with healthy subjects (CONT) and subjects with DRRR (Regmatogenous Retinal Detachment) - 19 and 22 cases, respectively - and the size of the RDP (4 subjects) and MISC (3 subjects) groups suggested us to use Dunn's Test to perform the pairwise comparison of the groups shown in Table 16.

Table 17. Kruskal-Wallis chi-squared test result

concentrazione	n	statistic	df	p	method
p2x7r_pg_ml	48	4,648084	3	0,1991	Kruskal-Wallis

Table 18 shows the result of the Dunn-Test between the control group (CONT) and the pathology and between the pathologies: the p-value obtained in the presence of the Bonferroni correction (p.adj.signif) proves that the Test is non-significant for any pair of groups.

Table 18. Dunn-test results without and with Bonferroni's correction

Figure 21. Scatter-plot representation of sP2X7r viterous/serum correlation

CHAPTER 6: DISCUSSION AND CONCLUSIONS

This study provided a fair amount of data on the presence of the soluble form of the P2X7 receptor (sP2X7R) in aqueous humour and vitreous humour and its involvement in inflammatory eye disease.

Analysis of sP2X7R concentrations was only possible in 168 samples compared to the 206 aqueous samples initially collected due to the small amount of biological fluid (<0.05ml) that could sometimes be taken from the anterior chamber of the eye, in order to ensure the subsequent planned surgery could be performed safely for the patient. A further obstacle encountered during the study was the relatively low number of vitrectomy procedures performed on patients meeting the inclusion criteria, which allowed only 50 samples to be collected. Finally, limitations also included the number of patients who denied their consent, but above all the shutdown of surgical turnover related to the COVID-19 pandemic, with a total restriction of surgeries scheduled in the period February - September 2020 and occasional lockdown periods between February 2021- February 2022.

- Check for the presence of the soluble form of the P2X7 receptor (sP2X7R) in aqueous humour and vitreous humour.

In this study, the soluble form of the P2X7 receptor was identified for the first time in aqueous humour and vitreous humour and was measurable using a specific ELISA kit.

The range of sP2X7R concentrations in the aqueous humour samples from the control group was 3.89 to 93.87 pg/ml; in the aqueous humour samples from the pathological groups the concentrations ranged from 3.55 to 277.04 pg/ml. In the vitreous humour, the range of sP2X7R concentrations in the control group was 4.21-76.92 pg/ml and in the group of cases with pathological conditions the range of concentrations was 28.52-284.57 pg/ml. Within the rhegmatogenous retinal detachment group, the range was 28.52-105.28 pg/ml. Within the proliferative diabetic retinopathy group, the range was 6.94 – 284.57 pg/ml.

From the data collected and considering that the sensitivity limit of the kit used with regard to sP2X7R concentrations is 7pg/ml, it is possible to state that the soluble form of the P2X7 receptor (sP2X7R) is released into ocular fluids both in the presence of ocular pathogenic inflammatory diseases and in their absence, but with different amount. In addition, concentrations of the soluble form of this receptor are measurable

by the ELISA kit used, defining a scientific and repeatable way of assessing concentrations of this analyte.

By performing the Kruskal-Wallis test on the sP2X7r concentration values (expressed in pg/ml) detected in the aqueous and vitreous humour samples in relation to the relative amount of material collected, we also showed that the median value of the detected concentration of sP2X7r does not depend on the amount of material collected in the sample, the difference in the median not being significant. This is especially important in aqueous samples, where sampling is limited by the small amount of aqueous that can be taken from the anterior chamber, so that the following steps of the surgery can then be carried out safely.

Further studies are needed to find the cellular source of the soluble form of this receptor, bearing in mind that the P2X7 receptor has been found on the membrane of many cells in the tissues of the eyeball and ocular adnexa, and some of them, such as corneal epithelial cells, retinal Müller cells, cells of the retinal pigment epithelium and photoreceptors, actively participate in ocular inflammatory processes [85]. In the search for sources, we should also build on the results of the study conducted at the University of Ferrara, which identified peripheral blood mononuclear cells (PBMCs) isolated from peripheral blood as a possible source of the plasma-soluble form of the receptor. PBMCs isolated from healthy subjects release sP2X7R into the culture medium after stimulation with BzATP [2',3'-O-(4benzoylbenzoyl)-ATP], an ATP analogue, and to a greater extent after pre-stimulation with LPS, simulating an inflammatory condition on an infectious basis in vitro. Furthermore, plasma sP2X7R is present to a large extent associated with microvesicles/microparticles (MVs/MPs), i.e. heterogeneous populations of particles of different sizes and cellular origins [84].

- Compare sP2X7R levels in healthy conditions and in the presence of different ocular pathological conditions.

In the second part of the study, a statistical analysis of the sP2X7R concentration values was carried out, comparing each individual group of patients with the ocular disease conditions under investigation with the control group for aqueous humour and vitreous humour.

The Kruskal-Wallis Chi-squared on the equality of the medians of the groups, both control and pathology groups of the aqueous samples, (Kruskal-Wallis chi-squared = 18.254, df = 10, p-value = 0.05082) estimates a p-value slightly above the test reliability

limit ($p=0.05$), confirming that the median value of the sP2X7r concentration measured in the pathology groups, when all the data are considered together, is significantly different from the control group. Despite the finding of high maximum concentrations of P2X7r in its soluble form in the disease groups, analysing each pathology group compared to the control group, statistical analysis using Dunn's Test to perform the pairwise comparison of the groups with the Bonferroni's correction factor, failed to confirm a statistically significant difference. It is interesting to note that by not applying Bonferroni's correction factor to the statistical analysis, the concentrations of the soluble P2X7 receptor in the rhegmatogenous retinal detachment and endothelial dystrophy groups were significantly different ($p=0.01$ in both groups). This is probably due to the fact that the Dunn Test takes into account the representativeness of the sample for each group. In fact, the sample size reflects on both the median and the sample dispersion. It should be noted that in our analysis, the control group consists of 69 aqueous samples, while the pathological groups have a range of 2 (i.e. retinal vascular occlusion) to 17 (i.e. glaucoma and myopia) aqueous samples.

The non-parametric hypothesis test performed with the Kruskal-Wallis Test on the equality of the median of the groups, both control and pathology groups of the vitreous samples (Kruskal-Wallis chi-squared = 4.6481, $df = 3$, $p\text{-value} = 0.1995$) does not allow the initial hypothesis to be rejected with probability $p\text{-value} = 0.1999$ (Table 17). The test result therefore does not allow the assertion that there is a significant difference between the P2X7r concentration in the vitreous of healthy patients and patients with the studied eye diseases. The difference between the sample size with healthy subjects (CONT) and subjects with DDRR (Regmatogenous Retinal Detachment) - 19 and 22 cases, respectively - and the size of the RDP (proliferative diabetic retinopathy - 4 subjects) and miscellaneous (3 subjects) groups suggested us to use Dunn's Test to perform the pairwise comparison of the groups.

The reason for the lack of significance in these analyses is probably due to the paucity of samples collected during the time available for the study. A clarification is however necessary: the overall amount of samples taken was relevant, nevertheless when stratified by singular diseases an under-reporting situation occurs, which could explain the test's drop in significance.

Other possible reasons of the loss of samples to be taken into account were: the impossibility of analysing some of the aqueous humour samples (loss of 38 samples out of the total of 206) due to the fact that the amount of aqueous humour that could be taken from the anterior chamber of the eye did not reach the minimum necessary for analysis using the ELISA kit (minimum sample quantity 0.05 ml); the limited number of vitrectomy operations carried out on patients compatible with the inclusion criteria during the data collection period; finally, the selected patients who refused to give consent. From this we can deduce that, in order to obtain reliable and statistically significant results, it would be necessary to continue collecting samples in order to enlarge the above-mentioned single pathology groups.

Although no statistically significant difference emerged, it is interesting to note that sP2X7r concentration values are elevated in the vitreous humor of proliferating diabetic retinopathy patients. A great deal of evidence from in vitro studies using cell cultures and in vivo studies using mouse models of diabetes has revealed an important role for P2X7R in the pathogenesis of diabetic retinopathy, one of the main microangiopathic complications of diabetes mellitus. Exposure of pericytes to high concentrations of glucose induces the activation of a P2X7R-mediated signalling pathway that promotes the acquisition by these cells of an inflammatory phenotype, as evidenced by the secretion of TNF- α and IL-1 β . In the same study that demonstrated this phenomenon, it was also found that hyperglycaemia-induced damage in retinal pericytes leads to cell lysis, accompanied by the release of ATP into the extracellular environment, which in turn binds P2X7R on neighbouring cells, activating the inflammasome and taking on the function of an inflammatory damage signalling device via an autocrinoparacrine mechanism [122]. Moreover, P2X7R activation is a powerful trigger for VEGF release. Indeed, the expression of the NLRP3 inflammasome, the activation of which can occur through P2X7R stimulation, is increased in the vitreous fibrovascular membrane of patients with diabetic retinopathy and dysregulation of NLRP3 in hyperglycaemic transgenic mice leads to vascular *leakage* and retinal neovascularisation [120]. These results support the hypothesis that the P2X7 receptor is a key factor in the onset of diabetic retinopathy.

It would therefore be interesting to further expand the data collection and include both diabetic patients without ocular complications and patients with diabetic retinopathy in

the analysis, in order to highlight possible different level of P2X7r expression in the different disease's stage.

- Compare the levels of sP2X7R in aqueous humour and vitreous humour with those in serum.

This comparison was conducted in an attempt to compare the concentration of the P2X7r receptor in its aqueous or vitreous soluble form and in serum. However, no statistically significant correlation between local and systemic concentration was found in the analysis. This confirms that the eye is a site of immunological privilege.

In conclusion, it is possible to extrapolate from this study interesting data that reflect a local and time-limited reality, but which could lay the foundations for further investigations. The presence of the soluble form of the P2X7 receptor in aqueous humour and vitreous humour was tested and confirmed, and the ELISA kit used proved to be a reliable tool. Due to the limited number of samples tested, it cannot be said that sP2X7R is a marker of ocular inflammation in general, but in our opinion still remain a field that deserves a deeper investigation.
