#110 - Abstract

HOW DO PATIENTS WANT US TO USE THE COMPUTER DURING MEDICAL ENCOUNTERS?

Cédric Lanier¹, Melissa Dominicé Dao², Dave Baer³, Dagmar Haller-Hester¹, Johanna Sommer¹, Noëlle Junod Perron¹

¹ Geneva Faculty of Medicine, Geneva, Switzerland

² Geneva University Hospitals, Geneva, Switzerland

³ Cité Générations Onex, Onex, Switzerland

Background

The Electronic Health Record (EHR) is now widely used during medical encounters. To avoid negative impact on doctor-patient communication, experts in clinical communication have issued recommendations for a patient-centered use of EHRs. However, these recommendations have never been validated by real patients. The aim of our study is to explore patients' preferences regarding doctors' EHR-related behaviours as well as the factors influencing their choice.

Methods

An exploratory study was conducted at two outpatient clinics in Geneva in 2018. French speaking patients, waiting for a medical consultation, were invited to watch videos displaying variations of EHR-related behaviors and indicate which one they preferred. The videos featured 4 specific physician EHR-related behaviours with 2 or 3 variations for each: 1) typing: continuous/intermittent/manual writing; 2) mean of maintaining contact while typing: visual and verbal/verbal/visual; 3) signposting the use of EHR: with/without; 4) position of physicians' hands and bust: on the keyboard and towards the patient/away from the keyboard and towards the patient/on the keyboard and towards the screen. Experienced clinicians blinded to the study identified and validated the videotaped variations of the different EHR-related behaviors. A short questionnaire collected patients' socio-demographics and attitudes/experiences of EHR use. We used multinomial logistic regression to analyze the factors associated with patients' choices.

Results

336 patients watched three different videotaped standardized encounters. A majority preferred intermittent typing versus manual writing or continuous typing (35.7% vs 28.0% or 16.3%). They favored visual and verbal contact (38.9%) over verbal (30.3%)

or visual (13.0%) contact only while typing, as well as signposting the use of EHR versus no signposting (58.9% vs 34.8). Finally, the position with the physician's bust toward the patient and hands away from the keyboard was chosen by a higher proportion of patients (49.7%). The multivariate analyses showed that among all patients' characteristics, only a positive attitude towards EHR was consistently associated with a preference towards intermittent or continuous typing.

Conclusion

Our results confirm patient's positive attitude toward the use of EHR by physicians as well as towards the use of the EHR that follows expert recommendations. Such recommendations should be more consistently taught during medical training.

#118 - Abstract

FROM THE PRIMARY CARE CLINIC TO THE INPATIENT DEPARTMENT AND BACK: CONTINUITY OF CARE AND PROVIDERS

Jenan Awesat, Boris Shvarts, Tali Shafat, Jacob Drieher, Shlomi Codish, Leonid Barski

Soroka University Medical Center, Beer Sheva, Israel

Background

During the last decades recurrent hospitalizations have become one of the main problems facing internal medicine and primary care staff. At our institute, patients are currently admitted sequentially to internal medicine wards. The staff of the primary care clinic does not know the ward's staff, and they have few opportunities for feedback to impact the course of admission.

Aim

To evaluate the effectiveness of an intervention to admit primary care clinic patients to a specific internal medicine ward, in terms of readmission rate, quality of care, patient and staff satisfaction.

Methods

The study included all patients from community clinic "E" who were admitted to internal medicine between June 2015 and December 2016, with two comparison groups: a historical cohort of Clinic "E" (June 2012-Dec 2013) and concurrent cohort of Clinic "A" patient's admissions. Outcomes included readmissions

rates, patients and staff satisfaction. Patients' and hospitalization characteristics were compared between the two clinics. We used generalized estimating equation (GEE) logistic regression model (unstructured matrix) to compare proportions of readmission between intervention vs. control groups, to account for the clustering of the responses by the same patient.

Results

During the study period 2015-2016, 217 patients of clinic "E" were admitted 454 times to ward "F". Meanwhile, 351 clinic "A" patients were admitted 617 times to all internal medicine wards. The historical cohort included 699 admissions of 396 patients of clinic "E" to all wards. Readmission rate during one week was 5.9% in intervention group, 8.0% in historical clinic "E" cohort, and 7.3% in clinic "A" cohort. During one month, proportions were 15.9%, 20.5% and 20.9% respectively. In multivariate analysis, readmission rate during one week was lower among intervention group compared to historical cohort of clinic "E" (OR=2.77 95% CI 1.73-4.44 P<0.001) adjusted to age and gender. During one month, there was a trend toward lower readmission rates in comparison to current cohort of clinic "A" (OR=1.38 95% CI 0.96-1.99 P=0.086) adjusted to age and gender.

Conclusion

Clustering primary care clinic patients to admission in a specific internal medicine ward was associated with decreased readmission rates and improves patient's satisfaction.

#349 - Abstract

THE IMPACT OF 24-HOUR AMBULATORY MEASUREMENT ON ANTIHYPERTENSIVE THERAPY MODIFICATION AND CHANGE IN DIPPER STATUS

Sebastjan Bevc^{1,2}, Jaime Blazquez-Saldana³, Nejc Piko¹, Cvetka Krel¹, Robert Ekart^{4,2}, Radovan Hojs^{1,2}

¹ Department of Nephrology, Clinic for Internal Medicine, University Medical Centre Maribor, Maribor, Slovenia

² Medical Faculty Maribor, University of Maribor, Maribor, Slovenia

³ Autonomous University of Nuevo Leon, Monterrey, Mexico

⁴ Department of Dialysis, Clinic for Internal Medicine, University Medical Centre Maribor, Maribor, Slovenia

Background

The 24-hour ambulatory blood pressure measurement is a useful, noninvasive tool for the evaluation of blood pressure status of the patients. Since arterial hypertension remains an important risk factor for development and progression of chronic kidney disease, the exact evaluation of blood pressure is crucial. The results of 24-hour ambulatory blood pressure measurements should lead to a modification in antihypertensive therapy and consequently optimization of blood pressure. However, less is known about the possible change in dipper status in these patients. The aim of this study was to determine the impact of 24-hour blood pressure

measurements on the change in drug prescriptions and if this change resulted in a decrease in blood pressure and/or dipper status of the patients.

Methods

11 patients (8 women - 72.7%), were included in the study. All patients had two 24-hour ambulatory blood pressure measurements in the period of 6 months. Therapy prior to first and after the second measurement of 24-hour ambulatory blood pressure was recorded. Blood pressure values and dipper status of all patients were recorded in the first and second measurement as well. SPSS statistical software was used for statistical analysis.

Results

The average systolic blood pressure in the first measurement was 150.8 +/- 23.2 mmHg (minimum 125 mmHg, maximum 209 mmHg) and diastolic 85.7 +/- 22.2 mmHg (minimum 58 mmHg, maximum 130 mmHg). 7 patients (63.6%) were either non-dipper (n=3, 27.3%) or reverse-dipper (n=4, 36.4%). Antihypertensive therapy was modified, a significant increase in combination therapy was observed (1 patient before the first measurement (9.1%), compared to 5 patients (45.5%) after the second measurement). Drug therapeutic groups remained unchanged. The average systolic blood pressure in the second measurement was 146.3 +/- 23 mmHg (minimum 109 mmHg, maximum 194 mmHg) and diastolic 83.5 +/- 21.5 mmHg (minimum 69 mmHg, maximum 144 mmHg). We observed change in dipper status where one patient became normal dipper and the number of patients in the reverse-dipper group decrease importantly (4/11 (36.4%) at the beginning vs 2/11 (18.2%) after therapy adjustment).

Conclusion

The results show the importance of 24-hour blood pressure measurement on the optimization of the antihypertensive treatment regimen, emphasizing the prevalence of combination therapy. An increase in combination therapy resulted in better blood pressure control and changed dipper status.

#509 - Case Report

THE TRADITIONAL CHINESE MEDICINE IN THE PRACTICE OF THE PUBLIC HEALTH SERVICE

Tereza Cabral Gomes

Municipal Health Department, Macaé, Brazil

Introduction

The interaction among different therapeutic practices in the ambulatory sphere was strengthened with the implementation in the Brazilian public sector of the National Policy of Integrative and Complementary Practices (NPICP), where Traditional Chinese Medicine (TCM) and other acupuncture practices, such as the Yamamoto New Scalp Acupuncture (YNSA), could reach populations which find it difficult the access to them. The work is

developed in the Municipal Nucleus of Integrative Health (MNIH) in the city of Macaé, as well as auriculotherapy and homeopathy.

Case description

The use of TCM has, as a target, to extend the medication response of conventional practices and decrease the time of use of symptomatic drugs, through the articulation of the TCM with the other medical and paramedical specialties available in the MNIH and in any other health services of the municipality.

The treatment based on the TCM addresses the patient having not only the nature of the disease as a parameter, but also the constitution of the individual restoring their homeostasis, and it is in this context of the therapeutic response that the study develops. To the traditional anamnesis were added the examination of the tongue and pulse, recognizing the constitution of the patient to draw the therapy. The integration of the practices carried out in the MNIH also allowed the association of these to the diagnosis and therapeutics of patients in homeopathic treatment that could be used of parameters such as the physical examination based on the TCM, as well as in the motor physiotherapy in neurological patients when performed simultaneously to the cranial pinning point, YNSA.

Discussion

The MNIH work experience allowed patients with autoimmune and neurological diseases to be treated simultaneously with the Integrative and Complementary Practices associated with conventional therapies, resulting in the reduction of the confirmed inflammatory process in imaging scans and serology tests, improvement of the dynamic balance and improvement of muscle strength and proprioception in neurological disorders and reduction or suppression of symptomatic medications.

The association of TCM with the traditional therapeutic arsenal provided treatment of relevance demonstrated by the clinical improvement and by complementary exams of the patients. Because it does not present side effects nor absolute contraindication, it has a range in pathologies beyond the syndromes traditionally described.

#912 - Abstract

INTEGRATING CONSCIOUS/UNCONSCIOUS FILM MESSAGES AS POST-HYPNOTIC SUGGESTIONS

António Pais-De-Lacerda¹, Noa De Lacerda²

¹ Hospital de Santa Maria, CHULN, Lisbon, Portugal

² Instituto Nacional de Cardiologia Preventiva Professor Fernando de Pádua, Lisbon, Portugal

Background

Suggestions can be answered with or without hypnosis so that they can be used consciously or subconsciously. Post-hypnotic suggestions are intended to generate a particular patient's response in his/her everyday life, in order to drive a modification

of some behaviour or belief, by processing stimuli during hypnosis in a modified state of consciousness. We intended to ascertain the effect of the "conscious" reinforcement in real life, of posthypnotic suggestions - during a playful activity - in which the passive (but emotionally involved) person observes, through the visualization of a movie, a reality of circumstances that mirror his/her own problems.

Methods

Study of 3 clinical cases (1. 24-year-old brother of a 18-year-old girl dying with irreversible disease - does not accept his sister's death; 2. Social isolation in a 45-year-old woman with peritoneal carcinomatosis; 3. Depression in a 56 years old woman with an "impossible" relationship with her mother). All patients underwent 2 sessions of hypnotic trance (15 days apart) with post-hypnotic suggestions. At the end of the second session of the 3 cases, the visualization at home of a particular film (related with the concerned problem) was recommended. Proposed movies: 1. "My Sister's Keeper" (by Nick Cassavetes, USA, 2009); 2. "Y tu mamá también" (by Alfonso Cuarón, Mexico, 2001); 3. "Boulevard" (by Dito Montiel, USA, 2014).

Results

In the 3 cases, there was a change in the unwanted behaviour in a period of less than one month (1. Acceptance and pacification, with a short early mourning depression; 2. Carrying out a long trip to the East that has long been dreamed, but never previously considered for "this actual" moment; 3. Understanding her father's homosexuality and insight into the tolerance of her mother, who never asked for divorce).

Conclusion

The phenomenon of hypnotic suggestions has emphasized the importance of the "cognitive unconscious" in modifying and generating personal behaviours and experiences. The interflow of unconscious post-hypnotic cues with a conscious verbal and non-verbal involvement of both cerebral hemispheres can accelerate and strengthen the behavioural modifications required by both the awakening of memories and the wider promotion of introspection. The visualization of films advised by an internist can promote the understanding of many situations difficult to manage, modifying behaviours and attitudes not only of the patients but also of their relatives.

#1022 - Abstract

STUDY OF PREVALENCE ON ALCOHOLISM AND ASSOCIATED CLINICAL FACTORS IN THE COMMUNITY

Pascual Valdez, Hugo Milione, Gabriela Lourtau, Eduardo Del Cerro, Miriam Otero, Juan Lamelza, Yesenia S Maldonado Torres, Yanina Mancuso, Daniela Mantella Gorosito, Matias Laguzzi, Michelle Schavartz, Nahir Alarcon, Noelia Sanchez, Paula Pañiagua National University La Matanza. Argentina., Buenos Aires, Argentina

Objectives

To quantify the prevalence and periodicity of alcohol consumption in the community, describe the AUDIT questionnaire items, quantifying responses in each one of them

Methods and Population

Prospective, observational, transversal, analytical study. Community of La Matanza. Accidental sampling approach on public roads prior consent. Descriptive and inferential statistics. 594 citizens were approached.

Results

Mean age \pm MAD 25.00 \pm 5.00, ranges: 11-89 years, highest prevalence between 17-23 years. Female predominance (52.8%). 57.9% consume alcohol habitually, 65.5% consumed in the last month. The consumption is daily in 8.2%, sporadic in 40.7% and only weekends in 51.1%. 52.3% drive vehicles. In 19% there are other consumptions. 53.7% have had acute symptoms (abstinence or drunkenness). 3.2% of women who have been pregnant consumed alcohol during the pregnancy. In the AUDIT questions the answers were: consume 2-4 times a month 30.6%; one to two drinks daily 60.5%. 9.9% consume 6 or more drinks in a day. 2.7% have not been able to do their activity once a month for having drunk. 5.1% have monthly regrets for drinking. The 16.2% had a damage by their consumption (the drinker or another person), In 13% someone was worried about their alcoholism. Medium AUDIT 4, people with AUDIT of 8 or more: 44 (7.45%).

Conclusion

Habitual consumption of alcohol is high. The AUDIT detects specific data that interfere with the quality of life.

#1032 - Abstract

COMPARATIVE STUDY OF THE CONTINUITY IN TREATMENT BETWEEN PATIENTS WITH DISORDER BY CONSUMPTION OF SUBSTANCES AND PATIENTS WITH DUAL PATHOLOGY

Pascual Valdez, Marina Riso, Cecilia Castelluccio, Adriana Bulacia Juan A. Fernandez Hospital. Toxicology Division. Government of the Autonomous City of Buenos Aires. Argentina., Caba, Argentina

Objective

To compare the continuity in the treatment for addictions between patients with and without associated psychosis.

Methods

Retrospective, observational, longitudinal and analytical design. We reviewed 180 medical records of patients treated over a year, collecting sociodemographic data, duration of treatment, drug preference, presence or absence of psychosis.

Results

Male dominance, 70% (n 125). Global average age 32.67 years. In patients with psychosis (n36) 29.97 years. Frequency of psychosis 19.44%. Continuity of treatment in patients with and without psychotic disorder: the continuity of treatment in patients with psychotic disorder was 70%, 44.44% and 22.22% at 1, 3 and 6 months respectively. The continuity of treatment in patients without psychotic disorder was 69%, 32.71% and 14.84% at the 1st, 3rd and 6th month. The differences observed in the greater continuity of treatment in patients with psychosis are not statistically significant ($p=0.91$, $p=0.86$ and $p=0.53$ at the 1st, 3rd and 6th month, respectively).

Conclusions

Contrary to what the literature refers to in dual pathology, in our experience, psychotic patients with substance dependence disorders have no less continuity in treatment than non-psychotic patients.

#1687 - Abstract

THE DEVELOPMENT OF AN ALGORITHM FOR IDENTIFYING PRIMARY CARE TREATABLE OUTPATIENT VISITS FOR PATIENTS WITH DIABETES

Wender Lin

Chang Jung Christian University, Tainan, Taiwan

Background

Patients can freely choose health care providers without referral under Taiwan's National Health Insurance program (NHI). Therefore, hospital outpatient departments are crowded with patients whose chronic conditions can be treated in primary care settings. Diabetes is the most common condition mentioned above. This study aimed at developing an algorithm for identifying patients with diabetes whose conditions are treatable in primary care settings.

Methods

Claim data from one million of randomly sampled beneficiaries enrolled in Taiwan's NHI in 2010 was used to develop an algorithm of classifying ambulatory care visits made by patients with diabetes into various primary care groups. Visits in the same group had a similar probability of visiting office-based physicians, similar comorbidities, and the same level of previous health care utilization pattern such as hospitalization, the numbers of emergency department visits, the numbers of drugs prescribed and continuity of care. Classification and regression tree (CART) tool in SAS enterprise miner 13.1 was applied as the classification method. Groups with the probability of being treated in primary care settings higher than 50% were classified as primary care treatable groups.

Results

There were 148,751 visits made by patients with simple diabetes.

About 44% of these visits were treated in tertiary hospitals. After classification tree analysis, patients with simple diabetes can be classified into 22 primary care groups. In the same group, the probability of getting care from primary care settings is similar, as well as the demographic characteristics and health care utilization pattern. The most predictive factors to identify visits treatable in primary care setting were the absence of previous hospitalization, comorbidities, and the number of emergency visits in 6 months. The classification error rate was 43%. The proportion of diabetic patients treatable in primary care setting who were instead treated in tertiary hospitals ranged from 35% to 56% among hospitals.

Conclusion

Nearly half of the patients with simple diabetes who were treated in tertiary hospitals had similar demographic characteristics, comorbidities, and previous health care utilization pattern as those who were treated in primary care settings. Health policy to redirect these patients into primary care settings is warranted to improve the efficiency of the health care system.

#1690 - Abstract

HOSPITAL AT HOME AND THE READMISSION OF PATIENTS TO CONVENTIONAL WARDS – CAN FUNCTIONAL STATUS BE A GOOD PREDICTOR OF RISK AND HOW CAN WE USE IT?

Jose Pedro Tadeu, Joana Malheiro, Heloisa Ribeiro, Maria José Monteiro, Marta Perez, Susana Pereira, João Duarte, Nilton Silva, Luís Teles

Centro Hospitalar de Entre Douro e Vouga, Santa Maria Da Feira, Portugal

Background

Hospital at Home (HaH) is becoming more common in Portugal. This project aims to treat a vast number of pathologies at the patients' homes, being that some require readmission to conventional in-hospital wards, becoming of paramount importance to understand which factors may contribute to this.

Methods

Retrospective study of patients admitted to the HaH Unit between November 2nd and April 30th. Data were collected from the electronic medical record. Comorbidities were evaluated using Age Adjusted Charlson Score (aaCS) and Modified Charlson Score (mCS) and functional capacity was accessed using AVD-DezIs score, a score validated in our hospital, that provides a patient global capacity based on the ability to perform the daily life and instrumental activities. Data was analyzed using SPSS v.20.0. Normality was tested using Kolmogorov-Smirnov test and differences between groups was accessed with Mann-Whitney Test. A value of $p \leq 0.05$ was considered statistically significant.

Results

During the first 6 months of activity we admitted 91 patients,

with median age of 66 (min 21, max 94), 51 (56%) males, 77% of which were admitted from the internal medicine ward. We had 87 discharges, 14 were in-hospital readmissions – 2 to surgery wards (1 programmed, 1 urgent) and 12 to the internal medicine ward (2 due to willingness, 10 because of clinical degradation).

Comparing with the patients that were not readmitted, there were no differences between age (68.5 vs 66, $p=0.785$), duration of in-hospital treatment previous to HaH admission (4.5 vs 3 days, $p=0.491$), aaCS (5.5 vs 4, $p=0.215$), mCS (1.5 vs 1, $p=0.301$). However, the readmitted patients were more dependent (AVD DezIs 82.5 vs 95, $p=0.034$), with bigger dependence on the instrumental activities (1 vs 0, $p=0.029$). Of the 10 readmissions being analysed, 6 were in individuals with more than 65 years. On this age group ($n=47$) there was no difference between aaCS (7 vs 6, $p=0.202$), mCS (3 vs 2, $p=0.214$). Considering AVD DezIs there seems to be a tendency for bigger incapacity on the readmissions (62.5 vs 85, $p=0.088$) with larger dependency on the instrumental activities (4.5 vs 1, $p=0.077$).

Conclusion

Even with such a small sample of patients, we can say that function is a better predictor of in-hospital readmission of HaH patients than comorbidities scores. Although AVD DezIs score being only formally validated for elderly (65+) patients in our Hospital, considering our results we are trying to expand this score to the general hospitalized population.

#2042 - Case Report

THE POTENTIALITIES OF A DAY HOSPITAL IN CLINICAL RESEARCH

Inês Moreira Sousa

Centro Hospitalar Universitário Lisboa Norte, Lisboa, Portugal

Introduction

Residency in Portugal relies on 5 years of clinical practice in different areas of medicine, and in some cases include one year of Internal Medicine internship. Although research is a valuable part of the residency, it mainly results from the effort of the resident, since there is no protected time during residency dedicated exclusively to research and logistic resources are sparse.

We would like to share the potentialities and advantages of day hospital in clinical research.

Case description

Day Hospital is a service specialized in ambulatory assessment (acute or chronic), integrated into the Medicine Department. It is made up of a multidisciplinary team - one administrative, one nurse and one operational assistant in full time and internal medicine and immunology physicians in part-time. It has 4 armchairs in an open space room for monitoring and treatment, a work station for nurses and another for doctors and a private office for medical appointments.

It is a place with excellent conditions to perform clinical research

since it has space with privacy, clinical instruments and a dedicated nurse that could work as a research nurse and help physicians in this job. Additionally, it is located near to the medicine ward, which allows easy access to clinicians and patients.

In the last 5 years, we amplified the use of this resource to develop clinical research. Firstly, with prospective longitudinal study in the diabetes field and currently there is ongoing the recruitment and cardiovascular risk assessment of Parkinson's disease patients and controls in the context of a Ph.D. project of one internal medicine resident. Outpatient parenteral antimicrobial therapy is another area we are now considering for research.

There are good conditions to perform medical histories, physical examination, and cognitive assessment and fulfill questionnaires. It is easy to perform blood and urine collection, and also simple exams like electrocardiography, echography and other non-invasive procedures.

Residency is an excellent opportunity to develop new skills not only in clinical medicine but also in research. There are opportunities and resources, like the Day Hospital, that could help residents who intend to follow an academic career.

Discussion

Day hospital is a service with excellent conditions to develop clinical research, due to its environment characteristics and the human and technical resources available.

#2245 - Case Report

SEVERE ANAEMIA RELATED TO DIOGENES SYNDROME: A CASE REPORT

João Rodrigues Barros, Maria Mercedes Calvo
Hospital do Espírito Santo de Évora, Évora, Portugal

Introduction

Megaloblastic anemia (MA) is caused by abnormal DNA synthesis of red blood cell precursors in the bone marrow. MA progresses gradually, allowing the development of cardiopulmonary compensatory mechanisms, with consequent delayed onset of manifestations (asthenia, dyspnoea, palpitations and jaundice). Diogenes Syndrome is a behavioural disorder characterized by hoarding and self-neglect, with a higher prevalence in females and older age (>60 years). These patients tend to have average or above average intelligence and to live in social isolation refusing help, which can complicate anamnesis and delay diagnosis. A trigger event, such as emotional stress in a predisposed individual, usually with obsessive-compulsive personality traits, can predispose to this disease. Due to frailty, nutritional deficits and lower adherence to treatment, mortality is higher in this population group.

Case description

A 46-year-old divorced female patient with medical history of chronic sciatica, refers to the Emergency Department due to mechanical lumbar pain for the last 7 days. The patient states that she lives with her younger daughter, and gets support from a close

friend. She presents lumbar tenderness points with no neurologic symptoms; however she appears apathetic, pale and tachycardic. She was given analgesia and an analytical control revealed MA with haemoglobin (Hb) of 2.1 g/dL. Peripheral blood smear showed marked anisopoikilocytosis, vitamin B12 and folic acid assays confirmed deficiency, Coombs test and reticulocyte determination were performed and the patient received red blood transfusion (3 units) and began supplementation. After Hb stabilization (5-6 g/dL), she was transferred to the Internal Medicine ward in order to continue etiologic study and further stabilization. On the day of discharge, the patients' close friend revealed that the she was living with her 11-year-old daughter in complete social isolation, marked anxiety (towards her ex-husband), presented severe hoarding behaviour and refused help for basic life care. The patient was discharged with anti-depressive and anxiolytic medication and went to live with her mother. Five months after, the patient recovered (Hb of 12 g/dL), regained weight and is now moving back to her house with her daughter.

Discussion

This case aims to demonstrate the importance of clinical suspicion and external information, that allowed to diagnose a case of severe anaemia and an unusual psychiatric pathology in a patient presenting with unrelated complaints.

CARDIOVASCULAR DISEASES

#13 - Abstract

BNP-PESI CORRELATION. BINDEX STUDY: COMPARATIVE ANALYSIS WITH STUDENT TEST FOR CONTINUOUS VARIABLES IN 30 PATIENTS WITH VENOUS TROMBOEMBOLISM. TRIENNIAL EXPERIENCE (2016-2018)

Maurizio Maria Ciammaichella

St. John's Hospital, Rome, Italy

Background

The BINDEX study, acronym resulting from "Brain natriuretic peptide – pulmoNary embolism severity inDEX", enrolled 30 patients with venous thromboembolism between the ages of 48 and 82. In all patients, the pre-lysis Pulmonary Embolism Severity Index (PESI) was measured and the pre-lysis BNP was dosed (NV=0-100 pg/ml). A comparative analysis with Student's "t" parametric test was carried out to verify if there is a significant relation between the pre-lysis BNP values and the pre-lysis PESI values.

Methods

The pre-lysis BNP values were compared with the pre-lysis PESI values for the 30 enrolled patients. Therefore, the test calculates the relative value (RV) of the t index to be associated to the differences detected according to the following formula: $t = (M1 - M2) / \sqrt{DS12 / N1 + DS22 / N2}$.

Results

Student's "t" test applied to the 30 patients shows a highly significant correlation ($p < 0.001$) of the two variables in question (pre-lysis BNP and PESI Values) and, thus, not attributable to chance. In fact, the "t" value obtained is 5.58 and the VC (critical value) of "t" for $p = 0.001$ is 3.659 with GL=29.

Conclusion

The "BINDEX" study shows how, in the group of 30 patients with venous thromboembolism (central pulmonary embolism), there is a highly significant correlation between the two variables in question: pre-lysis BNP and pre-lysis PESI. This correlation shows an absolute positive concordance according to Student's comparative analysis "t" test and is an expression, not of casual association, of a strong correlation between the pre-lysis BNP values and the pre-lysis PESI values.

#14 - Abstract

TAPSE-PESI CORRELATION. TAPESI STUDY: COMPARATIVE ANALYSIS WITH STUDENT TESTING FOR CONTINUOUS VARIABLES IN 30 PATIENTS WITH VENOUS TROMBOEMBOLISM. TRIENNIAL EXPERIENCE (2016-2018)

Maurizio Maria Ciammaichella

St. John's Hospital, Rome, Italy

Background

The "TAPESI" study, whose name comes from "TAPSE - Pulmonary Embolism Severity Index", enrolled 30 patients aged between 48 and 82 years with venous thromboembolism hospitalized in Complex Structure Internal Medicine for Emergencies Complex Structure in the period January 2016-December 2018. All patients were subjected to: thoraco-abdominal and pelvic CT with contrast medium; pulmonary angiography with loco-regional fibrinolysis; echocardiography with measurement of pre-lysis Tricuspidal Annular Plane Systolic Excursion (TAPSE) (NV > 2 cm). In all patients, the PESI score was measured pre-lysis and the TAPSE score was also measured pre-lysis (VN > 2 cm).

Methods

In the 30 patients enrolled with central pulmonary embolism the values of TAPSE pre-lysis with the values of PESI pre-lysis in the 30 patients enrolled were examined and compared. The test then calculates the relative value (RV) of the index t to be associated with the difference found using the following formula: $t = (M1 - M2) / \sqrt{DS12 / N1 + DS22 / N2}$.

Results

The Student's "t" test applied to the 30 patients showed a highly significant correlation ($p < 0.001$) of the two variables tested, which therefore cannot be attributed to chance. In fact, the value of "t" obtained is 14.96 and the CV (critical value) of "t" for $p = 0.001$ is 3.659 with GL = 29.

Conclusion

The "TAPESI" study showed that in the group of 30 patients with venous thromboembolism (central pulmonary embolism) there is a highly significant correlation between the two variables considered: TAPSE pre-lysis and PESI pre-lysis.

JUST HEART FAILURE?

Cristina Lojo, Pedro J. Maese, Isabel Melguizo, Jose Antonio Mira
Hospital Valme, Sevilla, Spain

Clinical summary

A 76-year-old male was admitted due to constitutional syndrome, dyspnea and edema. Examination manifested hypotension, S3 audible, bilateral crackles and bimalleolar edema. Chest radiography shows cardiomegaly and pulmonary congestion. Analytically, renal failure, high natriuretic peptide levels and proteinuria. Abdominal ultrasound was normal. The echocardiography shows concentric left ventricle hypertrophy and advanced diastolic dysfunction (restrictive cardiomyopathy due to infiltrative pathology). Cardiac MRI suggests cardiac amyloidosis. The free chains in urine and plasma are elevated (expense of lambda chains). We performed a rectal mucosa biopsy positive for Congo red staining and bone marrow aspirate that confirms the diagnosis of multiple light chain myeloma and therefore primary amyloidosis.

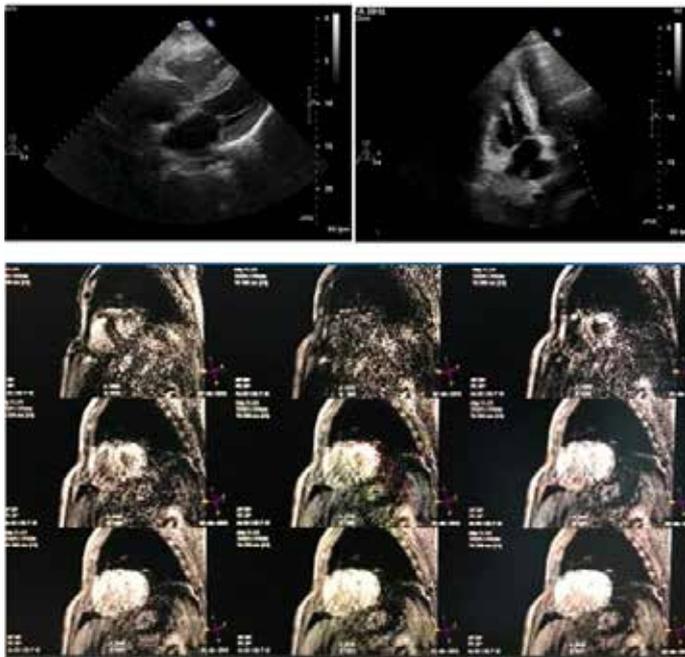

Figure #40.

#64 - Abstract

IMPACT OF PRETREATMENT WITH ACETYLSALICYLIC ACID ON THE SEVERITY OF A FIRST MYOCARDIAL INFARCTION

Ana Rita Moura, Mariana Saraiva, Nuno Craveiro, Maria João Vieira, Kevin Domingues, Vitor Martins
Hospital Distrital de Santarém, Santarém, Portugal

Background

Guidelines on the use of acetylsalicylic acid (ASA) for primary prevention of cardiovascular disease (CVD) are conflicting and

a reflection of no robust evidence accounting for unequivocal favourable benefit-to-risk balance of its use. An eventual advantage of ASA in reducing the severity and prognostic impact of a first episode of acute myocardial infarction (AMI) could be seen has an additional argument for the use of ASA in primary prevention. The present study aimed to evaluate the influence of ASA on the presentation, severity and in-hospital prognosis of AMI in patients without history of CVD.

Methods

Retrospective study based on the analysis of patients without previous evidence of CVD that were diagnosed with type 1 AMI in a district hospital between January 2016 and December 2017. The analysis was dichotomized according to whether or not patients were taking ASA previous to the event. The following endpoints were evaluated: type of AMI, angor refractoriness, maximal troponin, ejection fraction (EF), coronary grade flow (TIMI score), arrhythmic and mechanical complications, and in-hospital death.

Results

The study was accomplished for a total of 150 patients with a mean age of 71.6 ± 9.5 years, of which 71.3% were male. The group of patients that was receiving ASA (16.7%) was significantly older and had a higher prevalence of hypertension (96.0% vs 72.5%, $p=0.01$), and diabetes (68.0% vs. 29.2%, $p < 0.001$). Regarding the endpoints studied, in the group of patients taking the drug there was a lower prevalence of AMI with ST segment elevation (24.0% vs. 36.7%, $p=0.26$), lower prevalence of refractory angor (4.0% vs. 11.7%, $p=0.46$), a lower troponin elevation (7065 vs. 33412.0, $p=0.78$), a higher median EF (55.2 ± 3.5 vs. 47.5 ± 6.3 , $p=0.52$), less cases with TIMI score 0 or 1 (40.0% vs. 60.0%; $p=0.79$), lower complication rates (4.0% vs. 7.6%, $p=1$) and less in-hospital death (0% vs. 1.7%). However, none of the observations was associated with statistical significance.

Conclusion

The present study revealed that, although statistical significance was not reached, prior use of ASA to a first AMI was associated with a better profile of different parameters reflecting the extent and severity of the event. Adequately powered trials are needed to evaluate the relevance of these findings.

#71 - Abstract

INCREASED BETA BLOCKERS AND STATINS AND DECREASED CYTOPROTECTORS IN MYOCARDIAL INFARCTION: A COMPARISON OF HOSPITAL DRUG USE IN 2013 AND 2018

Ainagul Sarsenova, Lazzat Zhamaliyeva, Damira Zhamankulova
West Kazakhstan Marat Ospanov State Medical University, Aktobe, Kazakhstan

Background

Mortality from acute myocardial infarction (AMI) in Kazakhstan

remains high. In 2014, 2016 and 2017, in Kazakhstan, the clinical guidelines and standards on improving care for patients with AMI were updated. The aim of the study was to compare drug prescriptions for patients with AMI before and after the intervention.

Methods

The inpatient data of all patients with AMI who were discharged in 2013 (n=169) and 2018 (n=168) from the Medical University Clinic of Aktobe (Kazakhstan) were used.

Results

The average age of patients was 65.8 (13.4) and 63.7 (11.6), $p = 0.18$, in 2013 and 2018 respectively. The proportion of men was 72% (95% CI 65-79) and 77.4% (95% CI 71-84), presence of arterial hypertension was 76.3% (95% CI 70-83) and 84.5% (95% CI 79-90) in 2013 and 2018 respectively. A statistically significant reduction of trimetazidine from 53.8% (95% CI 46-61) in 2013 to 17.2% (95% CI 11-23) in 2018 and meldonium from 24.4% (95% CI 18-31) to 1.79% (95% CI 0-4) was revealed. At the same time, an increase in beta-blocker prescriptions was detected from 62.7% (95% CI 55-70) to 99.4% (95% CI 98-100), statins from 4.6% (95% CI 1-8) up to 100%.

Conclusion

The practice of drug therapy of AMI has changed significantly over 5 years, from 2013 to 2018. Highly effective drugs were used to all patients. Cytoprotectors with unproven effectiveness have almost completely ceased to be used.

#73 - Abstract

RISK FACTORS FOR CHRONIC THROMBOEMBOLI AFTER PULMONARY THROMBOEMBOLISM

Nuno Leal, Andreia Freitas, José Ribeiro Almeida, Marta Sousa
Centro Hospitalar de Vila Nova de Gaia/Espinho, Vila Nova De Gaia,
Portugal

Background

After an acute pulmonary embolism (PE) most of the thromboemboli achieve complete resolution. However, a significant proportion of patients will present chronic residual thromboemboli with an increasing risk of chronic thromboembolic pulmonary hypertension (CTPH) that can be as high as 4%.

The need for the definition of risk factors for residual thromboemboli is of uttermost importance for future prediction models of prognosis that identify patients with higher risk of CTPH.

Methods

We included all patients with PE followed in "Internal Medicine "Thromboembolism" consultation who were taking oral anticoagulants and presented Computerized Tomography

Angiography (CTA) or Ventilation/Perfusion Scintigraphy (VPS) performed at least 3 months after diagnosis.

Data were collected by consulting the computerized clinical process and were stored and treated statistically using IBM SPSS Statistics 25 software.

Results

In this study 148 subjects were included. Complete clearance of thrombi occurred in 92 (62.2%) and residual thrombi remained in 56 (37.8%) patients.

There was no association between history of cancer, trauma, hormonal therapy and oral contraceptives, pregnancy, smoker status and obesity, at diagnosis, and chronic residual thrombi.

There was a statistically significant association between chronic residual thrombi and previous history of thromboembolic event ($p < 0.05$; OR 3.12, CI 95%) and also presence of pulmonary infarction on the first diagnostic imaging study ($p < 0.05$; OR 1.98, CI 95%).

Conclusion

Despite anticoagulation, the presence of residual thrombi at least 3 months after PE was 37.8% using CTA and/or VPS. This percentage was reported to be between 20 to 30% in previous studies, although most of them used only CTA. The exact magnitude of residual thrombi as a factor of increased risk of CTPH is yet to be clearly defined.

We concluded that pulmonary infarction and previous thromboembolic event was positively associated with chronic thrombi.

#74 - Abstract

DAYLIGHT SAVING TIME TRANSITIONS AND CIRCULATORY DEATHS: A STUDY IN THE VENETO REGION OF ITALY

Roberto Manfredini¹, Rosaria Cappadona¹, Fabio Fabbian¹, Alfredo De Giorgi¹, Giulia Capodaglio², Ugo Fedeli²

¹ University of Ferrara, Ferrara, Italy

² Epidemiological Department, Veneto region, Padua, Italy

Background

Janszky & Ljung (N Engl J Med 2008) first reported an association between daylight saving time (DST) transitions and an increased frequency of acute myocardial infarction (AMI).

Methods

We performed a retrospective analysis on the archive of mortality records of the Veneto Region of Italy ($\approx 4,900,000$ inhabitants) from January 2000 to December 2015. Deaths were classified according to ICD-9 and ICD-10 broad categories used in standard reports of mortality statistics. The number of deaths observed in each of the 7 days after the spring and the autumn shift (post-transitional weeks) was compared with the mean number of deaths registered in the corresponding week-day of the 2 weeks

before and the 2 weeks after the post-transitional week (reference period).

Results

A total of 10,387 circulatory deaths were registered in the Spring and Autumn post-transitional weeks through study period. No overall excess mortality was found in the post-transitional weeks with respect to the reference period in both Spring and Autumn. When analyzing the day-of-week pattern of mortality, a statistically significant excess of deaths was registered on Tuesday only in the Spring ($p=0.011$), but not in the Autumn post-transitional week.

Conclusions

In agreement with previous studies on AMI and stroke, a significant excess of death was observed on Tuesday, only after the Spring shift. Phase advance, sleep deprivation and disruption of circadian rhythms could play a role. A proposal by European Commission of discontinuing seasonal changes of time is now pending at the European Parliament.

#75 - Abstract

DAYLIGHT SAVING TIME TRANSITIONS AND ACUTE MYOCARDIAL INFARCTION: A META-ANALYSIS OF THE AVAILABLE EVIDENCE

Roberto Manfredini¹, Fabio Fabbian¹, Rosaria Cappadona¹, Alfredo De Giorgi¹, Maria Elena Flacco², Lamberto Manzoli¹

¹ University of Ferrara, Ferrara, Italy

² Regional Healthcare Agency of Abruzzo, Pescara, Italy

Background

After the first observation by Janszky & Ljung (N Engl J Med 2008), it has been debated whether daylight saving time (DST) transitions could be associated with a higher frequency of acute myocardial infarction (AMI). We performed the first meta-analysis aimed at evaluating the risk of AMI following DST transitions.

Methods

We searched cohort or case-control studies evaluating the incidence of AMI, among adults, during the weeks following spring and/or autumn DST shifts, versus control periods. A summary odds ratio of AMI was computed after: (1) spring, (2) autumn, or (3) both transitions considered together. Meta-analyses were stratified by gender and age.

Results

Seven studies from five countries (Sweden, United States, Croatia, Finland, Germany) were included in the analyses, and total population was >115,000 subjects. A significantly higher risk of AMI (Odds Ratio [OR]: 1.03; 95% CI: 1.01-1.06) was observed during the two weeks following spring or autumn DST transitions. However, although AMI risk increased significantly after the spring shift (OR: 1.05; 1.02-1.07), the incidence of AMI during the

week after winter DST transition was comparable with control periods (OR 1.01; 0.98-1.04). No differences were observed by age or gender.

Conclusion

A modest, but significant, increase in the risk of AMI is confirmed after DST transitions, particularly after the Spring shift, regardless of gender and age. Disruption of circadian rhythms and even mild sleep deprivation secondary to phase advance may be potential underlying factors. These findings, which require additional evidence, may support the European Commission proposal of DST shifts discontinuation.

#99 - Abstract

CARDIOVASCULAR RISK FACTORS IN PATIENTS WITH ACUTE HEART FAILURE IN AN INTERNAL MEDICINE SERVICE DURING A YEAR

Rita Reis Correia, Fabia Cruz, Pedro Leite Vieira, Sandra Martin, Maria Eugenia André

Amato Lusitano Hospital, Castelo Branco, Portugal

Background and Aim

The onset of Heart Failure (HF) may be delayed or aggravation prevented with modifying risk factors. Almost all these factors are the same for cardiovascular risk. For example: the control of hypertension will delay the onset of HF and reduce mortality; Statins reduce the rate of cardiovascular events and mortality; there is also reasonable evidence that they prevent or delay the onset of HF. This study aims at characterizing the prevalence of cardiovascular risk factors in patients with acute HF in an Internal Medicine Service (IMS).

Methods

A prospective, cross-sectional, observational study of hospitalized patients diagnosed with acute HF in an IMS, April 2017 to April 2018. On admission, the degree of HF was assessed by the NYHA scale. The presence of cardiovascular risk factors and cardiovascular disease (CVD) was evaluated. Transthoracic echocardiography was performed to evaluate left ventricular ejection fraction (EF). Patients in palliative care were excluded. Analysis was performed by SPSS.

Results

118 patients were included (59.3% women, average of 84±7.9 years old). 84.6% in III and IV classes of NYHA. 60.5% with preserved HF. The average of BNP at entrance was 803±797µg/dL. The average hospitalization time was 12±15.4 days.

Cardiovascular risk factors: 47.5% with dyslipidemia; 39.6% with diabetes mellitus; 70.3% with hypertension and 15.3% with chronic kidney disease. On average the sample presented two risk factors.

39% presented CVD (stroke or ischemic heart disease). The CVD

correlates with mortality ($p < 0.05$). The patient with cardiovascular disease presented lower EF (48.6% vs 55.2%; $p = 0.05$).

The average of high-density lipoprotein cholesterol (HDL) was 38.3 ± 13 mg/dL; low density lipoprotein cholesterol (LDL) was 71.7 ± 30.7 mg/dL; triglycerides was 108.7 ± 61.6 mg/dL.

Regarding the patients with dyslipidemia history, 78.6% were on medication with statins that presented lower lipid profile: total cholesterol (118 ± 34 vs 178.5 ± 43 , $p = 0.01$), LDL (61.7 ± 30 vs 101 ± 28 , $p < 0.05$), triglycerides (97.89 ± 40.6 vs 177 ± 114 , $p < 0.01$).

Conclusion

The presence of CVD is an important factor of severe heart failure and mortality in our sample. The importance and efficiency of the use of statins in the control of the lipid profile was thus verified. The control and prevention of cardiovascular risk factors are of great importance in patients with HF to minimize their onset and progression.

#100 - Abstract

IRON DEFICIENCY IN PATIENTS WITH ACUTE HEART FAILURE IN AN INTERNAL MEDICINE SERVICE DURING A YEAR.

Rita Reis Correia, Fabia Cruz, Pedro Leite Vieira, Sandra Martin, Maria Eugenia André

Amato Lusitano Hospital, Castelo Branco, Portugal

Background

Iron deficiency (ID) is the leading cause of anemia in patients with heart failure (HF). Several studies have demonstrated that ID is an independent factor of poor prognosis in HF (without anemia). This study aims at characterizing the prevalence of anemia and ID in hospitalized patients with acute HF in an Internal Medicine Service (IMS).

Methods

A prospective, cross-sectional, observational study of hospitalized patients diagnosed with acute HF in an IMS, April 2017 to April 2018. On admission, the degree of HF was assessed by the NYHA scale. The presence of comorbidities was evaluated. The presence of anemia (hemoglobin $\text{♀} < 12$ g/dL and $\text{♂} < 13$ g/dL), ferropenia (serum iron < 40 $\mu\text{g/dL}$, ferritin < 15 ng/mL or transferrin saturation $< 20\%$) was checked. Transthoracic echocardiography was performed to evaluate left ventricular ejection fraction (EF). Patients in palliative care were excluded. Analysis was performed by SPSS.

Results

118 patients were included (59.3% women, average of 84 ± 7.9 years old). 84.6% in III and IV classes of NYHA. 60.5% with preserved HF. The average of BNP at entrance was 803 ± 797 $\mu\text{g/dL}$. The average of hospitalization time was 12 ± 15.4 days.

Most frequent comorbidities: atrial fibrillation (78.8%), hypertension (70.3%) and diabetes mellitus (39%). On average,

they presented 3 comorbidities.

Anemia was present in 37.1% of men and 66.7% of women. The average of serum iron was 54 ± 45 $\mu\text{g/dL}$, ferritin was 265.7 ± 293 ng/mL and transferrin saturation $19 \pm 16.3\%$. The iron deficiency was present in 52.7% of the sample.

There was an association between anemia and iron deficiency ($p < 0.05$). The patient with ferropenia presented lower hemoglobin (11 vs 12.2 g/dL; $p < 0.05$).

Lower transferrin saturation had reduced ejection fraction and a class III or IV NYHA ($p < 0.05$). Iron serum and transferrin saturation correlated inversely with mortality ($p < 0.05$).

Conclusion

Iron deficiency was the most frequent cause of anemia in our sample. The lower transferrin saturation and iron serum correlated with the mortality regardless of the presence of anemia. As such, the results are in agreement with the current literature showing the importance of measuring iron deficiency with or without anemia.

#109 - Case Report

YOUNG WOMAN WITH CHEST PAIN

Neuza Soares, Ana Cunha, Francisco Ferrão, Maria Majob, Clara Gomes, Fernando Friões

Centro Hospitalar São João, Porto, Portugal

Introduction

Prinzmetal's angina (PA) is a temporary increase in coronary vascular tone (vasospasm) causing a marked, but transient reduction in luminal diameter. Patients are predominantly younger women who may not have the classical cardiovascular risk factors. However, smoking is one of the major risk factors for coronary spasm.

Case description

The authors describe a case of a 40-year-old woman, smoker, with a history of recurrent episodes of breathlessness and chest pain for the past 20 days. These episodes would occur randomly at rest, especially late at night, thereby waking up the patient. In the emergency department, she was conscious, normotensive and normocardic. The electrocardiography showed a heart rate at 61 bpm and ST-segment depression was noticed in V3, V4, V5 and V6. Echocardiography showed areas of hypokinetic middle apical on the anterior and lateral walls. The troponin I level was 0.139 $\mu\text{g/L}$. She did treatment with AAS 300 mg, ticagrelor 90 mg and low-molecular-weight heparin 1mg/kg and she was admitted in intermediate care unit. On the next day, she received cardiac catheterization that ruled out coronary artery disease. Cardiac resonance was also unchanged. However, chest pain returned and cardiac catheterization was repeated. Once again, even with no coronary artery disease, a significant increase in caliber after intracoronary nitrates had revealed. The symptoms disappeared gradually with up-titration of a calcium channel blocker and a nitrate.

Discussion

The provocative test is not firmly established. Most patients with PA respond to medical management with nitrates and calcium channel blockers, with dramatic improvement in their symptoms. Our patient also improved with medical management. Patients with medically refractory symptoms and those who have organic stenosis on coronary angiogram can be treated with intracoronary stenting of the vasospastic segment.

#111 - Case Report

AMYLOIDOSIS AND CARDIAC MAGNETIC RESONANCE

Filipa Lucas¹, Miguel Alves², Fredo Renato Roberto¹, Ana Teresa Boquinhas¹, Carolina Spulveda¹

¹ Hospital de Cascais, Cascais, Portugal

² ULS Nordeste, Bragança, Portugal

Introduction

Advances in cardiac imaging, especially with cardiac magnetic resonance (CMR) may provide a method for evaluation of cardiac involvement and have resulted in greater recognition of light-chain (AL) cardiac amyloidosis in everyday clinical practice.

AL amyloidosis is a rare and multisystem disease characterized by deposition of misfolded immunoglobulin light chain (LC) in the heart, that causes a restrictive cardiomyopathy.

Case description

We describe the case of a 50-year-old melanodermic male that is followed at our Hospital with AL amyloidosis diagnosed since 2016, with renal and cardiac involvement. He has also a medical history of heart failure (NYHA II-III) with chronic pleural and pericardial effusions, 1st-degree atrioventricular block; nephrotic syndrome; α -sickle cell carrier; monoclonal gammopathy IgG lambda and bilateral pulmonary embolism (2016), chronically medicated with bisoprolol, torasemide, ivabradine, spironolactone, and rivaroxaban. At the time of diagnosis, the echo showed left ventricular hypertrophy with moderately impaired function and typical apical sparing. A CMR demonstrated pleural and pericardial effusions; diffuse subendocardial staining pattern and remarkable difficult “nulling” of the myocardium of the left ventricle after gadolinium administration. An abdominal biopsy was positive for amyloidosis. He underwent 4 CyBorD cycles and bortezomib support therapy, with complete remission. In the last consultation, June 2018, the echo showed a moderately decreased of the left and the right ventricular function and blood and urine tests with NT-pro BNP of 4048 ng/l, hsTnTc 30 ng/L and albuminuria 0.58 g/day with MDRDd 64ml/min.

Discussion

Improved medical recognition is necessary for earlier diagnosis and treatment and prompt outcomes. Ventricular hypertrophy or heart failure without a known case maybe the first red flag for cardiac amyloid fibril infiltration and CMR should be considered.

The CMR analyses heart structure, ventricular volumes and function and is useful in distinguishing ventricular wall thickening as a result of amyloid infiltration. Late gadolinium enhancement adds a unique advantage in evaluating myocardial tissue characterization. T1 mapping can also measure the amyloid burden and the myocyte response to infiltration with advantages for tracking change during therapy. To sum up, CMR is a non-invasive exam that overcomes cardiac biopsy and delayed hyper-enhancement imaging may lead to the development of new classification and prognostic systems.

A 39 YEARS WOMAN WITH SUDDEN HEART FAILURE AFTER PARTUM

Nuno Vieira E Brito, Ricardo Taborda, Paula Alcantara

Centro Hospitalar de Lisboa Norte, Lisboa, Portugal

Introduction

Postpartum cardiomyopathy is a rare condition of unclear origin affecting woman at the late stages of pregnancy of up to 6 months after partum. This condition is often diagnosed late due to variable clinical manifestations and a heart disease that may not be suspected at first, since some symptoms are similar to those caused by pregnancy.

Case description

A 39-year-old African ascendancy female was admitted to the emergency department due to shortness of breath, lower limb edema and fatigue a week after childbirth. She was previously healthy with no relevant medical history with two other healthy children aged 6 and 8 and had a monitored pregnancy. At presentation she was dyspneic with 87% saturation, crackles in both lungs and edema of lower limbs. Her laboratory test showed anemia of 11.2 g/dL a low erythrocyte sedimentation rate, positive D-dimer and an elevation of the NT-proBNP. Due to her recent pregnancy state and partum a chest CT was conducted which excluded the presence of embolism and showed signs of lung stasis and a small pleural effusion. The echocardiography showed a reduced ejection fraction of 39% (by Simpson 4 chambers) with a hypokinetic left ventricle and signs of left heart dilation. She showed no signs of infection had a negative troponin level, serologies for common agents of cardiomyopathy were negative and while she had a positive ANA screening the title was low and a repeat measure months after was negative relating the value to the short time after pregnancy and delivery. She was immediately started with heart failure therapy with diuretics, spironolactone, beta blocker and later sacubitril with valsartan was indicated due to the maintenance of symptoms with an improvement in NYHA score from III to II. Eight weeks after diagnosis and maintaining therapy with entresto, a new evaluation was performed showing an improved ejection fraction of 55% with no hypokinesia a normalization of NT-proBNP and a NYHA class of I.

Discussion

This case shows a remarkable improvement of a rare serious condition with a normal bad prognosis using the new heart failure modulation therapies. In this case the recuperation of the patient requires constant monitoring as not only can this condition reappear but the long term management of this patients is still unknown and there are no studies using this new class of drugs in these patients or its impact on long term survival and quality of life.

#122 - Abstract

MANAGING RISK OF CONTRAST INDUCED NEPHROPATHY (CIN) FOLLOWING CORONARY ANGIOGRAPHY

Laura Virginia Gonzalez, Jessica Abbey

Great Western Hospital, Swindon, United Kingdom

Background

CIN is a iatrogenic renal injury following administration of intra-vascular radio-opaque contrast media. It is classed as a 25% increase in serum creatinine within 72 hours of contrast exposure. CIN accounts for one third of all hospital-acquired acute kidney injuries. It affects up to 50% of high risk sub-groups following angiography or PCI.

NICE and the European Society of Cardiology (ESC) guidelines recommend to assess the risk of acute kidney injury before offering iodinated contrast agents to adults for emergency or non emergency imaging.

There is a stratification risk according to risk factors: hypotension, IABP, CHF, anaemia, DM, contrast media volume, age>75, serum creatinine >1.5mg/dl or GFR<60ml/min.

The ESC guidelines recommend in each category to reduce the risk of AKI :

Low risk (oral hydration,

Moderate/high risk->alternative imaging, IV hydration pre/post procedure, discontinuation of nephrotoxic drugs, lowest volume of contrast, repeat renal function at 48-72 hours. If necessary treat AKI as per guidelines.

Methods

Retrospective review of 40 patients that had PCI between 12/10/18 – 04/01/19 in our hospital, with the intention to analyse the assessment of risk score and prevention measures taken before having coronary angiogram, as well as the assessment of renal function 48-72 hours later.

Results

18 female, 22 male. Age: 49-92.

Wards: 18 from cardiology, 22 from other medical wards.

CIN risk score:

25/40 patients were low risk for CIN (score ≤ 5)

10/40 scored moderate risk (score 6-10)

5/40 scored high risk (score 11-16)

We were unable to ascertain if nephrotoxic medications were held before procedure or if the contrast volume used was reduced.

Fluid administration:

In the Moderate/High risk (15)

Only 1 patient had IV fluid management as per recommended guidelines. Three had 500ml N. Saline in the Cath lab and 11 patients had no IV fluids pre or post procedure.

Renal function assessment:

- 17/40 had no post-procedure U&Es. From this group, three were high risk, four moderate risk and 10 low risk.
- 9/23 who had U&Es only had them done at 24 hours (before the recommended 48 – 72hrs).

Conclusion

Many of the patients with moderate/high risk score did not receive the recommended hydration, and, even worse, the renal function was not properly measured at 48-72 hours post procedure.

Actions:

To create a protocol for all patients going for c. angiogram, and facilitate the assessment of renal function in ambulatory care if necessary.

Discussion with Cardiologist in progress.

#127 - Case Report

CRITICAL UPPER LIMB ISCHEMIA: AN UNUSUAL PRESENTATION OF EXTRACRANIAL GIANT CELL ARTERITIS

Katalin Mako, Eموke Horvath

University of Medicine and Pharmacy Targu Mures, Targu Mures, Romania

Introduction

Aiming to emphasize the emerging role of Doppler ultrasound in the diagnostic work-up of extracranial presentation of giant cell vasculitis we report the case of a 70-year-old female, who presented unilateral critical upper limb ischemia.

Case description

The patient presented severe rest pain at the left arm limb, coldness, pallor and paresthesia of the left hand. Due to the age and presence of cardiovascular risk factors, atherosclerotic peripheral upper limb arterial disease would have been the most likely diagnosis in this case but the color Doppler ultrasound of the upper limbs revealed severe left axillary arterial stenosis with hypoechoic wall swelling being highly suggestive for arteritis. Temporal artery ultrasound demonstrated occlusion in right side and was suggestive for arteritis in left side; biopsy was performed and confirmed giant cell arteritis. An excellent clinical response was obtained two weeks after initiation of treatment with systemic corticosteroids.

Discussion

Upper limb arterial ultrasound is a simple and quick examination and provides characteristic findings in extracranial giant cell

arteritis and in disease monitoring. The routine use of this method in patients with arm pain or weakness and the fact that atypical localizations of disease are common leads to fewer delayed or missed diagnosis.

#128 - Abstract

INFLUENCE OF STATINS USED IN THE CONTEXT OF PRIMARY PREVENTION ON THE SEVERITY OF A FIRST ACUTE MYOCARDIAL INFARCTION

Ana Rita Moura¹, Mariana Saraiva², Nuno Craveiro², Maria João Vieira², Kevin Domingues², Vítor Martins²

¹ Hospital Distrital de Santarém, Gondomar, Portugal

² Hospital Distrital de Santarém, Santarém, Portugal

Background

Statins role in primary prevention of cardiovascular disease (CVD) is not well-established. An eventual advantage of statins in reducing the severity of a first episode of acute myocardial infarction (AMI) could be seen has an additional argument for its use in primary prevention in high risk patients. The present study aimed to evaluate the influence of the use of previous statin in the form of presentation, severity and short-term prognosis of AMI in patients without history of CVD.

Methods

Retrospective study based on the analysis of patients without previous evidence of CVD that were diagnosed with type 1 AMI in a district hospital between January 2016 and December 2017. The analysis was dichotomized according to whether or not patients were taking statin before the event. The following endpoints were evaluated: type of AMI, angor refractoriness, maximal troponin, leukocytes and C-reactive protein (CRP), ejection fraction (EF), coronary grade flow (TIMI score), number of coronary arteries with significant disease, arrhythmic and mechanical complications, and in-hospital death.

Results

The study was accomplished for a total of 145 patients with a mean age of 70.9 ± 8.7 years. The group of patients that was receiving statin (20.7%) was significantly older and had a higher prevalence of dyslipidemia (83.3% vs 47.0%, $p < 0.001$), and diabetes (53.3% vs. 31.3%, $p = 0.03$). Regarding the endpoints studied, in the group of patients taking the drug there was a lower prevalence of AMI with ST segment elevation (26.7% vs. 37.4%, $p = 0.27$) and refractory angor (3.3% vs. 12.2%); a lower maximum troponin (8958 vs. 28121, $p = 0.56$), leukocytes count (8666.7 vs. 11266.7; $p = 0.69$) and CPR (2.06 vs. 2.52; $p = 0.76$). It was also seen an higher median EF (54.0 vs. 49.0; $p = 0.67$), less cases with culprit lesion with TIMI score ≤ 1 (25.0% vs. 47.8%; $p = 0.06$), lower number of coronary arteries with significant disease (50% vs. 53%) and lower complication rates (0% vs. 8.7%, $p = 0.12$). Those results did not have an impact on the in-hospital mortality rate which was

higher in patients taking the drug (1.7% vs. 0%; $p = 0.37$). None of the results was associated with statistical significance.

Conclusion

This study revealed that, although statistical significance was not reached, use of statin prior to a first AMI was associated with a better profile of different parameters reflecting the extent and severity of the event. Adequately powered trials are needed to evaluate the relevance of these findings.

COMPLICATED ACUTE MYOCARDIAL INFARCTION - A DOUBLE TROUBLE

Ana Rita Moura¹, Mariana Saraiva¹, Maria João Vieira¹, Miguel Alves¹, Álvaro Laranjeira², Luz Pitta³

¹ Hospital Distrital de Santarém, Santarém, Portugal

² Centro Hospitalar de Lisboa Central, EPE / Hospital de Santa Marta, Lisboa, Portugal

³ Hospital Distrital de Santarém, Santarém, Portugal

Clinical summary

Women, 67-year old, caucasian. Previous history of arterial hypertension controlled with captopril 50mg id and amlodipine 5mg plus valsartan 80mg id. She presented to the emergency department with persistent precordial pain radiating to the left arm and shoulder and dyspnea at rest. At examination she was hemodynamically stable initially but with sudden evolution to hypotension; lung auscultation revealed diffuse wheezing and bibasal crackles. No clear heart murmurs. Enlarged neck veins were seen but no peripheral edema. Electrocardiogram showed ST segment elevation in DIII and aVF and diffuse ST segment depression in V2-V6, DI, aVL. Echocardiogram showed severe mitral regurgitation in the context of papillary muscle rupture. Cardiac catheterization revealed right coronary artery occlusion.

IS HEART FAILURE ASSOCIATED WITH HIGH LEVEL OF VISCERAL ADIPOSITY INDEX?

Sakir Ozgur Keskek, Nuri Aslanoglu

Adana City Training and Research Hospital, Adana, Turkey

Background

The Visceral Adiposity Index (VAI), which is an empiric mathematical model, is indicative of fat distribution and function in human body. It is based on body mass index (BMI), waist circumference (WC), triglycerides (TG) and HDL cholesterol levels. The aim of this study was to investigate the level of VAI in patients with heart failure.

Methods

A total of 58 subjects from both genders, with a minimum age of 18 years old, were included in this case control study. The study group was comprised of 26 patients with heart failure and the control group was comprised of 32 healthy subjects. Patients with a diagnosis of chronic disease other than heart failure were excluded. Ejection fraction percentages (EF), BMI, WC, triglyceride and HDL cholesterol levels of all subjects were recorded. The VAI was calculated by $(WC/(39.68+(1.88*BMI)))*(TG/1.03)*(1.31/HDL)$ for males and $VAI = (WC/(36.58+(1.89*BMI)))*(TG/0.81)*(1.52/HDL)$ for females. The MedCalc V17.4 software (Belgium) was used for all statistical analyses. T test or Mann Whitney U test was used for the comparison of the quantitative measurements between the two groups. Chi-square test was used

to test the statistical significance of differences in frequencies.

Results

Groups were matched in terms of age, sex ($p=0.135$ and 0.666 , respectively). There was statistically significant difference between ejection fraction percentages of the groups. Patients with heart failure have lower EF levels (30.8 ± 5.5 vs. 58.4 ± 6.2 , $p<0.001$). The VAI of patients with heart failure was higher than healthy subjects (2.7 ± 2.4 vs. 1.2 ± 0.7 , $p=0.002$).

Conclusion

Visceral adipose tissue is a metabolically active organ and it is an independent risk factor for metabolic alterations and development of cardiovascular diseases. In this study, we have shown high levels of VAI in patients with heart failure. VAI can give an idea about heart failure in various patient populations.

VARICOSE VEINS

Catarina Carvalho, Rodrigo Rufino, Alexandra Albuquerque, Fátima Campante

Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Clinical summary

We present an image of varicose veins of an obese male patient, 58 years old in a hemodialysis program, with hypertension admitted in the hospital with the diagnosis of pancreatitis, in need of an intensive care unit.

The varicose veins were previously unknown and this diagnosis was incidental, although the important previous cardiovascular risk.

Figure #146. Right thigh.

#150 - Abstract

ATRIAL FIBRILLATION AND STROKE... WHAT WE STILL LACK...

César Matos¹, Rui Marques², Inês Frois Cunha², Ana Filipa Viegas², Margarida Neto³, Ana Gomes²

¹ UCSP Azeitão, Setúbal, Portugal

² Centro Hospitalar Tondela-Viseu, Viseu, Portugal

³ Centro Hospitalar de Setúbal, Setúbal, Portugal

Background

Atrial fibrillation (AF) is a major cause of stroke, with increasing diagnosis and indication for anticoagulation in the majority of the patients. AF, a disease that affects 200,000 Portuguese people, is responsible for one in three strokes. This stroke risk factor is higher than diabetes, hypertension, smoking and sedentarism.

Methods

The study aims a demographic characterization of the population with AF and evaluation of patients with AF with CHA₂DS₂-VASc \geq 2 who were not under anticoagulation. It was also intended to compare the presence of cardiovascular risk factors among the populations with and without AF as well as to evaluate the differences in mortality in both populations.

Observational and retrospective study of 411 patients hospitalized at the stroke unit in a central hospital in 2017, consulting the SClinico[®] database and statistically analyzed using SPSS[®].

Results

108 patients (26.3%) had previous diagnosis of AF (24 haemorrhagic strokes and 84 ischemic strokes). AF was more prevalent in males in hemorrhagic stroke vs ischemic stroke patients (78.6% vs 53.1%), mean age (79.6 vs 79.3 years) was similar. Among the cardiovascular risk factors (with vs without AF): 24.5% vs 14.3% were diabetics, 71.4% vs 63.3% were hypertensive, 42.8% vs 59.2% had dyslipidemia and with heart failure 30% vs 7%. It was found that in 14.3% hemorrhagic stroke vs 28.6% ischemic stroke, patients did not take antiplatelet or anticoagulant therapy and had a CHA₂DS₂-VASc \geq 2. In the mean duration of hospitalization in ischemic stroke patients with and without AF 4.6 vs 4.2 days and hemorrhagic stroke with and without AF 9.1 vs 7.2 days. Mortality in this period in ischemic stroke patients with and without AF 14.3% in patients with AF vs 8.7% without AF and in hemorrhagic stroke 28.6% with AF vs 20.4% without AF.

Conclusion

The prevalence of AF accompanies the high rise in life expectancy. There are no differences in cardiovascular risk factors in both populations. The stroke in patients with AF is associated with higher mortality. This study shows the importance of integrated management of AF through a strategy that is based on stroke prevention, symptom management, and risk reduction of comorbidities especially in this age group and more fragile in terms of therapeutic compliance and access to health care.

#154 - Abstract

OBESITY PARADOX IN PATIENTS UNDERGOING PERCUTANEOUS MITRAL VALVE EDGE-TO-EDGE REPAIR USING MITRACLIP[®] PROCEDURE

Karsten Keller^{1,2}, Lukas Hobohm^{1,2}, Martin Geyer², Carl J Lavie³, Thomas Münzel², Ralph Stephan Von Bardeleben²

¹ Center for Thrombosis and Hemostasis (CTH), University Medical Center Mainz (Johannes Gutenberg-University Mainz), Mainz, Germany

² Heart Center Mainz, Center of Cardiology, Cardiology I, University Medical Center Mainz (Johannes Gutenberg-University Mainz), Mainz, Germany

³ Department of Cardiovascular Disease, John Ochsner Heart & Vascular Institute, Ochsner Clinical School, The University of Queensland School of Medicine, New Orleans, United States

Background

Obesity is an important risk factor for cardiovascular diseases (CVD), CVD events and mortality. Despite these negative consequences of obesity on CVD, several studies demonstrated that obese CVD patients had a better prognosis compared to their leaner counterparts, which is called "obesity paradox". The influence of obesity on outcomes of patients with valvular heart diseases (VHD) are sparse.

Mitral regurgitation (MR) is a frequent cause of VHD and an important cause of morbidity and mortality. Patients with severe MR are often referred for surgical or interventional correction. While surgical MR repair is recommended for the majority of patients with severe primary MR (at low surgical risk), transcatheter edge-to-edge valve repair with the MitraClip[®] (Abbott, Menlo Park, CA, USA) for patients at high surgical risk is widely accepted and performed at increasing numbers. We investigated the impact of obesity on adverse in-hospital outcomes in patients with MitraClip[®] implantation.

Methods

We analyzed data on characteristics of patients and in-hospital outcomes for all percutaneous MR repairs using the MitraClip[®] in Germany 2011-2015 stratified for obesity vs. normal-weight/over-weight, excluding patients with rapid weight loss and underweight.

Results

The nationwide inpatient sample included 13,563 inpatients undergoing MitraClip[®] implantations. Among them, 1,017 (7.5%) patients were coded with obesity.

Obese patients were younger (75 vs. 77 years, $P < 0.001$), more often female (45.4% vs. 39.5%, $P < 0.001$), had more often heart failure (87.1% vs. 79.2%, $P < 0.001$) and renal insufficiency (67.0% vs. 56.4%, $P < 0.001$).

Obese and non-obese patients were comparable regarding MACCE and in-hospital death. Adverse in-hospital events (composite outcome of in-hospital death, mechanical ventilation and cardio-pulmonary resuscitation) were more often in non-

obese than in obese patients with a trend towards significance (20.6% vs. 18.2%, $P=0.066$).

Obesity was an independent predictor of reduced adverse in-hospital events (OR 0.75, 95%CI 0.64-0.89, $P<0.001$), but not for reduced mortality ($P=0.355$) and MACCE rate ($P=0.108$). Obesity class III was associated with an elevated risk for pulmonary embolism (OR 5.66, 95%CI 1.35-23.77, $P=0.018$).

Conclusion

We observed an obesity paradox regarding adverse in-hospital events in patients undergoing MitraClip® implantation, but our results failed to confirm an impact of obesity on in-hospital survival or MACCE.

#158 - Abstract

BERBER ETHNIC PATIENTS ADMITTED FOR ACUTE HEART FAILURE IN A CROSS-BORDER HOSPITAL OVER 1 YEAR

Julio Osuna Sánchez¹, Antonio Ubiña Carbonero²

¹ Hospital Comarcal Melilla, Melilla, Spain

² Centro de Salud San Andrés-Torcal, Málaga, Spain

Background

A retrospective descriptive study of Berber ethnic patients admitted for heart failure (HF) in the Internal Medicine service during 2017.

Methods

This is a cross-sectional descriptive analysis of patients admitted to internal medicine for HF in 2017 who were of Berber ethnicity. A detailed study was carried out of all the risk factors presented by the patients, the associated comorbidities, as well as personal history. We have analyzed the discharge reports of our service along with the review of medical records. A descriptive study of the characteristics of patients using frequency measurements was carried out, analyzing the type of sample by seeing whether or not they followed normality.

Results

There were a total of 120 patients hospitalized for HF, of which 50.8% were of Berber ethnicity. 55% were women. The mean age was 73.71 ± 9.74 years. 5% of the patients were institutionalized, 15.8% were dependent for all the basic activities of daily life. 79.2% had social security. Regarding personal history, 25.8% previous ischemic heart disease; 62.5% HBP; 45.8% DM; 34.2% A-fib, 12.5% COPD, 25% dyslipidemia; 5.8% sleep apnea; 10% anemia; previous stroke 6.7% and 9.2% neoplasia (active or not). The most frequent causes of admission were the ischemic cause with 35.4% and the valvulopathy with 33.8%. As an important finding, 8.3% of the patients presented cognitive impairment to some degree. 98.3% of patients had 2 or more pathologies at the time of admission. 21.7% of them had a decreased ejection fraction. The mean stay of hospital admission was 9.88 ± 8.92 days, with 13.3% of patients who died.

Conclusion

The HF is a problem both for public health and for the doctor who must face it every day. Once the prognosis is diagnosed, it becomes ominous, since approximately 50% of patients die within the next 5 years. The diagnosis and early treatment of HF is important to prevent its complications, slow its evolution, reduce its symptoms and avoid the need for hospitalizations once the diagnosis is confirmed. Given our geographical location we have the Berber ethnic group as a reference population, so it was interesting to know how this class of patients was, and create a typical profile of them. Patients admitted for acute heart failure of Berber ethnicity have a multi-pathological profile with multiple diseases that make them patients with a more complicated management in the plant. This is basically due to our geographical location.

#168 - Case Report

A CASE OF AORTIC ROOT ABSCESS AS A COMPLICATION OF ENDOSCOPY

Gregory Offiah, Aine Gorman, Cara Gill, Paul Shiels, Ausaf Mohammad

Midlands Regional Hospital Tullamore, Offaly, Ireland

Introduction

Infective endocarditis (IE) has an incidence of 3-9 per 100,000, with the risk increased by prosthetic heart valves. The in-hospital mortality is 15-22%, with ~40% 5 year mortality. Prevention, recognition and treatment of this potentially life threatening condition are imperative.

Case description

An 81-year-old male presented with melena and hypotension. Past history included aortic valve replacement (AVR), treated with warfarin. On admission, his international normalised ratio was 3.5. Oesophagogastroduodenoscopy (OGD) confirmed an ulcer requiring clipping and the patient was discharged. He represented 6 days later with delirium, cough and fever. His white cell count was $12.6\times 10^9/L$ and C-reactive protein 116 mg/L. He was treated for presumed pneumonia with piperacillin-tazobactam and escalated to meropenem due to persistent pyrexia. Blood cultures (BC) grew enterococcus in one bottle. Two subsequent BC were negative, transthoracic echocardiogram and computed tomography of thorax abdomen and pelvis were normal. Microbiology advised repeat BC two weeks after antibiotics. At this point two sets of BC confirmed enterococcus faecalis, which was highly gentamicin resistant. Transoesophageal echocardiogram and computed tomography angiogram revealed an AVR vegetation and aortic root abscess. He was treated for IE with amoxicillin and referred for a second AVR.

Discussion

8.1% of IE cases are related to endoscopy (gastroscopy - 3.6%). IE is associated with therapeutic OGD in those with cardiac defects. Enterococcus IE is classically associated with

proctosigmoidoscopy. This is the first case describing enterococcus IE post OGD. European Society of Cardiology guidelines do not recommend prophylactic antibiotics for endoscopy. However, this case raises the question of its potential role.

#181 - Case Report

AN IGNORED, ALMOST FATAL, HYPOKALEMIA

Cristina Martins, Diana Gonçalves, Pedro Ribeiro, Armando Carvalho

Centro Hospitalar e Universitário de Coimbra - Hospital Geral, Coimbra, Portugal

Introduction

Hypokalemia is defined as a serum potassium (K) level of less than 3.5 mmol/L. It may result from inadequate K intake, increased K excretion, or a shift of K from the extracellular to the intracellular space, being the second the most frequent cause. When severe (K less than 2.5 mmol/L), it can be a potentially life-threatening imbalance.

Case description

A 60 years old man is admitted to the Intensive Care Unit (ICU), after an episode of cardiac arrest in the Emergency Room (ER), where he presented previously, complaining of progressive muscle weakness and sudden inability to walk. In the ER, he was conscient, but disoriented, hemodynamically stable and afebrile, but with a flaccid tetra-paralysis. While on observation, he progressed into a cardiac arrest. Immediate advanced life support was initiated with successful return of spontaneous circulation. A hypokalemia of 1.5 mmol/L on the blood gas analysis was identified and immediate aggressive correction was initiated. In the ICU, patient's medical history was revised: he had been diagnosed with hypertension (HT) at the age of 40, by his general practitioner; since then he also had persistent hypokalemia (with a mean value of 2.5 mmol/L). No study to exclude secondary HT was made, and the patient was progressively medicated with higher doses of different anti-hypertensive drugs (except for thiazide diuretics), and with oral K tablets. When admitted in the ER, though, he had recently changed his usual prescription and had initiated a high dose thiazide. The hypothesis of a primary hyperaldosteronism was raised and confirmed after dosing of aldosterone plasma levels and plasma renin activity: 340 ng/dL and 0.33 ng/mL/h, with an aldosterone to renin ratio of 1030. Spironolactone and an ACE inhibitor were initiated, with improvement of the patient's HT and K levels. A renal CT was performed revealing a left adrenal adenoma and a right adrenal hyperplasia. After discharge of the ICU, the patient continued his study on the Internal Medicine ward, and was proposed to a left adrenalectomy.

Discussion

The evaluation of a patient with HT depends upon the likely cause and the degree of difficulty in achieving acceptable blood pressure

control. Patients who have clinical clues suggesting the possible presence of secondary HT, like our patient, should undergo a more extensive evaluation. Since it isn't cost effective to exclude secondary HT in every hypertensive patient, it is important to be aware of the clinical clues that may suggest it.

#188 - Abstract

ECHOCARDIOGRAPHIC ASSESSMENT AND CARDIAC BIOMARKERS IN HEMODYNAMICALLY STABLE PATIENTS WITH ACUTE PULMONARY EMBOLISM

João Fernandes Serodio¹, Lígia Pires², Luis Melo¹, Rita Pereira³, Daniel Ferreira³, Nuno Cardim^{3,4}

¹ Department of Internal Medicine IV, Hospital Prof. Doutor Fernando Fonseca, Amadora, Portugal

² Intensive Care Unit, Centro Hospitalar do Algarve, Faro, Portugal

³ Echocardiography Lab, Cardiovascular Centre, Hospital da Luz, Lisboa, Portugal

⁴ Centre for the Study of Chronic Diseases (CEDOC), Nova Medical School Lisboa, Lisboa, Portugal

Background

Acute pulmonary embolism is still associated with significant mortality, morbidity and hospitalization. The role of echocardiography in the diagnosis and management of acute pulmonary embolism in hemodynamically stable patients (APE-HSP) is still uncertain. Our aim was to assess the incidence of echocardiographic signs of right heart overload in acute APE-HSP and to evaluate the performance of cardiac biomarkers to identify right heart strain.

Methods

A retrospective analysis of all APE-HSP hospitalized for acute pulmonary embolism between 2015 and 2017 was performed. All patients underwent transthoracic echocardiography within the first 24h of hospitalization. Several signs of right heart overload were assessed: pulmonary artery systolic pressure (PASP), right ventricle end-diastolic diameter, abnormal septal motion (D-shape), tricuspid annular plane systolic excursion (TAPSE), right ventricle S' wave on tissue Doppler imaging (S'RV) and the presence of right heart thrombus. Laboratory analysis included high-sensitive troponin I and NT-pro brain natriuretic peptide (NT-pro BNP).

Results

The population consisted of 63 patients with median age of 66 years (51-77), 59% female. In this population, 62% of patients presented at least one sign of right heart overload and increased PASP was most frequently found echocardiographic sign (60%). When PASP is excluded from the analysis, up to one third of patients (33%) present with right heart overload. Troponin I was elevated in 32% of cases and NT-pro BNP in 41%. A positive strong correlation was found between troponin I or NT-proBNP and PASP (respectively,

$\rho=0.526$, $p\text{-value}=0.0001$; $\rho=0.547$, $p\text{-value}=0.0003$). TAPSE showed a negative strong correlation with troponin and NT-pro BNP ($\rho=-0.559$, $p\text{-value}=0.0001$; $\rho=-0.577$, $p\text{-value}=0.0002$, respectively). There was a negative correlation between S'RV and NT-proBNP ($\rho=-0.342$, $p\text{-value}=0.0498$).

Conclusion

In conclusion, one third of the patients showed echocardiographic signs of right heart overload, which was similar to the proportion of patients with raised cardiac biomarkers (32% for troponin I and 41% for NT-pro BNP). There was a significant correlation between TAPSE, S'RV or PASP and cardiac biomarkers. Therefore, echocardiography may play an important role in clinical management and risk stratification of APE-HSP.

#199 - Abstract

THE USEFULNESS OF 18F-FDG PET/CT IMAGING IN PATIENTS WITH CARDIAC SARCOIDOSIS

Yutaka Kajikawa, Masae Ikeda, Aki Ueda, Minoru Hirota

National Hospital Organization Fukuyama Medical Center, Fukuyama, Japan

Background

Sarcoidosis is a systemic granulomatous disorder of unknown etiology and can present as a wide variety of clinical courses, depending on the affected organs. Cardiac involvement is often not easy to diagnose, in recent years, newer imaging techniques, such as 18F-FDG PET/CT, have evolved to determine cardiac involvement of sarcoidosis.

The aim of this study was to evaluate the usefulness of 18F-FDG PET/CT in detecting cardiac sarcoidosis.

Methods

We investigated the frequency of organ involvement at the time of diagnosis in 26 patients with sarcoidosis, based on retrospective review of electronic medical records from April 2014 to March 2019.

Results

The study population comprised 8 men (31%) and 18 women (69%), and the average age was 60 ± 16.1 years. Abnormal laboratory findings pertaining to the eye, skin, lungs, and heart were seen in 10 (38.4%), 10 (38.4%), 16 (61.5%), and 6 (23.3%) cases, respectively. Prednisolone treatment was administered in 7 cases (26.9%). The serum levels of angiotensin-converting enzyme and soluble interleukin-2 receptor were 20.4 ± 9.8 U/mL and 565.8 ± 388.0 U/mL, respectively. With regard to the respective electrocardiogram findings, the cardiac sarcoidosis patients (CS group) and the patients with sarcoidosis without cardiac lesion (non-CS group) had similar PQ interval (160.1 ± 27.4 msec vs. 168.7 ± 20.2 msec). Compared with the non-CS group, the CS group had significantly more frequent third degree atrioventricular blocks (2 (33%) vs.

0 (0%), $p < 0.05$). BNP level in the CS group was also higher than that in the non-CS group (290.1 ± 104.4 pg/mL vs. 12.8 ± 12.4 pg/mL, $p < 0.05$). On echocardiography, the intraventricular thickness was less in the CS group than in the non-CS group (4.6 ± 1.7 mm vs. 8.5 ± 1.9 mm, $p < 0.001$). In the CS group, two patients were in the active stage of sarcoidosis, three patients were in the healing or non-active stage of sarcoidosis, and one patient was in the terminal stage of ovarian cancer. 18F-FDG PET/CT imaging was performed on four patients and gallium-67 citrate scintigraphy was performed on three patients. In both cases, 18F-FDG PET/CT was superior to gallium-67 citrate scintigraphy in detecting the cardiac lesion and the activity of sarcoidosis.

Conclusion

This study suggested that 18F-FDG PET/CT can detect both the early and healing stages of cardiac sarcoidosis, in which few perfusion abnormalities and high inflammatory activity are noted before advanced myocardial impairment.

#208 - Abstract

THE HEART OF STROKE - CEREBROVASCULAR RISK ASSESSMENT BASED ON A DESCRIPTIVE ANALYSIS OF 171 PATIENTS

Sara Lopes Fernandes, Rita Ribeiro Carvalho, Luís Graça Santos, Behnam Moradi, Helia Martins, João Morais

Leiria Hospital Center, Leiria, Portugal

Background

Stroke is the leading cause of death in Portugal and it is more frequent in men, aged 65-74 years. The continuum and interrelationship between heart disease and cerebrovascular disease is unquestionable.

Methods

This study presents a descriptive and retrospective analysis of patients with ischemic stroke followed in a Cerebrovascular Risk Consultation, from January 2016 to December 2017.

Results

A total of 171 patients were selected, with a mean age of 65 ± 12 years and 57% males. The main cardiovascular risk factors identified were: arterial hypertension in 142 patients (83%); dyslipidemia in 139 (81%); type 2 diabetes mellitus in 50 (29%), smoking in 39 (23%); alcohol consumption in 32 (19%) and previous cardiovascular events in 43 (25%) cases. Electrocardiographic changes identified atrial fibrillation in 31 patients (18%), 19 of them aged ≥ 70 years, showing the highest prevalence in elderly patients (31%). The Holter records collected in 94 patients showed supraventricular extrasystoles with a trimmed mean of 217 ± 1540 / 24h. Echocardiograms performed on 132 patients revealed septum hypertrophy (> 11 mm) in 89 patients (67%); Left ventricular ejection fraction $< 50\%$ in 9 patients (6.5%) and

left atrium greater than 35 ml/m² in 113 patients (93%). In 10% (n=15) of the cases, a patent foramen ovale was identified, with a higher prevalence among patients ≤ 55 years (n=11, 31%), most of them carrying a thrombophilia gene (85% of patients evaluated).

Conclusion

Patients with ischemic stroke have a high prevalence of cardiovascular risk factors. The results of this series show the rationale and importance for all these patients to be investigated from the cardiac point of view, in order to find out changes in heart rhythm and structural abnormalities, which contribute to a better etiological clarification and help in therapeutic decision.

#220 - Abstract

THE IMPORTANCE OF HEMATOLOGICAL PARAMETERS IN HEART FAILURE PROGNOSIS-EVIDENCE FROM THE REFERENCE STUDY

Mário Barbosa¹, Andreia Matos^{2,3}, Manuel Bicho^{2,3}, Luiz Menezes Falcão^{4,3}

¹ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisbon, Portugal

² Genetics Laboratory and Environmental Health Institute-ISAMB, Lisbon, Portugal

³ Lisbon Faculty of Medicine, Lisbon, Portugal

⁴ Department of Internal Medicine, Santa Maria Hospital, Lisbon, Portugal

Background

In patients with heart failure (HF), anemia and iron deficiency are predictors of poor long-term outcome.

The purpose of this study was to examine the association of anemia, iron deficiency, and related hematological parameters with early (defined as the period of 90 days post-discharge) rehospitalization due to HF and all-cause mortality, and long-term all-cause mortality in HF patients.

Methods

Anemia, iron deficiency, red cell distribution width (RDW) and erythropoietin (EPO) were assessed in patients hospitalized with acute decompensated heart failure in class III or IV of NYHA to an Internal Medicine ward.

Univariate Cox proportional hazard model was used to assess the relationship between variables and outcomes.

Results

In total, 65 patients were followed for a median of 13.7 (Q1-Q3 6.7-18.9) months. Mean age was 79.2 (SD 10.8) years and 56.9% were female.

The mean left ventricular ejection fraction was 50.38 ± 19.07 %.

Variables associated with an increased risk for early rehospitalization were RDW (hazards ratio [HR] 1.35; 95% confidence interval [CI] 1.16-1.58), anemia (HR 3.81; 95% CI 1.29-11.28), and anemia with iron deficiency (HR 3.50; 95% CI 1.30-9.38).

Increased risk for early mortality was associated with RDW (HR 1.83; 95% CI 1.29-2.59), EPO (HR 1.38; 95% CI 1.04-1.82), absolute iron deficiency (HR 7.22; 95% CI 1.50-34.81), and anemia with iron deficiency (HR 4.48; 95% CI 1.26-15.88).

Variables associated with an increased risk for long-term mortality were RDW (HR 1.31; 95% CI 1.12-1.54) and EPO (HR 1.29; 95% CI 1.11-1.49).

Conclusion

Anemia, iron deficiency, RDW and EPO were associated with early rehospitalization, early mortality, and long-term mortality. Our findings may provide insight into HF prognosis and may raise the interest in some neglected hematological parameters.

#230 - Case Report

LATENT BRUGADA SYNDROME MANIFESTO POSITION WITH PROPAFENONE

Isabel Moreno Lucente, Vanesa Muñoz Mendoza, Letizia Marie Silvie Mournoval Morales, Amalia Inmaculada Fernández Alamán
Hospital Obispo Polanco, Teruel, Spain

Introduction

Brugada syndrome (SBr) is a hereditary cardiac channelopathy with an electrocardiographic morphology similar to that of right bundle branch block. The high incidence of syncope and ventricular arrhythmias suggests that the BrS may be responsible for 5% of the total sudden cardiac death (SCD) and up to 12% of sudden death (SD) in patients without structural heart disease.

Case description

A 79-year-old woman with hypercholesterolemia as the only cardiovascular risk factor, evaluated by the Cardiology service in 1992 for palpitations and a syncopal episode; during the study, Holter of arrhythmias supraventricular extrasystole (ESV) was isolated without episodes of supraventricular tachycardia (SVT) objectivable during the recording. After ruling out structural heart disease, amiodarone was started. After 12 months of treatment, it was discontinued due to subclinical hypothyroidism, starting propafenone. Followed periodic reviews until 1995, being discharged from clinical stability consultations. In 2014, the patient was referred again to consultations for a new syncopal episode. Reinterrogating the patient reports three syncopal episodes from the previous discharge.

The physical examination did not present findings. In the same consultation, an ECG showing supradeslevelization of the ST segment in V1-V2 compatible with the Brugada syndrome "coved type" pattern was performed. Given the new findings, the patient's previous ECGs were systematically reviewed, showing the electrocardiographic fluctuations in relation to taking propafenone and suspending it when SBr is suspected. An electrophysiological study was performed that was interpreted as negative and the study was completed with laboratory tests, chest radiography and echocardiography with normal results.

After the withdrawal of propafenone, the ST segment in the right precordialis is normalized in ECG. Given the diagnosis of “latent SBr revealed with propafenone”, the patient was instructed to avoid antiarrhythmic drugs, tricyclic antidepressants and first generation antihistamines. Currently, the patient is asymptomatic and without electrocardiographic changes.

Discussion

The BrS is included within the group of channelopathies, a hereditary heart disease with autosomal dominant inheritance, which is associated with ventricular arrhythmias and SCD. Incomplete penetrance and variable expressivity hinder the correct diagnosis, the stratification of the risk of sudden death and the specific therapeutic approach for each patient.

#233 - Abstract

LONG-TERM (10-YEAR) FOLLOW-UP ON PATIENTS DIAGNOSED WITH MYOCARDITIS IN A DISTRICT GENERAL HOSPITAL

Sara Santos, Sara Gomes, Helder Santos, Celia Carmo, Carla Nobre, Boban Thomas

Centro Hospitalar Barreiro-Montijo, Setúbal, Portugal

Background

19 patients diagnosed and treated for myocarditis in a district general hospital in Portugal, between the years of 2009 and 2014, patients were assessed 5 to 10 years later to evaluate the long-term outcome of the disease.

Methods

The patient population had the following features: males (17), females (2), ages (18-38 years), History of cardiovascular risk factors (2), family history of cardiac disease in young age (0), precordial chest pain (17), pleuritic chest pain (9), tiredness/orthopnea (1), Acute systemic disease (14), Abnormal EKG (11), EKG with ST elevation segment (8), T wave inversion (2), Mean troponin peak (10,52), Mean CKMB peak (56,13), Mean RCP (71,77), Leucocytosis (10), neutrophilia (3), Systolic dysfunction on echocardiogram (3), segment changes seen in echocardiogram (5), Pericardial effusion seen on echo (5).

Results

In this cohort of patients only one patient was readmitted with myocarditis and there were no long term cardiovascular complications or mortality.

Conclusion

Our data suggest that the clinical spectrum of myocarditis in Portugal may be benign with a good long-term prognosis devoid of cardiovascular complications.

#239 - Abstract

IMPACT OF ATRIAL FIBRILLATION ON THE IN-HOSPITAL MORTALITY OF SURGICAL PATIENTS

Karsten Keller, Lukas Hobohm

Center for Thrombosis and Hemostasis (CTH), University Medical Center Mainz (Johannes Gutenberg-University Mainz), Mainz, Germany

Background

Atrial fibrillation is the most common sustained cardiac arrhythmia worldwide. It is associated with increased mortality, thromboembolic events, and heart failure. We aimed to investigate the impact of AF on adverse in-hospital outcomes in hospitalized surgical patients.

Methods

The nationwide German inpatient sample of the year 2014 was used for this analysis. Surgical patients were identified based on the code for surgical and interventional procedure codes (OPS codes 5-) and patients were further stratified by atrial fibrillation/flutter (AF; ICD code I48) (source: RDC of the Federal Statistical Office and the Statistical Offices of the federal states, DRG Statistics 2014, own calculations).

We compared surgical patients with and without AF as well as survivors vs. non-survivors in AF patients. Logistic regression models were used to investigate the impact of AF as a predictor for adverse in-hospital outcomes.

Results

Overall, 7,043,514 hospitalized surgical patients (54.5% females, 31.6% aged >70 years) were included in the analysis. Of these, 546,019 patients (7.8%) were diagnosed with AF. Overall, 1.4% of the surgical patients and 5.8% of the surgical patients with additional AF died during in-hospital stay.

All-cause death (RR 6.14 [95%CI 6.05-6.22], $P<0.001$) and adverse in-hospital events (composite of all-cause in-hospital death, mechanical ventilation, and/or cardio-pulmonary resuscitation) (RR 3.35 [95%CI 3.32-3.38], $P<0.001$) occurred both more often in patients with AF in comparison to those without.

AF was an important predictor for in-hospital death in surgical patients (OR 1.58 [95%CI 1.56-1.61], $P<0.001$) and for adverse in-hospital events (OR 1.63 [95%CI 1.62-1.65], $P<0.001$) independent of age, sex and comorbidities.

Additionally, AF is accompanied with an elevated risk to develop a pneumonia (OR 1.80 [95%CI 1.77-1.82], $P<0.001$), high-risk pulmonary embolism (PE) (1.56 [95%CI 1.43-1.70], $P<0.001$), fatal PE (OR 1.64 [95%CI 1.47-1.83], $P<0.001$), shock (OR 1.84 [95%CI 1.81-1.88], $P<0.001$), as well as (ischemic or haemorrhagic) stroke (OR 2.50 [2.45-2.55], $P<0.001$).

Conclusion

AF in surgical patients is associated with higher in-hospital case-fatality rate, higher rate of adverse in-hospital events, pneumonia, high risk and fatal PE, shock and stroke.

#245 - Abstract

SOFA SCORE IS ASSOCIATED WITH INCREASED RISK OF SHORT-TERM MORTALITY IN ACUTE DECOMPENSATED HEART FAILURE.

Adi Elias¹, Walid Saliba², Johad Khoury², Fadel Bahouth¹, Jeries Nashashibi³, Zaher Azzam¹

¹ Internal Medicine B, Rambam Health Care Campus, Haifa, Israel

² Carmel Medical Center, Haifa, Israel

³ Internal Medicine D, Rambam Health Care Campus, Haifa, Israel

Background

Heart failure (HF) is one of the leading causes for hospitalization and mortality. Patients hospitalized due to acute decompensated heart failure (ADHF) are at high risk for short- and long-term mortality. Identifying high risk patients is essential to ensure proper monitoring and management. Sequential Organ Function Assessment Score (SOFA) is considered an excellent score to predict short-term mortality in sepsis and other life threatening conditions. ADHF shares similar pathophysiologic mechanism such as; systemic hypoperfusion and inflammatory state. We aimed to assess the capability of SOFA score to predict short and long-term mortality in ADHF.

Methods

Patients with first hospitalization with primary diagnosis of ADHF were retrospectively identified between the years (2008-2018) using computerized database of Rambam Health Care Campus. The SOFA score was calculated for all patients. Patients were divided into 5 categories by 2 points intervals; Category 1 (0-2 points), Category 2 (3-4 points), Category 3 (5-6 points), Category 4 (7-8 points) and Category 5 (above 8 points).

Results

3232 patients were included in the study, the in-hospital mortality, 10-days and 30-days mortality rate were 7.2% (234 patients), 7.6% (260 patients) and 11% (377 patients) respectively. The SOFA score was significantly associated with in-hospital mortality, 10-days mortality and 30 days mortality. The hazards ratios for 1-point increase in the SOFA score were 1.425 (95% CI, 1.347-1.506), 1.425 (95% CI, 1.347-1.506) and 1.479 (95% CI, 1.394-1.608) respectively.

Furthermore, when divided into the 5 categories as demonstrated above, the hazard ratios for 30 mortality were increased by 2.284 (CI 1.4-3.719) for category 2, 5.48 (CI 3.35-8.975) for category 3, 12.49 (CI 19.4-91.9) for category 4 and 42.2 (CI 19-91) for category 5. The SOFA Score demonstrated a good predictive capability. The areas under the receiver operating characteristic curves for in-hospital mortality, 10-days mortality and 30 days mortality were 0.719 (95% CI, 0.684-0.754), 0.691 (95% CI, 0.655-0.727) and 0.653 (95% CI, 0.622-0.685) respectively.

Conclusion

SOFA score is associated with increased risk of in-hospital and

short-term mortality in acute decompensated heart failure. SOFA can be used as a simple score to screen high risk patients that should be considered for intensive care units. Larger prospective studies are needed to validate our results.

#256 - Abstract

RENIN-ANGIOTENSIN-ALDOSTERON SYSTEM BLOCKADE AND ARTERIAL STIFFNESS IN RENAL TRANSPLANTS RECIPIENTS

Zbigniew Heleniak¹, Sarah Illersberger², Susanne Brakemeier², Alicja Debska-Slizien¹, Klemens Budde², Fabian Halleck²

¹ Department of Nephrology, Transplantology and Internal Medicine Medical University of Gdansk, Gdansk, Poland

² Medizinische Klinik mit Schwerpunkt Nephrologie und Internistische Intensivmedizin Charité Universitätsmedizin, Berlin, Germany

Background

Cardiovascular disease (CVD) is the main cause of death among RTRs (renal transplant recipients). The occurrence of CVDs is affected by a lot of CV risk factors, which increase the arterial stiffness. Pulse wave velocity (PWV) measurement is noninvasive, methods for estimating aortic stiffness. Additionally, renin angiotensin aldosterone system (RAAS) blockade mitigate arterial stiffness in general population.

The aim of this study was to assess the influence of RAAS blockade on aortic stiffness in RTRs.

Methods

344 stable RTRs were randomly enrolled to the study. 204/59.3% of them received RAAS blockers (Angiotensin Convertase Inhibitors – ACEi or angiotensin receptor blockers - ARBs): group RAAS (+) and 140/40.7% RTRs were without such medication: group RAAS (-). The median time of dialysis and after kidney transplantation was 58.5 and 78 months respectively. Immunosuppressive regimen was based on calcineurin inhibitors (tacrolimus or cyclosporin), antiproliferative drug (MMF or MPS) and steroids. In RAAS(-) group more patients used steroids than in RAAS(+). Following parameters of arterial stiffness as brachial ankle and carotid femoral pulse wave velocity (baPWV left and right, cfPWV) were measured in each patient by ABI system 100.

Results

In RAAS (+) group 55.4% of patients used ARBs, 43.8% ACEIs. The majority of RAAS (+) patients received candesartan or ramipril. The mean doses of ARBs and ACEIs were 0.25 and 0.5 of their maximal recommended doses, respectively.

CVD (coronary artery disease, peripheral obliterans artery disease) was diagnosed in 27.9 and 14.3% of patients in RAAS (+) and RAAS (-) group respectively. Graft function as far as serum creatinine and eGFR were 1.58, 1.36 mg/dl and 47.9, 54 ml/min/1.73m² in RAAS (+) and RAAS (-) patients, respectively

The values of baPWV left and right were as follow: 11.9, 11.9m/s (left) and 12.1, 11.7 m/s (right) in RAAS (+) and RAAS (-) group,

respectively. cfPWV was 8 and 7.8 m/s in RAAS (+) and RAAS (-) patients, respectively.

In RAAS (+) patients with CVD, the measurements of arterial stiffness parameters (baPWV right 15 vs 12.9m/s, baPWV left 14.4 vs 13.2m/s and cfPWV 10.6 vs 8.6m/s) shown higher results as compare to RAAS (-) group with CVD.

Conclusion

- RAAS blockade was used in the majority of RTRs population.
- Arterial stiffness was increased in RTRs with CVD.
- RAAS blockade did not ameliorate arterial stiffness in RTRs.

#280 - Abstract

STRESS AT WORKPLACE AND RISK OF ACUTE CARDIOVASCULAR DISEASES IN POPULATION 25-64 YEARS IN RUSSIA/SIBERIA. MONICA-PSYCHOSOCIAL EPIDEMIOLOGICAL STUDY

Valery Gafarov¹, Elena Gromova², Dmitriy Panov², Igor Gagulin², Almira Gafarova², Eldar Krymov²

¹. Collaborative Laboratory of Cardiovascular Disease Epidemiology, Novosibirsk, Russia

². Research Institute of Internal and Preventive Medicine, branch of Institute of Cytology and Genetics SB RAS, Novosibirsk, Russia

Background

The aim is to determine the impact of stress on work on the risk of cardiovascular disease over 16-years of follow-up in an open population of 25-64 years in Russia/Siberia.

Methods

Under the third screening of the WHO MONICA-psychosocial program (MOPSY) random representative sample including both genders aged 25-64 years was surveyed in Novosibirsk in 1994 (n=1346, 48.8% males; mean age 44.9 ± 0.4 years; response rate was 77.3%). Stress at work was assessed by means Karazek scale. New-onset cases of myocardial infarction (MI), stroke were identified from 1994 to 2010.

Results

A high level of stress at work was in 29.5% of men and in 31.6% of women. The middle level was in 48.9% of men and in 50.7% of women ($\chi^2=2.574$ v=2 p=0.276). The risk of MI over 16-years period in persons experiencing stressful situations at work was as follow: in men HR=3.592 and women HR=3.218 (95%CI 1.146-9.042); stroke risk was in men HR=2.603 (95%CI, 1.06-4.153) and in women HR was 1.956 (95%CI 1.008-3.795). In multivariate analysis risk of MI in men was HR=1.15 (95%CI 0.6-2.2) and in women HR=2.543 (95%CI 1.88-7.351); risk of stroke in men was HR=3.8 (95%CI 1.6-8.8) and in women it was HR=1.95 (95%CI 0.984-3.887). The risk of stroke was higher in those who are living alone, divorced and widowed men HR=4.2 (95% CI 1.5-13.2) and in women with high school or primary education degree HR=3 (95%CI 0.852-11.039).

Conclusion

It was established that a high level of stress at work is not gender-specific. The risk of MI incidence over a 16-years period is higher in women than in men but stroke in men; the risk of myocardial infarction and stroke is affected by the social gradient in both genders.

PULMONARY EMBOLISM – THE GREAT MASQUERADE

Flávia Marília Ferreira Santos, Cátia Faria, Cátia Santos, Vera Frazão, Diana Moura, João Santos

Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

Pulmonary embolism (PE) has a highly variable clinical presentation. Sudden-onset dyspnea is the most reported compliant among patients. Other symptoms include cough, haemoptysis, fever, anxiety, nausea, acute chest, tachycardia, lipothymia, convulsions, cyanosis or edema of the lower limbs.

Case description

We present the case of a 65-year-old male with past medical history of hypertension and diabetes mellitus. He was asthenic, with dyspnea at rest, non-productive cough and loss of strength in the lower limbs. In the past 4 days he had 2 episodes suggestive of lypotimia. He had been previously observed at consultation with the diagnosis of a respiratory infection and empirically medicated with azithromycin. At examination the patient was conscious, cooperative and oriented. Sudoretic, with a heart rate of 129 bpm), with hyperglycemia (360 mg/dL). No changes in cardiac and pulmonary auscultation and no edema in the lower limbs, without suggestive signs of deep venous thrombosis. Blood analysis showed relative neutrophilia without associated leukocytosis. Creatinine 1.54 mg/dL, Urea 12.7 U/L, High sensibility troponin 220, BNP 5720 pg/L. Blood gas gas with hypoxemia and hypocapnia. Chest X ray showed bronchovascular reinforcement on the right, with no evidence of condensation or effusion. Electrocardiogram with sinus rhythm, 122bpm, inversion of the T wave from V1 to V6. Thorax computed tomography and angiography showed PE involving the common trunk and, more extensively, the distal region of both main pulmonary arteries and all emerging lobular arteries as well as some lower predominant segmental arteries. The patient started anticoagulation with lower molwcular weight heparin. Performed transthoracic echocardiogram for stratification of the severity of the condition that did not show affection of the right cardiac cavities function.

Discussion

The authors intend to demonstrate that PE is a serious and potential life- Threatenning condition that may occur with highly variable clinical presentation. Therefore it is very important that the physician to considerate this as a possible hypothesis when

observing patients with a nonspecific or atypical clinic in order to improve outcome.

#301 - Abstract

ABBC (AGE, NT-PROBNP, BARTHEL INDEX AND C-REACTIVE PROTEIN) LONG-TERM SCORE IN THE PREDICTION OF DEATH AFTER AN ACUTE PULMONARY EMBOLISM

José Luis Alonso-Martínez, Francisco Javier Annicchérico-Sanchez, Sara Pérez-Ricarte
Hospital Complex of Navarra, Pamplona, Spain

Background

Several prognostic indexes are available for use in daily clinic to classify the risk of death of patients diseased with pulmonary embolism (PE), generally with a suitable 30 days prediction power. Venous thromboembolic disease has become a disease of the elderly that may cause important aftermaths. We have developed a long-term prognostic score of mortality after a PE based in our registry.

Methods

All consecutive patients image-diagnosed with pulmonary embolism were included, and the survival and the causes of early and late death were traced.

Results

In 611 patients diagnosed with PE, the median age was 76 interquartile range (IQR) 61-79 years, female 342 (56%), They were traced for a median time of 29 IQR 15-63 months. 196 (32%) patients died during the follow-up at a median time of 13 IQR 2.3-47 months. All-causes 30-days mortality was 5.5% and pulmonary related 30-days mortality was 2%. Simplified PESI classified as low risk 6% of dead patients.

Retrograde logistic regression analysis showed Age (β 0.64 $p=$.0005 OR 1.90 CI95% 1.01-1.07), plasma NT-ProBNP (β 0.47 $p=$.001 OR 1.60 CI95% 1-1.0002), Barthel (β -0.49 $p=$.0001 OR 0.61 CI95% 0.96-0.98) and C-Reactive protein (β 0.29 $p=$ 0.01 OR 1.33 CI95% 1.0008-1.008) all of them associated with risk of death with a logit of survival of 9.7%. A score was derivate with Age greater than 75 years: 1.5 points, NT-ProBNP higher than 850 ng/mL: 1 point, Barthel lower than 85 points: 2 points and CRP higher than 30 mg/L: 1 point. A score equal or higher 2 points showed a probability of death of 91% (OR 9.04, CI 95% 3.66-22.33).

Among the dead patients 6 (3%) did not meet any of the parameters. Area under curve ROC showed a value of 0.757 (CI 95% 0.716-0.799).

Conclusion

ABBC score had a high prediction value of death in patients diagnosed with pulmonary embolism. An external validation test would be necessary to confirm our results.

#303 - Abstract

FACTORS INFLUENCING THE LENGTH OF IN-HOSPITAL STAY IN ACUTE PULMONARY EMBOLISM

Francisco Javier Annicchérico-Sanchez, Jose Luis Alonso-Martinez, Sara Pérez-Ricarte
Hospital Complex of Navarra, Pamplona, Spain

Background

In-hospital stay of acute pulmonary embolism (PE) goes being decreased with trend to home treatment in patients with small burden of thrombi and hemodynamic stability and because the use of direct action anticoagulants. We investigate factors associated with the length of hospital stay.

Methods

In 611 patients diagnosed with acute PE with preserved blood pressure, we search for factors influencing the length of stay.

Results

The median age was 76 interquartile range (IQR) 61-79 years, female 342 (56%), median stay 7 (5-9) days.

Male patients had a stay of 7 (6-10) days and mean age of 68±15 years and female patients 7(5-9) and 75±14 years ($p<$ 0.05 and $<$ 0.001 respectively).

The stay of provoked PE was 7(5-9) days and 7(6-10) days in patients with unprovoked PE ($p<$ 0.05). Patients with cancer diagnosed in the evolution had a stay of 8 (6-13) days while patients without cancer has 7(5-9) days ($p<$ 0.01).

Patients with Barthel index lower than 90 ($p<$ 0.05), sPESI higher 1 ($p<$ 0.01) and diabetes ($p<$ 0.05) had higher stay than patients without.

MANCOVA analysis showed the association of length of stay with the age, sPESI and Barthel index ($p=$ 0.006 for the model and $p<$ 0.01 for every one).

Logistic regression model with independent variable unprovoked PE, showed that gender male (OR 1.40 CI95% 1.33-1.29), cancer diagnosed in evolution (OR 0.76 CI95% 0.25-0.77), sPESI (OR 1.31 CI95% 1.04-1.62), Barthel index (OR 0.34 CI95% 0.93-0.96) an diabetes mellitus ($=$ R 1.24 CI95% 1.02-3.53) were independent factors enlarging the in-hospital stay.

Conclusion

Male gender, sPESI, Barthel index and diabetes all influenced on the length of in-hospital stay of patients with PE and preserved blood pressure.

#307 - Abstract

CHARACTERIZATION AND STUDY OF THROMBOEMBOLIC DISEASE: A RETROSPECTIVE HOSPITAL-BASED STUDY

Marta Rafael Marques, Susana Marques Sousa, Dolores Vazquez, Vera Seara, Sónia Fernandes, Maria Luz Dobao

Hospital Center of Póvoa de Varzim / Vila do Conde, Póvoa De Varzim, Portugal

Background

Pathogenesis of thrombosis is multifactorial and usually a risk factor can be identified in over 80% of patients.

Our objective is to analyse the main risk factors for venous and arterial thrombosis and the mechanisms by which they mediate the disease.

Methods

A descriptive and retrospective cohort study of patients with thrombotic events followed at a first level hospital center, from January 2016 to April 2019. Age, gender, diagnosis, risk factors, hemorrhagic and thrombotic events and recurrence score (DASH score) were analysed.

Results

86 patients were included. The median age was 56 (14.92) years and 72.1% were females. The frequency of venous thromboembolism (VTE) was 88.4% and 11.6% for arterial thrombosis (AT). The primary clinical events were: 42 deep venous thromboses (DVT), 12 pulmonary embolisms (PE), 9 DVT and PE, 13 VTE in uncommon localizations and 10 AT. 61 clinical events (70.9%) were considered provoked. The main risk factors for VTE were oral contraceptives or hormone therapy (n=19), surgery (n=8) and immobilization (n=7). Chronic venous insufficiency (n=31) and malignancy (n=9) were also particularly relevant as potential risk factors. The most frequent risk factors for cardiovascular disease were hypertension (n=26) and dyslipidemia (n=26). In 15 patients thrombophilia was detected. Antiphospholipid syndrome was the most common cause of acquired thrombophilia (20%) and, in hereditary thrombophilias, was Leiden factor V mutation (40%). Anticoagulation therapies used were direct oral anticoagulants (n=42), vitamin K antagonists (n=41) and low molecular weight heparin (n=3). Median anticoagulant treatment was 6 (1,12) months. Long-term anticoagulation was considered in 51% of patients. 20% had DASH score > 1 at the end of anticoagulation. The recurrence of thrombosis was 6.9% (mean follow-up of 24.6 months). Haemorrhagic events occurred in 2.3% (only one major bleeding).

Conclusion

As described in the literature, the majority of the thrombotic events were provoked. The correct identification of these risk factors is essential, in order to assess the individual risk of thrombosis and promote more targeted prophylactic and therapeutic options. The use of recurrence scores seems to be a

useful tool at the time of the therapeutic decision, but prospective validation studies are still required. The close follow-up of these patients, as well as the control of the risk factors, could reduce the complications associated with antithrombotic therapy.

#308 - Abstract

IMPEDANCE CARDIOGRAPHY IN THE EVALUATION OF PATIENTS WITH ARTERIAL HYPERTENSION

Helena Martins Da Fonseca¹, Rodrigo Nazário Leão², Pedro Marques Da Silva²

¹ Centro Hospitalar e Universitário Lisboa Central, EPE, Lisboa, Portugal

² Centro Hospitalar e Universitário Lisboa Central, EPE - Núcleo de Investigação Arterial (NIA), Lisboa, Portugal

Background

Arterial hypertension (AH) is responsible for high morbidity and mortality. Despite increasing awareness blood pressure (BP) control rates are suboptimal and approximately half of the patients do not reach the recommended targets. Defined as an increase in BP, AH is characterized by hemodynamic abnormalities in cardiac output, systemic vascular resistance or arterial compliance. Therefore, the approach to AH can be improved by the knowledge of the hemodynamics underlying the BP increase. One of the objectives of our clinical trial was to evaluate with impedance cardiography (ICG) the hemodynamic profiles of a group of treated hypertensive patients.

Methods

Treated hypertensive patients (grade 2 or resistant AH) without heart failure, arrhythmias, ischemic or valvular disease, were prospectively recruited. ICG was performed accordingly with our centre protocol. Patients were classified as vasoconstrictor (systemic vascular resistance >2500 dyn.s.cm⁻⁵.m²), hyperdynamic (cardiac index >4.2 l/min/m²), hypervolemic (thoracic fluid content in male > 34 /kOhm or >24 /kOhm in women) or balanced profile. Demographic variables and therapeutic were registered.

Results

A total of 157 patients, 56% male, aged 63±18 years, with 4±1 anti-hypertensive drugs were included. The mean hemodynamic values were: systolic blood pressure 135±44mmHg, diastolic blood pressure 93±27mmHg, heart rate 65±28 cycles/min, systemic vascular resistance 2665±1904 dyn.s.cm⁻⁵.m², cardiac index 2.8±2.1 l/min/m², thoracic fluid content 32±11/kOhm. Regarding the hemodynamic profile, 54.5% were classified as vasoconstrictors, 20% hyperdynamic, 32.7% hypervolemic, 23.6% presented a balanced profile, 45.2% presented two or three hemodynamic profiles concomitantly.

Conclusion

In this study we found that 76.4% of our patients had uncontrolled hemodynamic profiles. Hypertensive patients treated accordingly

current guidelines frequently do not achieve the BP goals. ICG is a differential technique in the assessment of cardiovascular and hemodynamic status. The application of therapeutic adjustment algorithms, based on the parameters found by ICG, demonstrated that it is possible to improve the diagnosis and prognosis of patients with hypertension. Therefore, ICG can emerge as an important tool to guide anti-hypertensive therapeutic and improve BP control rate.

#331 - Abstract

THE ROLE OF KIDNEY FUNCTION ON SURVIVAL OF PATIENTS WITH LEFT MAIN CORONARY ARTERY DISEASE TREATED WITH PERCUTANEOUS CORONARY INTERVENTION

Igor Balevski¹, Vigor Arva¹, Sandra Burja², Tadej Petreski³, Nejc Piko³, Vojko Kanic¹, Sebastjan Bevc^{3,2}

¹ Department of Cardiology and angiology, Clinic for internal medicine, University Medical Centre Maribor, Maribor, Slovenia

² Medical faculty, University of Maribor, Maribor, Slovenia

³ Department of Nephrology, Clinic for internal medicine, University Medical Centre Maribor, Maribor, Slovenia

Background

Chronic kidney disease (CKD) is associated with a high burden of stable coronary artery disease and an increased incidence of acute coronary syndromes (ACSs). Left main coronary artery (LMCA) disease is the highest-risk lesion of ischemic heart disease, where revascularization with either percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) is needed. Presence of CKD in these patients may increase the risk of complications and mortality connected to revascularization procedures.

The aim of our study was to determine the role of CKD in the survival of patients after undergoing PCI for ACS in LMCA disease.

Methods

In our retrospective study, 102 patients (73 male (71.6%)) were included. All patients underwent primary PCI of LMCA between January 1st, 2008 and December 31st, 2016. The patients were observed from PCI until their death or by December 20th, 2018 (average time of observation was 3.2 years). Mean age of included patients was 70.3 +/- 9.6 years (minimum 52 years, maximum 86 years). CKD was defined as estimated glomerular filtration rate (eGFR) <= 60 ml/min/1.73 m² by using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation. Comorbidities, such as arterial hypertension (AH), diabetes mellitus (DM), and dyslipidaemia were recorded. Survival rates were analyzed using Kaplan-Meier survival curves. The Cox regression model was used to assess the influence of CKD, AH, DM and dyslipidaemia.

Results

82.8 % of patients had AH, 40.8 % had DM and 75.8 % had dyslipidaemia. 32.4 % of patients had eGFR <= 60 ml/min/1.73 m². Mean survival time of patients in the CKD group (eGFR <= 60 ml/

min/1.73 m²) was 925 days +/- 213 days (95% CI 507.7-1342.1 days) and in the non-CKD group was 1796 +/- 154 days (95% CI 1495-2097 days). 23 (30.3%) CKD and 28 (58.8%) non-CKD patients died. Kaplan-Meier survival analysis showed higher risk of death for CKD patients (log rank test; p < 0.001). In Cox multivariable regression model, CKD remained a predictor of all-cause mortality in our patients (HR was 1.459 (95% CI 1.255-1.825; P=0.009)). The impact of AH (p=0.444), DM (p=0.272) and dyslipidaemia (p=0.070) on patient survival was not statistically significant.

Conclusion

The results indicate an association between CKD and all-cause mortality in patients after undergoing PCI for ACS in LMCA disease.

PREVALENCES AND CONTROL ASYMMETRIES IN HYPERTENSION IN DIABETIC PATIENTS, BETWEEN URBAN AND RURAL POPULATIONS IN THE NORTH OF PORTUGAL (NUTII)

Mario E Macedo¹, Tiago T Gomes², Maria E Santo³, Pedro M Silva⁴, Rui C Ferreira⁵

¹ Programa Nacional para as Doenças CérebroCardiovasculares da DGS, Porto, Portugal

² USF Covelo, ACES Porto Oriental, ARS Norte, Porto, Portugal

³ ULS Matosinhos, Porto, Portugal

⁴ Núcleo de Investigação Arterial, Medicina 4, Hospital Santa Marta, Lisboa, Portugal

⁵ Serviço de Cardiologia, Hospital Santa Marta, Lisboa, Portugal

Background

High blood pressure is the leading risk factor for cardiovascular morbidity and mortality in Portugal. Hypertension and diabetes frequently coexist, leading to additive increases in the risk of life-threatening cardiovascular events. To deliver an effective and high-quality care to patients, it is very important to know their diseases. Likewise, for health systems to be effective, it is necessary to understand the key challenges in efforts to improve populations health and how these challenges can be changed. The objectives of this study are to estimate the prevalence and control of hypertension in diabetics in urban and rural regions of the North of Portugal (NuttII).

Material and Methods

A retrospective analysis was conducted of all patients-based electronic medical records, during 2017/2018 years. The data belong to adult (age >18years old) populations registered in all primary care centers of the North of Portugal, i.e. approximately 3 million people.

Results

The overall prevalence of hypertension was 31.5%. It was higher in female than in male (32.3% vs 29.9% (p<0.0001)), and control

was 48.9% in male and 54.8% in female ($p < 0.001$). Among patients with diabetes the hypertension was present in 77.7% of males and 79.4% of females ($p < 0.0001$).

According to the different NUTs III the prevalence of hypertension was higher in rural areas (82.5%) than in urban (72.2%). The control varies between 30.1% and 54%, with the higher values in rural areas.

Conclusion

This study identified an increased prevalence and poor control of hypertension in diabetic patients in most rural regions of the North of Portugal. This provides an important opportunity to study the underlying factors and design tailored interventions to address this disparity in health outcome.

The objectives of this study are to estimate the prevalence and control of hypertension in urban and rural regions of the North of Portugal.

Material and Methods

A retrospective analysis of all patients-based electronic medical records, during 2017/2018 years, was conducted. The data belong to adult (age > 18 years old) populations registered in all primary care centers of the North of Portugal approximately 3 million people.

Results

The overall prevalence of hypertension was 31.5%. It was higher in female than in male (32.3% versus 29.9%), and control was 48.9% in male and 54.8% in female.

According to the different NUTs III, the prevalence of hypertension varies between 30.5% and 38.6%, with the higher values in rural areas. The control of hypertension have the same tendency with

higher values in urban areas (54%) and the lower values in the rural areas (30.1%).

Conclusion

This study identified an increased prevalence and poor control of hypertension in most rural regions of the North of Portugal. This provides an important opportunity to study the underlying factors and design tailored interventions to address this disparity in health outcome.

HYPONATRIEMIA AND BRUGADA ECG PATTERN: A CASE REPORT

Andrea Pizzuto, Chiara Ferrante, Stefano Pantaleoni, Simona Maria Sipari Merlo, Cesare Poletto, Giuseppe Montrucchio
AOU Città della Salute e della Scienza di Torino - Università degli Studi di Torino, Torino, Italy

Introduction

Brugada syndrome (BrS) is a life-threatening condition due to genetic alteration in cardiac sodium channel with typical ECG pattern. There are two main patterns: type 1 (coved) and type 2 (saddle-back). The term "Brugada phenocopy" (BrP) is used to describe a Brugada-like ECG pattern due to various conditions (e.g. electrolyte disturbances) without genetic mutation.

Case description

We report a case of BrP induced by acute onset of hyponatremia. A 90-years-old male presented with confusion and disorientation. He assumed thiazidic diuretic for arterial hypertension. No personal or familiar history of syncope, arrhythmia or sudden cardiac death; a previous ECG showed absence of typical pattern. Physical examination was unremarkable. Blood tests only showed hyponatremia (114 mmol/L). ECG displayed a new "coved pattern". After fluid replacement and diuretic withdrawal, we observed normalization of sodium value with simultaneous clinical improvement and ECG coved pattern disappearance with signs of "saddle-back pattern".

Discussion

To our knowledge only six other cases described an association between hyponatremia and BrP, and just in four of them hyponatremia was the only electrolyte alteration. Hyponatremia can induce a Brugada-like ECG pattern via reduction of inward sodium current by decreasing its gradient, even in non-mutated channels. Our clinical case can be classified as a type 1B BrP according to classification system proposed by Gottschalk, since provocative testing with a sodium channel blocker has not been performed because the patient declined. Despite it is known that combination of electrolytes imbalance could lead to BrP, hyponatremia alone might be an important cause. We would like to point out that BrP is a benign and reversible condition, so it is important to perform drug challenge to rule out a real BrS.

FLUOROURACIL AND LONG-TERM CARDIOTOXICITY: A CASE DESCRIPTION

Raquel Santos, Mylene Costa, Cristina Rosário
Hospital Pedro Hispano, Matosinhos, Portugal

Introduction

Fluorouracil (5-FU) is a chemotherapeutic drug of the group of fluoropyridines with known cardiac toxicity. The mechanisms of heart damage, that occurs most commonly during the first cycle of administration, include vascular endothelial damage, coronary artery spasm and direct toxicity on the myocardium. Clinically, it manifests acutely as angina, myocardial infarction, arrhythmias, pericarditis and heart failure that lead to withdrawal of 5-FU. However, studies are lacking about its long-term cardiovascular effects.

Case description

We present the case of a 64-year-old woman who was admitted at the hospital with acute heart failure. She had a past history of rectum adenocarcinoma 10 years before treated with surgery and 5-fluorouracil chemotherapy. During the infusion of the drug she developed atrial fibrillation (AF) and the infusion was stopped and not repeated. She was treated with beta-blocker and oral hypocoagulation.

During the current hospitalization, transthoracic echocardiogram revealed impaired right ventricular and normal left ventricular systolic functions, high left ventricular filling pressure and severe pulmonary hypertension (PH).

An extensive study of the heart failure and the PH was performed. No coronary disease was found in heart catheterization that revealed increased pulmonary artery systolic and pulmonary capillary wedge pressures (56 and 30 mmHg, respectively). Cardiac magnetic resonance showed an anterior late intramural enhancement, compatible with nonischemic myocardial fibrosis. The pulmonary ventilation/perfusion scintigraphy suggested a bilateral peripheral pulmonary thromboembolism (PTE). Autoimmune, viral or endocrine causes of heart failure and PH were excluded. There was no evidence of recurrence of rectal adenocarcinoma (after thoraco-abdominopelvic CT, colonoscopy and PET). Myocardial biopsy excluded active inflammation and infiltrative disease.

The final diagnosis was multifactorial PH: pre-capillary PH due to pulmonary thromboembolism and post capillary PH due to heart disease caused by myocardial scar possibly induced by 5-FU. After clinical stabilization, the patient was discharged.

Discussion

In this case, the authors hypothesize that the 5-FU toxicity lead to irreversible heart damage with resulting heart failure with contribution of pulmonary thromboembolic disease and AF. Although rare, long term cardiovascular toxicity of fluoropyridines should always be considered mainly in patients with acute manifestations during or after therapy.

A RARE CAUSE OF INFECTIVE ENDOCARDITIS WITH AN UNFORTUNATE END

Carla Marques Pires, Sandra Correia, Isabel Eira, Renata Carvalho, Cindy Tribuna, Cristina Ângela, Carlos Capela
Hospital de Braga, Braga, Portugal

Introduction

Infective endocarditis (IE) is a disease with a high risk of mortality. Gram-positive bacteria, such as *Staphylococcus* spp. and *Streptococcus* spp. are the main responsables, while gram-negative bacteria are the etiologic agents in a minority of cases, usually included in the HACEK group (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella* and *Kingella*)

Case description

A 71-years-old male with chronic kidney disease and cystectomy with Bricker derivation as relevant antecedents.

Admitted 28 days in the Urology service for renal failure with bilateral hydronephrosis, treated with bilateral percutaneous nephrostomy. During the hospitalization he developed an urinary tract infection with fever and started empirical antibiotic therapy with ceftriaxone. Later, the urine culture presented an *Enterobacter cloacae* (*E. cloacae*), multi-sensitive, with negative blood cultures.

In view of the deterioration and multiorgan dysfunction he was transferred to the Intermediate Care Unit and the antibiotic was escalated to piperacillin-tazobactam.

The persisting fever and the detection of systolic heart murmur, most evident at cardiac apex, led to the performing of transthoracic and transesophageal echocardiography which revealed a 18x14mm mass on the anterior leaflet of the mitral valve. Three blood cultures were collected, and all revealed an Extended-Spectrum B-lactamase producing *E. cloacae*.

Thus, for native valve IE the patient started gentamicin and meropenem adjusted to renal function. In the first 14 days the patient improved, however a second worsening characterized by fever, generalised congestion and significant anemia occurred. Follow-up echocardiography revealed a 27x12 mm mass on the anterior leaflet and severe mitral regurgitation and new set of blood culture were negative.

For this reason, the patient was transferred to Cardiac Surgery Service for mitral valve replacement by biologic prosthesis. Two days after surgery he developed an acute right inferior limb ischemia caused by septic emboli from mitral valve endocarditis. He was treated with thromboembolectomy. However he died the following day.

Discussion

E. cloacae is a gram-negative bacteria non-HACEK and a rare and extremely severe cause of IE. Nowadays, there are few number of cases reported in the literature and best treatment strategy is not consensual. In this particular case, although target antibiotic therapy and surgery were tried the outcome was negative. Thus, additional studies are necessary to improve our approach.

#361 - Abstract

HEMODYNAMIC EVALUATION OF TREATED HYPERTENSIVE PATIENTS WITH IMPEDANCE CARDIOGRAPHY: RESULTS OF IMPEDDANS STUDY

Rodrigo Nazário Leão¹, Cláudia Janeiro², Helena Fonseca¹, Pedro Marques Silva¹

¹ Núcleo de Investigação Arterial, Hospital Santa Marta, Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

² UF Medicina 2.1, Hospital Santo António dos Capuchos, Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

Background

The prevalence of arterial hypertension (AHT) in Portuguese adult population is higher than 40%. Historically defined by sustained elevation of blood pressure (BP), AHT results from hemodynamic changes characterized by cardiac output, systemic vascular resistance and/or arterial compliance abnormalities, with significant implications for diagnosis, risk stratification and treatment. Impedance cardiography (ICG) is a noninvasive method for hemodynamic profile evaluation. It allows to access risk and optimize therapy. In this study we analyzed the resistant hypertensive patients with controlled blood pressure values in order to evaluate and characterize their hemodynamic profile by ICG.

Methods

Resistant hypertensive patients without heart failure, ischemic heart disease, valvular heart disease or dysrhythmia were prospectively selected. After ICG were classified as: vasoconstrictor (systemic vascular resistance (SVR) > 2500 dyn.s.cm-5.m²), hyperdynamic (cardiac index (CI) > 4.2 l/min/m² and/or heart rate (HR) > 80 cycles/min), hypervolemic (thoracic fluid (TFC) > 341/kOhm) or balanced (hemodynamic parameters below the established limit values). All patients underwent transthoracic echocardiography to exclude major changes. In this sub-analysis of patients from the IMPEDDANS study we included only those who, according to international recommendations, had office and outpatient blood pressure values within the therapeutic goals.

Results

From 157 initial patients, 38 were included, 57.9% male, with 62±10 years old, under 4±1 antihypertensive agents. The mean hemodynamic values were: systolic blood pressure (BP) 123 ± 13, diastolic BP 75±4, HR 67±11, SVR 2726±29, CI 2.7±0.5, TFC 31±5. According to the hemodynamic profile 63.2% appear to be vasoconstrictors, 13.2% hyperdynamic, 28.9% hypervolemic and 23.7% balanced.

Conclusion

These results suggest that, despite polymedicated and with arterial pressure within the recommended values, the majority of patients were not hemodynamically stabilized, confirming that

BP is an hemodynamic variable supported by several processes, tendentially redundant, in which inhibition of one element tends to favor the activation of another. ICG is, therefore, an useful method in the evaluation of hypertensive individuals, capable of contributing to adequate therapeutic optimization.

#362 - Abstract

EVALUATION OF CARDIOVASCULAR FUNCTIONAL RESPONSE TO ORTHOSTATISM IN TREATED HYPERTENSIVE PATIENTS: RESULTS OF THE IMPEDDANS STUDY

Rodrigo Nazário Leão¹, Cláudia Janeiro², Helena Fonseca¹, Pedro Marques Silva¹

¹ Núcleo de Investigação Arterial, Hospital de Santa Marta, Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

² UF Medicina 2.4, Hospital de Santo António dos Capuchos, Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

Background

Arterial Hypertension (AHT) is one of the main causes of morbidity and mortality in the world. Generally defined as an increase in blood pressure (BP), it is characterized by hemodynamic changes that have implications for diagnosis, risk stratification and therapy. In this study we intend to characterize the hemodynamic response to orthostatism in a group of treated hypertensive patients using impedance cardiography (ICG).

Methods

Resistant hypertensive patients without heart failure, ischemic heart disease, valvular heart disease or dysrhythmia were prospectively selected. All patients underwent ICG in the supine position and in orthostatism. After ICG, they were classified into patterns: vasoconstrictor (systemic vascular resistance (SVR) > 2500 dyn.s.cm-5.m²), hyperdynamic (cardiac index (CI) > 4.2 l / min / m² and / or heart rate HR > 80 cycles / min), hypervolemic (thoracic fluid (CFT) > 34 l / kOhm) or balanced (hemodynamic parameters below the established limit values). All patients underwent transthoracic echocardiography to exclude major morphologic changes.

Results

We included 157 patients, 56.1% males, age 63 ± 10 years, medicated with 4±1 antihypertensives. In ICG, 56.1% were vasoconstrictors, 12.1% hyperdynamic, 33.1% hypervolemic and 23.6% had a balanced hemodynamic profile. In the supine position the patients had systolic blood pressure 135 ± 19 mmHg, diastolic blood pressure 78±10 mmHg, HR 65±11 cycles/min, indexed ejection volume 44±10 ml/m², pre-ejection period 94±18 ms, ejection time 329±18 ms, systolic time ratio 0.29±0.07, RVSI 2655±617 dyn.s.cm-5.m², cardiac index 2.8±0.5 l/min / m² and CFT 31 ± 5 l / kOhm. In the orthostatic position some of these values were significantly higher: diastolic blood pressure 81±13 (p < 0.001), HR 71±13 (p < 0.001), pre-ejection period 116±25 (p

<0.001), systolic time ratio 0.39 ± 0.10 ($p < 0.001$). The indexed ejection volume 40 ± 9 ($p < 0.001$), ejection time 302 ± 47 ($p < 0.001$) and CFT 29 ± 4 ($p < 0.001$) were significantly lower.

Conclusion

Although polymedicated, most patients had an unbalanced hemodynamic profile. The analysis of the impedance waveform with postural modification can be used to clarify the response to orthostatism and to better characterise the hemodynamic phenotype.

INFERIOR VENA CAVA AGENESIS AND DEEP VEIN THROMBOSIS: A RELATIONSHIP TO CONSIDER IN YOUNG PATIENTS

Inês Esteves Cruz¹, Francisco Silva²

¹ Hospital Egas Moniz, Lisbon, Portugal

² CHLO, Lisbon, Portugal

Introduction

Inferior vena cava agenesis (IVCA) is a rare congenital abnormality, with an estimated prevalence of 0.0005–1% in the general population. Embryological dysgenesis seems to be the most commonly proposed origin. Generally is diagnosed after ultrasonographically (US) documented deep vein thrombosis (DVT), abdominal and pelvic computed-tomography (CT) scans or magnetic resonance imaging (MRI). IVCA is found in almost 5% of DVT patients under 30 years old.

Case description

A 20-year-old male, with no relevant personal history, was admitted in ER with back and abdominal pain, with mechanical characteristics and inability to walk, aggravated with Valsalva maneuvers. There was progressive immobilization during hospitalization and subsequent onset of pain in the lower limbs. US was performed with evidence of DVT of both femoral and external iliac veins, and anticoagulation with low molecular weight heparin was initiated.

Abdominal and pelvic CT scan presented agenesis of the distal segment of the inferior vena cava, receiving the perivertebral lumbar veins as venous tributaries. The left renal vein drained into the homolateral lumbar perivertebral vein and the right renal vein drained into the portal system by porto-renal anastomoses. Angiography demonstrated L5 lumbar arteries originated in the medial sagittal artery, with the left L5 lumbar artery hypoplastic and its territory irrigated by anastomoses by the left L4 lumbar artery.

Diagnostic of IVCA-associated DVT was assumed. Thrombophilia screening was performed without abnormalities (antithrombin, protein C, protein S, antiphospholipid antibody syndrome, homocysteine, factor V Leiden [G1691A] mutation and prothrombin gene [G20210A] mutation). It was decided to maintain long-term vitamin K antagonist.

By patient's request, although there is no clinical evidence supporting use of direct factor Xa inhibitors in this condition, therapy with rivaroxaban 20mg/day has been instituted, and in 5 years follow-up there is no evidence of thrombotic events' recurrence.

Discussion

IVCA should be suspected if DVT involving the iliac veins is seen in patients 30 years of age or younger. US is not useful for IVCA diagnosis but CT scans or MRI can provide the diagnosis. Patients with both an anomaly and thrombosis may be at higher risk for thrombotic recurrence, so prolonged anticoagulation, perhaps even life-long, is usually prescribed. No follow-up data are available concerning this indication and use of direct factor Xa inhibitors in these cases.

PERICARDIAL EFFUSION, A DIAGNOSIS EASILY MISSED

Carla Marques Pires, Paulo Medeiros, Cátia Oliveira, Isabel Campos, Rui Flores, Fernando Mané, Alberto Salgado, Nuno Antunes, Jorge Marques

Hospital de Braga, Braga, Portugal

Introduction

Pericardial effusion has multiples aetiologies and according to recent studies in developed countries up to 50% are idiopathic while 5 to 15% are associated with immune and inflammatory diseases. The clinical impact depends on the rate of accumulation, the amount of pericardial fluid and the aetiology.

Case description

A 58 years-old male with multiple cardiovascular risk factors and history of myocardial infarction (MI), submitted to medical approach, in 2005 as relevant antecedents.

Admitted on the 31st of March at the Cardiology Service for MI without ST-segment elevation with left main and three vessel coronary artery disease on the coronarography. For this reason, the patient was submitted to a coronary artery bypass surgery on the 9th of April, without early complications. Discharged 7 days after surgery.

Patient returned to the Emergency Department on June 13th due to exertional dyspnoea with progressive worsening, orthopnoea and pleuritic chest pain. At admission the patient exhibited tachycardia, muffled heart sounds, without hypotension or pulsus paradoxus. Analytically there was no elevation of markers of inflammation and myocardial injury. There were no electrocardiogram changes, but the transthoracic echocardiography showed a large pericardial effusion with right cavities compression. For this reason, the patient was submitted to pericardiocentesis allowing the removal of 1500 ml of pericardial fluid, characterized as exudate according to Light criteria. The bacterial and mycobacterial cultures of pericardial fluid were

negative. In addition, a pericardial drain was kept until the 16th of June and extract a total of 2300 mL. Anti-inflammatory non-steroids were also administered as a complement.

On discharge, 19th of June, the patient was asymptomatic, with a thin layer of pericardial effusion in follow-up echocardiography. At 6 month and one-year follow-up the patient remained asymptomatic and without recurrence of pericardial effusion.

Discussion

The term post-cardiac injury syndromes includes the pericardial inflammation after MI, pericardiotomy or traumatic pericarditis. Such syndromes are presumed to have an autoimmune pathogenesis triggered by initial damage to pericardium.

This must be differentiated from post-surgical pericardial effusion, transudative or haemorrhagic and usually self-limited, and should be suspected if pleuritic chest pain with fever or haemodynamic instability, weeks or months, after surgery occurred.

#396 - Abstract

CAN CLASSIC BIOMARKERS BE PROGNOSTICATORS IN HEART FAILURE? DATA FROM THE REFERENCE STUDY

Mário Barbosa¹, Andreia Matos^{2,3}, Manuel Bicho^{2,3}, Luiz Menezes Falcão^{4,3}

¹ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisbon, Portugal

² Genetics Laboratory and Environmental Health Institute-ISAMB, Lisbon, Portugal

³ Lisbon Faculty of Medicine, Lisbon, Portugal

⁴ Department of Internal Medicine, Santa Maria Hospital, Lisbon, Portugal

Background

Although the role of natriuretic peptides and troponins as risk stratification markers is gaining importance, the European Society of Cardiology considers that, still, the amount of evidence is not sufficient to recommend its use as heart failure (HF) prognosticators.

We explored the relationship of aminoterminal B-type natriuretic peptide (NT-proBNP) and highly sensitive troponin T (hsTnT) with short-term prognosis (defined as the period of 90 days post-discharge), namely readmission due to HF and overall death, and long-term overall death.

Methods

NT-proBNP and hsTnT were assessed in patients hospitalized with acute decompensated heart failure in class III or IV of NYHA.

Univariate Cox proportional hazard model was used to evaluate the relationship between variables and outcomes.

The optimal cut-off value for each biomarker to predict the events was defined using the Youden Index.

Results

In total, 65 patients were followed for a median of 13.7 (Q1-Q3

6.7-18.9) months. Mean age was 79.2 (SD 10.8) years and 56.9% were female. The mean LVEF was 50.38 ± 19.07 %.

The hazard of short-term mortality increased 0.5% per increments of 100 ng/L of admission NT-proBNP (HR: 1.005, 95% CI: 1.002-1.009, P-value=0.002) and with a cut-off value of 21336 ng/L the risk was 10.5 times greater (HR: 10.524, 95% CI: 3.013-36.757, P-value<0.001).

The hazard for long-term mortality increased 0.3% per increments of 100 ng/L of admission NT-proBNP (HR: 1.003, 95% CI: 1.001-1.006, P-value=0.013) and the risk increased close to 5 times with determinations ≥21336 ng/L (HR: 4.791, 95% CI: 1.885-12.178, P-value<0.001).

Long-term mortality risk increased 0.6% per increments of 100 ng/L of discharge NT-proBNP (HR: 1.006, 95% CI: 1.001-1.011, P-value=0.028).

Long-term mortality risk increased 7.7% per increments of 10 ng/L of hsTnT (HR: 1.077, 95% CI: 1.007-1.151, P-value=0.030).

For values of hsTnT ≥52 ng/L and NT-proBNP ≥21336 ng/L the risk of early readmission increased 8.6 times (HR: 8.607, 95% CI: 1.413-52.427, P-value=0.020).

As for long-term mortality, values of hsTnT≥52 ng/L aggravated the hazard close to 5 times (HR: 4.942, 95% CI: 1.044-23.388, P value=0.044), which heightened to almost 6 times if NT-proBNP at admission ≥21336 ng/L was considered (HR: 5.827, 95% CI: 1.168-29.075, P value=0.032).

Conclusion

Elevated NT-proBNP and hsTnT determinations correlated with short and long-term outcomes. Moreover, their combined use provided complementary prognostic data and superior risk stratification.

#399 - Abstract

COMPRESSION LEG BANDAGING IS BENEFICIAL FOR PRIMARY PREVENTION OF POSTURAL HYPOTENSION AMONG ELDERLY PATIENTS IN AN INTERNAL MEDICINE WARD

Oleg Gorelik¹, Benny Papismadov^{1,2}, Irma Tzur¹, Shimon Izhakian¹, Dana Barchel¹, Muhareb Swarka¹, Hanni Phatel¹, Ilana Livshitz-Riven²

¹ Department of Internal Medicine, Zerifin, Israel

² Department of Nursing, The Leon and Mathilde Recanati School for Community Health Professions (affiliated to Faculty of Health Sciences, Ben-Gurion University of the Negev), Beer-Sheba, Israel

Background

Postural hypotension (PH) is a very common and often symptomatic disorder among elderly hospitalized patients. Little is known about measures for prevention of previously unknown PH in this population. We aimed to evaluate the effectiveness of lower limb high compression bandaging in preventing seated PH during the initial phase of ambulation, among elderly internal medicine inpatients.

Methods

Included were 200 patients hospitalized in internal medicine wards for various acute conditions, aged ≥ 70 years, bedridden for ≥ 12 hours and without a history of PH. Blood pressure, heart rate, dizziness and palpitations were registered before and at 1, 3 and 5 minutes following the first seating. In the intervention group (n=100), high compression extensible bandages were applied along both legs prior to seating. A comparison group (n=100) comprised unbandaged patients who were matched to participants from the bandaged group, by age, sex and bed rest duration. The primary outcome was the development of seated PH (composite of classic and delayed PH), defined according to the current guidelines.

Results

The rate of seated PH was significantly lower in the bandaged than the unbandaged group (27% vs. 51%, $p < 0.001$, relative risk reduction 47%, and the number of patients needed to treat 4.2). On multivariate analysis, not wearing leg bandaging was one of the variables most significantly associated with eventual occurrence of PH ($p = 0.002$, odds ratio 2.65 and 95% confidence interval 1.42–4.97).

Conclusion

During ambulation of elderly inpatients, high compression leg bandaging is beneficial to prevent seated PH.

#400 - Abstract

INSIGHTS FROM THE PREDICTORS OF EARLY READMISSION IN CHRONIC HEART FAILURE (REFERENCE) STUDY

Mário Barbosa¹, Andreia Matos^{2,3}, Manuel Bicho^{2,3}, Luiz Menezes Falcão^{4,3}

¹ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisbon, Portugal

² Genetics Laboratory and Environmental Health Institute-ISAMB, Lisbon, Portugal

³ Lisbon Faculty of Medicine, Lisbon, Portugal

⁴ Department of Internal Medicine, Santa Maria Hospital, Lisbon, Portugal

Background

Albeit we have assisted to a consistent decline in the rate of heart failure hospitalizations, surprisingly, short-term readmission and mortality persist high, irrespective of clinical innovations and guideline directed management, representing a tremendous health care burden. The main purpose of this study was to characterize at risk patients for early (defined as the period of 90 days post-discharge) readmission due to heart failure and overall death.

Methods

Adult patients admitted, to an Internal Medicine ward, with acute decompensated heart failure in class III or IV of NYHA were assessed.

Subgroup analysis was performed according to the left ventricular

ejection fraction (LVEF) in light of the current European Society of Cardiology guidelines.

Univariate Cox proportional hazard model was used to evaluate the relationship between variables and outcomes.

Results

In total, 65 patients were followed for a median of 13.7 (Q1-Q3 6.7-18.9) months. Mean age was 79.2 (SD 10.8) years and 56.9% were female. The mean LVEF was $50.38 \pm 19.07\%$.

The 90-day post-discharge readmission rate was 33.8% and the 30-day post-discharge readmission rate was 13.8%. The year readmission percentage was 61.5%.

The 30-day mortality prevalence was 10.8% and the 90-day mortality prevalence was 18.5%. The year mortality was 36.9% and 40% of the patients deceased at the end of the follow-up.

The length of stay (LOS) represented a risk factor for short-term readmission in the general population study (HR: 1.022, 95% CI: 1.009-1.036, P-value < 0.001).

In patients suffering from Heart Failure with Reduced Ejection Fraction (HFrEF) short-term readmission risk, due to the LOS, was slightly superior to that of the general population (HR: 1.029, 95% CI: 1.008-1.050, P-value = 0.006).

The number of hospitalizations was related with short-term readmission in the general population (HR: 1.543, 95% CI: 1.224-1.945, P-value < 0.001) and in the Heart Failure with Mid-Range Ejection Fraction (HFmrEF) subgroup (HR: 2.814, 95% CI: 1.075-7.365, P-value = 0.035).

A trend towards the LOS and short-term mortality, close to reaching statistical significance (HR: 1.016, 95% CI: 0.999-1.032, P value = 0.062), was identified in the general population study.

Conclusion

The high short-term readmission and mortality rates acknowledged are consentaneous with other studies. The LOS and the number of hospitalizations were associated with worse short-term outcome.

STROKE AND ENDOCARDITIS - WHEN THE CULTURES ARE NEGATIVE

Marco Ferreira Fernandes, Maria João Correia, Catarina Araújo Faria, Nuno Ribeiro Ferreira, Teresa Mesquita, Luís Campos Hospital São Francisco Xavier, Lisbon, Portugal

Introduction

Blood culture-negative infective endocarditis (IE), occurring in 2-7% of IE cases, is defined as endocarditis without etiology following inoculation of at least three independent blood samples with negative cultures after five days. The frequency is higher in patients who have already been treated with antibiotics. The most frequent agents are fastidious organisms including zoonotic agents and fungi. Stroke is one of the most frequent embolic complications of this clinical condition.

Case description

We report the case of a 70 years old male with a 4 week history of fever and consumptive symptoms. He was treated with cefuroxime, considering the diagnosis of acute bacterial prostatitis. Admitted at the ER with sudden onset of left motor deficit, facial asymmetry and oculocephalic right deviation lasting 6 hours. The neurologic evaluation showed signs consistent with right medial cerebral artery total occlusion, NIHSS 17. CT-angiography revealed M1 segment occlusion of this artery without indication for thrombolysis or trombectomy. Laboratory findings included a normocytic normochromic anemia, without leucocytosis or neutrophilia but a C-reactive protein of 21 mg/dL. Transthoracic echocardiogram documented an aortic valve vegetation with significant leaflets destruction, prolapse and severe aortic regurgitation, confirmed by transesophageal echocardiography. Empiric antimicrobial therapy with ceftriaxone, gentamicin and vancomycin was initiated. Despite favorable laboratory evolution, the patient developed acute heart failure and cardiogenic shock and was submitted to aortic valve replacement with a biologic prosthesis. The pathologic analysis of the valve confirmed the presence of gram + organisms, although the blood cultures remained negative for 6 weeks.

Discussion

Despite extensive valve destruction, cardiogenic shock evolution and systemic embolization with stroke, suggesting systemic involvement by a pathogenic organism, no organism was identified on the repeated blood cultures. Previous treatment with cefuroxime may have contributed for these negative cultures. We point out the surgical valve replacement importance in cases of endocarditis complicated by severe systemic embolization.

#409 - Abstract

THE COMPLEMENTARY ROLE OF NOVEL CARDIAC FIBROSIS BIOMARKERS IN HEART FAILURE PROGNOSIS- A REPORT FROM THE REFERENCE STUDY

Luiz Menezes Falcão^{1,2}, Mário Barbosa³, Andreia Matos^{4,2}, Manuel Bicho^{4,2}

¹ Department of Internal Medicine, Santa Maria Hospital, Lisbon, Portugal

² Lisbon Faculty of Medicine, Lisbon, Portugal

³ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisbon, Portugal

⁴ Genetics Laboratory and Environmental Health Institute-ISAMB, Lisbon, Portugal, Lisbon, Portugal

Background

The vast data addressing emerging cardiac fibrosis markers as adjunctive to conventional clinical risk factors and natriuretic peptides dosing, led the American College of Cardiology/ American Heart Association to grant Galectin-3 (Gal-3) and Suppression of Tumorigenicity 2 (ST2) evaluation a class II recommendation for heart failure (HF) prognosis, in 2013. Yet, in Europe this

endorsement is not valid.

We studied the association of Gal-3 and ST2 with early (defined as the period of 90 days post-discharge) rehospitalization and overall mortality, and long-term overall mortality in HF patients.

Additionally, aminoterminal B-type natriuretic peptide (NT-proBNP) was considered to test if a multi-marker strategy could yield supplementary information.

Methods

Gal-3, ST2 and NT-proBNP were assessed in patients hospitalized, to an Internal Medicine ward, with acute decompensated HF in class III or IV of NYHA.

Univariate Cox proportional hazard model was used to assess the relationship between variables and outcomes.

Since there are no standardized cut-offs for Gal-3 and ST2, the multiclass Area Under the Curve Receiver-Operator Characteristic (AUCROC) as defined by Hand and Till was used to evaluate the overall performance of each biomarker as a predictor of the outcomes.

Results

In total, 65 patients were followed for a median of 13.7 (Q1-Q3 6.7-18.9) months. Mean age was 79.2 (SD 10.8) years and 56.9% were female. The mean LVEF was 50.38 ± 19.07 %.

Gal-3 correlated with early rehospitalization (HR: 9.886, 95% CI: 2.027-48.214, P-value=0.005), early death (HR: 13.731, 95% CI: 1.650-114.276, P value=0.015) and long-term mortality (HR: 4.492, 95% CI: 1.594-12.656, P-value=0.004).

The combination of elevated NT-proBNP determinations to Gal-3 further increased the risk for the mentioned outcomes (HR: 11.985, 95% CI: 1.962-73.218, P value=0.007), (HR: 18.837, 95% CI: 2.193-161.811, P-value=0.007) and (HR: 78.025, 95% CI: 7.592-801.926, P-value<0.001), respectively.

An association between ST2 and long-term mortality was acknowledged (HR: 4.846, 95% CI: 1.396-16.825, P-value=0.013). The risk augmented if elevated NT-proBNP values were also considered (HR: 5.953, 95% CI: 1.683-21.055, P-value=0.006).

Conclusion

High Gal-3 determinations correlated with early rehospitalization, early mortality and long-term mortality; whereas ST2 predicted long-term mortality.

Combined analysis with elevated NT-proBNP values further increased the outcome risk.

#411 - Abstract

THE PARAMOUNT IMPORTANCE OF RENAL FUNCTION IN HEART FAILURE PROGNOSIS - CONCLUSIONS FROM THE REFERENCE STUDY

Luiz Menezes Falcão^{1,2}, Mário Barbosa³, Andreia Matos^{4,2}, Manuel Bicho^{4,2}

¹ Department of Internal Medicine, Santa Maria Hospital, Lisbon, Portugal

² Lisbon Faculty of Medicine, Lisbon, Portugal

³ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisbon, Portugal

⁴ Genetics Laboratory and Environmental Health Institute-ISAMB, Lisbon, Portugal

Background

In heart failure (HF) patients renal dysfunction represents impaired tissue perfusion and is a predictor of poor outcome.

We investigated the association of customarily used renal function parameters with early (defined as the period of 90 days post-discharge) rehospitalization due to HF and all-cause mortality, and long-term all-cause mortality in HF patients.

Methods

Baseline and admission urea, creatinine and glomerular filtration rate (GFR) and type 1 cardiorenal syndrome (CRS) were evaluated in patients hospitalized with acute decompensated HF in class III or IV of NYHA.

Descriptive analysis was performed using t test or Wilcoxon Rank test.

Categorical variables were compared using chi-squared test or Fisher's Exact test.

Univariate Cox proportional hazard model was used to assess the relationship between variables and outcomes.

Results

In total, 65 patients were followed for a median of 13.7 (Q1-Q3 6.7-18.9) months. Mean age was 79.2 (SD 10.8) years and 56.9% were female. The mean left ventricular ejection fraction was 50.38±19.07%.

Variables associated with an increased risk for early rehospitalization were baseline urea (HR: 1.098, 95% CI: 1.022-1.179, P-value=0.01), admission urea (HR: 1.048, 95% CI: 1.013-1.084, P-value=0.006), baseline creatinine (HR: 1.111, 95% CI: 1.004-1.229, P-value=0.041), admission creatinine (HR: 1.047, 95% CI: 1.005-1.092, P-value=0.027), admission GFR <30 mL/min (HR: 3.535, 95% CI: 1.467-8.518, P-value=0.005).

Increased risk for short-term mortality was associated with baseline urea (HR: 1.145, 95% CI: 1.032-1.270, P-value=0.010), admission urea (HR: 1.076, 95% CI: 1.021-1.135, P-value=0.006), baseline creatinine (HR: 1.157, 95% CI: 1.009-1.328, P-value=0.037), admission creatinine (HR: 1.127, 95% CI: 1.055-1.204, P-value<0.001), admission GFR <30 ml/min (HR: 9.791, 95% CI: 2.855-33.580, P-value<0.001).

Variables associated with an increased risk for long-term

mortality were admission urea (HR: 1.056, 95% CI: 1.019-1.094, P-value=0.003), admission creatinine (HR: 1.104, 95% CI: 1.054-1.156, P-value<0.001), admission GFR <30 ml/min (HR: 3.906, 95% CI: 1.7208.871, P-value=0.001).

According to descriptive analysis short-term mortality risk was related with prior of chronic kidney disease (P-value=0.024). Type 1 CRS was linked to short-term mortality (P-value=0.004) and long-term mortality (P-value=0.011).

Conclusion

Renal dysfunction was a reliable predictor of worse prognosis as several parameters correlated with the proposed end-points.

#412 - Abstract

THE IMPACT OF LOW BLOOD PRESSURE IN HEART FAILURE OUTCOME - RESULTS FROM THE REFERENCE STUDY

Luiz Menezes Falcão^{1,2}, Mário Barbosa³, Andreia Matos^{4,2}, Manuel Bicho^{4,2}

¹ Department of Internal Medicine, Santa Maria Hospital, Lisbon, Portugal

² Lisbon Faculty of Medicine, Lisbon, Portugal

³ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisbon, Portugal

⁴ Genetics Laboratory and Environmental Health Institute-ISAMB, Lisbon, Portugal

Background

It urges to define short-term risk stratification given that in heart failure (HF) patients mortality is highest during the first 90 days post-discharge.

Low blood pressure plays a role in HF outcome as it is indicative of lack of tissue perfusion and more severe disease.

Decreased systolic blood pressure (SBP) and diastolic blood pressure (DBP) values correlate with impaired survival.

We studied the association of SBP <100 mmHg and DBP <60 mmHg at admission with early (defined as the period of 90 days post-discharge) all-cause mortality and long-term all-cause mortality in HF patients.

Methods

At admission SBP <100 mmHg and DBP <60 mmHg were evaluated in patients hospitalized, to an Internal Medicine ward, with acute decompensated HF in class III or IV of NYHA.

Subgroup analysis was performed according to the left ventricular ejection fraction (LVEF) in light of the current European Society of Cardiology guidelines.

Univariate Cox proportional hazard model was used to assess the relationship between variables and outcomes.

Results

In total, 65 patients were followed for a median of 13.7 (Q1-Q3 6.7-18.9) months. Mean age was 79.2 (SD 10.8) years and 56.9% were female. The mean LVEF was 50.38±19.07%.

In general population study, the hazard of short-term mortality for patients with admission SBP <100 mmHg was 5.3 times higher than that for patients with admission SBP \geq 100 mmHg (HR=5.330, 95% CI: 1.407-20.193, P-value=0.014).

As for long-term mortality, comparatively to short-term mortality, for the referred value of admission SBP (i.e. <100 mmHg) the risk declined to 3.6 times (HR: 3.629, 95% CI: 1.239-10.631, P-value=0.019).

Subgroup discrimination evidenced that long-term mortality hazard rose up to 6.3 times in the Heart Failure with Reduced Ejection Fraction (HFrEF) subgroup (HR: 6.303, 95% CI: 1.224-32.452, P-value=0.028).

The univariate Cox proportional hazard model estimated an increased risk of 11.1 times for short-term mortality in the HFrEF patients with admission DBP <60 mmHg (HR: 11.116, 95% CI: 1.000-123.564, P-value=0.05).

During follow-up the hazard declined to 8.5 times in the mentioned subgroup (HR: 8.462, 95% CI: 1.662-43.096, P-value=0.010).

Conclusion

The patients with admission SBP <100 mmHg or DBP <60 mmHg evolved with substantial increased risk of short and long-term mortality.

Interestingly, the hazard declined along follow-up which consubstantiates the assumption that the first 90 days post-discharge are critical in HF management.

#425 - Abstract

DESCRIPTIVE STUDY ABOUT THE PREVALENCE, TREATMENT AND CONTROL OF ARTERIAL HYPERTENSION IN THE PATIENTS OF INTERNAL MEDICINE.

Francisco Da Mata Alves, Isabel Arvanas Serrano, Beatriz Guerrero Sanchez, Laura Rueda Carrasco, Aurelia Elena Fuentes Caraballo, Julia Gonzalez Granados, Raquel Rostro Galvez, Rafael Aragon Lara

Hospital Universitario Badajoz, Badajoz, Spain

Background

Primary Objective: to study the antihypertension treatments used in internal medicine patients and their results.

Secondary Objectives: 1) To understand the prevalence of this cardiovascular risk factor in internal medicine patients. 2) To understand if the actual guidelines are used in the clinical practice. 3) To confirm if the treatments are adjusted in the cases in which the control is not maximized.

Material and Methods

Observational and descriptive study in which we included 120 patients discharged from the Internal Medicine service of our Hospital during the first 10 days of May of 2017, from which we excluded the ones discharged because of voluntary discharge or death. To select the patients we used electronic clinical histories

from our National Health Care Data Base (JARA®) and for the statistic analysis we used SPSS® (v15.0.1 de 2006).

Results

We included 120 patients, of which 73 has a diagnosis of arterial hypertension (HT), 42 women and 31 men, (58% and 42%), between the ages of 48 and 97 years old (average 78 years old). 5% of our patients only had dietary measures, 22% with only one antihypertension drug, 43% with an association of two drugs and 30% with three or more drugs.

If we consider the actual guidelines that suggest values lower than 140 mmHg systolic tension and 90 mmHg diastolic tension (and in cases of associated diabetes lower than 130 and 80 mmHg respectively) we observed that 75% of our patients were well controlled with the actual treatment. Between the patients with worst results (50% of them with grade 1 hypertension and 50% with grade 2 or superior hypertension) 78% received a therapeutical readjustment at the moment of discharge.

Discussion

HT is one of the main cardiovascular risk factors and one of the most frequently seen diseases in internal medicine services today. We consider that the majority of our patients are well treated and well controlled. Between the non controlled patients, the majority received a readjustment at discharge, using the actual guidelines, individualizing considering the possible comorbidities and other diseases.

Conclusions

With this study we observed that HT is a very frequent cardiovascular risk factor in our patients and that, in general, is well managed by the internist. It will be interesting to do a temporal follow-up in this patients to determine control after readjustment and quantify the incidence of complications from HT per se and treatment caused.

#426 - Abstract

DESCRIPTIVE STUDY ABOUT THE PREVALENCE OF CARDIOVASCULAR DISEASE, CONTROL OF ITS FACTORS AND ESTIMATION OF RISK IN INTERNAL MEDICINE PATIENTS

Francisco Da Mata Alves, Laura Rueda Carrasco, Aurelia Elena Fuentes Caraballo, Isabel Arvanas Serrano, Julia Gonzalez Granados, Beatriz Guerrero Sanchez, Raquel Rostro Galvez, Rafael Aragon Lara

Hospital Universitario de Badajoz, Badajoz, Spain

Background

Primary Objectives: Study the prevalence of the multiple cardiovascular risk factors (CVRF) either the ones changeable and the non changeable and the prevalence of Cardiovascular Disease (CVD) in our patients. Secondary Objectives: 1) To understand how

usable are the estimate risk tables in our patients. 2) To understand the risk of CV events at 10 years. 3) To see the prevalence of comorbidities the rise the prevalence of CVD.

Methods

Observational and descriptive study in which we included patients discharged from the Internal Medicine service of our Hospital during the first 10 days of May of 2017, from which we excluded the ones discharged because of voluntary discharge or death. We used electronic clinical histories from our database (JARA®) and for the statistic analysis with SPSS® (v 2006). To estimate the CVR we used SCORE tables till the age of 65 and the SCORE OP tables in older than 65.

Results

120 patients (55 female) were included, from 19 to 97 years old (average of 74 yo). 73 with the diagnosis of arterial hypertension (71% with good tensional control), 58 with the diagnosis of dyslipidemia (52% with good control), 44 patients diagnosed of diabetes (64% with good diabetic control), 28 patients had been smokers (currently 50% non smokers). If we consider as a non changeable risk factor sex/age, in relation to women older than 55 yo and men older that 45 yo, we can assume that 86% of our patients have this CVRF. 38% presented at least one major CVD event and 8% at least one minor event. 26% had a glomerular filtration estimation (GFS) less than 60 mL/min (factor of high risk of CVD) and 11% had a GFS less than 30 mL/min (factor of very high risk of CVD). About the risk estimate, 64% had a probability of >10% of having a letal event of CVD in 10 years and only 14% had a probability lower than 5% in 10 years. About the prevalence of comorbidities that raise the CVD risk, 77% of our patients had at least one.

Conclusion

We conclude that majority of our patient have, at least, one CVRF that raise the risk of CVD and that at a higher age there is a higher CVRF and prevalence of CVD events, as expectable. We recognize the good control of the changeable CVRF. Probably because of internal medicine patient profile, the average age and the pluripathology that it include, the results using the risk estimation tables were expectable. It will be interesting to do a follow-up to see the incidence of CVD, evolution of control of CVRF and the applicability of CVD stimation using SCORE tables.

#428 - Abstract

DESCRIPTIVE STUDY ABOUT THE PREVALENCE, TREATMENT AND CONTROL OF DIABETES MELLITUS IN THE PATIENTS OF INTERNAL MEDICINE

Francisco Da Mata Alves, Laura Rueda Carrasco, Julia Gonzalez Granados, Isabel Arvanas Serrano, Beatriz Guerrero Sanchez, Aurelia Elena Fuentes Caraballo, Rafael Aragon Lara, Raquel Rostro Galvez

Hospital Universitario Badajoz, Badajoz, Spain

Background

Primary Objectives – To study the antidiabetic treatments used in the internal medicine patients and the results obtained.

Secondary Objectives: 1) To understand the prevalence of this cardiovascular risk factor in internal medicina patients. 2) To understand if the actual guidelines are used in the clinical practice. 3) To confirm if the treatments are adjusted in those cases in which the control is not maximized.

Methods

Observational and descriptive study including 120 patients discharged from the Internal Medicine service of our Hospital during the first 10 days of May of 2017, from which we excluded the ones discharged because of voluntary discharge or death. To select the patients, we used electronic clinical histories from our National Health Care Data Base (JARA®) and for the statistic analysis we used SPSS® (v15.0.1 de 2006).

Results

We included 120 patients, 50 of which had the previous diagnosis of diabetes mellitus, 28 women and 22 men, between 68 and 90 years old (average 80 years old). 10% were treated only with dietary measures, 19% only with metfomine, 39% with an association of metformine and another oral antidiabetic, 23% oral antidiabetic associated with insuline and 9% only with insuline. The average glicosilated hemoglobine (HbA1c) was from 6.89%. Considering the actual guidelines that suggest levels of HbA1c under 7% we can assume that 68% of our patients are well controlled. Between the patients not controlled 73% are older than 75 years old and 83% received a readjustment in therapy at discharge.

Conclusion

DM is one of the main cardiovascular risk factor and one of the most frequent diseases seen in internal medicine services today. We consider that the majority of our patients are well treated and well controlled (68%) according to the actual guidelines. On the other hand, most of the patients not controlled are older than 75 yeras old and guidelines tend to be less restrictive in the control of this kind of patients (because of the high level of comorbidities and complications): approximately 80% of these patients have the HbA1c less than 8%. Between the other non controlled patients, the majority received a readjustment at discharge, using the actual guidelines and individualized considering the possible comorbidities and other diseases.

It will be interesting to do a temporal follow-up in these patients to determine control after readjustment and quantify the incidence of complications from HT per se and treatment caused.

SEVERE HYPOKALEMIA MIMICS MYOCARDIAL INFARCTION

Yaser Hussein Alwali, Wasim Saeed Derma
Alsadaka Teaching Hospital, Aden, Yemen

Introduction

A severe body potassium deficit may produce remarkable changes in the ECG. These changes can result in incidental findings on the 12 lead ECG or precipitate potentially life threatening arrhythmias. Although usually readily recognized, at times these abnormalities may be confused with myocardial infarction. The objective was to report a case of severe hypokalemia mimicking myocardial infarction.

Case description

A 45 year old diabetic woman was referred from Cholera center to Medical ICU in Alsadaka hospital presented with progressive weakness and shortness of breath. The ECG showed a ST segment depression in lead I, II, aVL, aVF, V3. The initial diagnosis was flaccid V6, quadriparesis for evaluation and non ST elevation myocardial infarction. Cardiac enzymes were within normal limits and echocardiography was not done at that time. A more detailed history revealed that the patient had an episode of acute gastroenteritis with diarrhea and vomiting due to cholera. Serum chemistries were notable for a potassium concentration of <1 mmol/L. With aggressive electrolyte correction, the ECG changes reverted as potassium levels became near normal range.

Discussion

Hypokalemia induced STsegment depression may simulate myocardial infarction. The differential diagnosis might be difficult, especially when ST changes occur in the patients with risk factors.

#444 - Abstract

LENGTH OF STAY AND ACUTE HEART FAILURE

Sandra Díaz De Castellví¹, Francesc Formiga¹, Rafael Moreno-Gonzalez¹, David Chivite¹, Michelle Friscia², Xavier Corbella¹

¹ Bellvitge University Hospital, Barcelona, Spain

² Hospital Esperit Sant, Barcelona, Spain

Background

Heart failure is a major public health concern. It commonly affects older population and has a high morbimortality rate. Our purpose is to evaluate in elderly patients experiencing a first admission for acute heart failure (HF) the importance of HF hospitalization length of stay (LOS) as a predictor of a negative event, either hospital HF unplanned readmissions or all-cause mortality within 30 days.

Methods

We reviewed the medical records of 846 consecutive patients >74

years of age admitted within a three-year period because of a first episode of AHF. LOS was categorized in four quartiles as Q1 0-2 days (n=242), Q2 3-4 days (n=244), Q3 5-7 days (n=173) and Q4 ≥8 days (n 187). The association between LOS and readmissions and mortality were evaluated.

Results

Mean age was 83.5 ± 6 years. There were 59.7% women. The mean of LOS, The median (interquartile range) of LOS was 4 (2-7) days. At 30 days after discharge, 43 patients died (5%) and 113 (13.4%) patients showed an unplanned admission by HF. In total, 156 patients (18.4%) showed a negative event within 30 days after discharge either HF readmissions or death. Multivariate analysis confirmed the association between long LOS and higher risk of presenting combined event of global mortality or HF readmissions (hazard ratio 1.197, 95% CI: 1.023–1.401, p=0.025). Lower systolic blood pressure (Hazard Ratio 0.986), and lower estimated glomerular filtration rate values (Hazard Ratio 0.991) were also associated with a negative outcome within 30 days after discharge.

Conclusion

In elderly patients hospitalized for the first acute HF episode, longer LOS, is a predictor of early global mortality or HF readmission within 30-days after discharge.

#451 - Case Report

FROM PRIMARY TO SECONDARY HYPERTENSION

Sara Santos, Sara Gomes, Célia Carmo, Fátima Campante
Centro Hospitalar Barreiro Montijo, Setúbal, Portugal

Introduction

About 90 to 95% of high blood pressure (HBP) cases are classified as essential, because there is not an identified aetiology. The others are classified as secondary hypertension, since they are a secondary manifestation of an underlying disease.

The authors present a case of a woman with the diagnosis of essential hypertension, that due to sudden resistance to antihypertensive drug therapy, the etiologic study for secondary hypertension had to be redone and a primary hyperaldosteronism was diagnosed.

Case description

A 39 year old, female patient with a know history of hypothyroidism and HBP.

Usual medication: levothyroxine 0.25 mcg, amlodipine 5 mg/ losartan 160 mg, amlodipine 10 mg and spironolactone 25 mg.

She was first diagnosed at the age of 36, when she had a blood pressure (BP) of 190/140 mmHg and complaints of intense headache and neck pain.

Secondary etiologies were excluded in an outpatient setting and so essential hypertension was presumed. Her BP values were

stable under the prescribed medication.

The patient got pregnant and had her BP controlled with methyldopa and 6 months after delivery, restarted the previous medication.

On follow up she mentions a BP of 150/100mg, without other complaints.

On her routine blood samples hypokalemia was present.

Therefore the authors decided to repeat the workup for secondary aetiologies.

On blood and urine samples were evident a hyperaldosteronism, high levels of catecholamines and noradrenaline.

Through abdominal computed tomography (CT) scan a mass of well defined limits was seen in the right adrenal gland, with a length of 1.7cm, suggestive of an adenoma.

It was surgically removed and the pathology report confirmed a primary hyperaldosteronism.

After excision the patient no longer needed antihypertensive medication.

Discussion

Conn's syndrome or primary hyperaldosteronism is the most common secondary aetiology for HBP, but it can be a challenge to diagnose.

Initial complaints of headache and neck pain in a young patient with HBP are suggestive but the workup with hormonal dosing is difficult due to physiological variations and also CT scan's low sensitivity for small adenomas.

Probably hormonal changes during pregnancy were responsible for the increase in the adenoma's size and activity, leading to a worsening of symptoms with new onset of hypokalemia and HBP resistant to therapy.

After its excision, the BP was normal, confirming the hypothesis of an unnoticed primary hyperaldosteronism from the beginning.

ARTERIAL CALCIFICATION

Rodrigo Rufino, Catarina Carvalho, Alexandra Albuquerque, Fátima Campante

Centro Hospitalar Barreiro-Montijo, Barreiro, Portugal

Clinical summary

We present a male 81 years old patient, admitted in the hospital with the diagnosis of chronic heart failure and a history of venous and arterial insufficiency.

As he was complaining of pain in his left knee, we performed a x-ray where it was identifiable the calcification of the popliteal artery.

#483 - Abstract

PREVALENCE OF NEOPLASIA IN PATIENTS WITH PULMONARY EMBOLISM IN AN INTERNAL MEDICINE WARD

Tiago Barroso, Joana Caetano, José Delgado Alves

Hospital Professor Doutor Fernando Fonseca, Amadora, Portugal

Background

In patients with unprovoked pulmonary embolism (PE), the incidence of newly diagnosed cancer is approximately 5%. Our goals were to determine the prevalence of occult cancer in the population of patients admitted in our Internal Medicine ward and to find predictors of occult cancer which could help further investigation.

Methods

Retrospective review of all patients admitted in our Internal Medicine ward with a new diagnosis of PE, between 2010-2017. The presence of occult cancer was defined as any cancer diagnosed at the time of the PE up to one year after discharge. Variables analyzed: clinical and demographic characteristics, provoked/unprovoked PE, known risk factors for PE, CT scan performed for occult cancer screening, proposed predictors of occult cancer: constitutive symptoms (anorexia, weight loss) and laboratory features (complete blood count, erythrocyte sedimentation rate, liver tests, prostate specific-antigen).

Results

A total of 169 patients had a diagnosis of PE, median age of 71 years, 64% women. The most common risk factors were arterial hypertension, tobacco use, obesity and immobilization. A total of 6 cancers were diagnosed: breast cancer (n=2), pancreatic adenocarcinoma (n=1), colon adenocarcinoma (n=1), hepatocellular carcinoma (n=1 and metastases of unknown

primary cancer (n=1). The incidence of occult cancer was 3.8%. The incidence in patients with no known cancer and unprovoked PE was 5.6%. Forty-five abdominal and pelvic CT scans were performed. Of those, an occult cancer was diagnosed in 4 patients. The thoracic CT scan performed for the diagnosis of PE found 1 cancer. The presence of anorexia and weight loss was specific (<5% of patients without cancer), but not sensitive (40% of patients with cancer). Prevalence of the remaining variables was similar in both groups. In 4 of the cancers, symptoms and initial lab evaluation were enough to direct the investigation of the cancer. We did not find any variables that performed clearly better than the clinical judgement of the attending medical doctor.

Conclusion

The incidence of cancer in patients with unprovoked PE is low (5.6%), in line with the values published in the literature. No single clinical or laboratory variable can be used to decide whether screening for cancer should be pursued. Both history and clinical examination can help to decide whether or not to search for cancer in this subgroup of patients and are more useful than screening by CT scan.

#493 - Abstract

DETERMINANTS OF ORAL ANTICOAGULANT PRESCRIPTION IN OLDER PATIENTS WITH NON-VALVULAR ATRIAL FIBRILLATION IN A MEMORY CLINIC: IS IT ALL ABOUT FALLS?

David Folino, François Herrmann, Max Scheffler, Gemma Gabriel, Giovanni B. Frisoni, Gabriel Gold, Dina Zekry, Aline Mendes
Geneva University Hospitals - Hôpital des Trois-Chêne, Geneva, Switzerland

Background

Atrial fibrillation (AF) is the most common arrhythmia in the older population and the main indication of oral anticoagulant (OAC) prescription.

Although the prescription of OAC in patients with AF worldwide increased since the introduction of direct oral anticoagulants, patients with dementia have lower odds of receiving OAC.

We aim to investigate which factors are associated with the prescription of OAC in patients with AF in a memory clinic.

Methods

Cross-sectional retrospective analysis of 613 patients from in-patient and out-patient memory clinic from Geneva University Hospitals. All patients underwent standardized brain MRI and neuropsychological assessment with diagnosis confirmed by an expert. Clinical data, including all comorbidities and ongoing treatment were collected retrospectively from patient's medical records at the time of brain MRI. We compared three subgroups of patients: without AF (N=542), with AF under OAC (N=49) and with AF without OAC (N=22).

Results

Our cohort of 613 patients is composed of 63.8% of female patients, the mean age is 77.5 years old and half of them live alone. 52.3% of patients were diagnosed with Alzheimer's, vascular or mixed dementia.

The prevalence of AF was 12% (71/613), of whom 69% (49/71) had an OAC prescription. Patients with AF without OAC in comparison to patients with AF under OAC and patients without AF had increased prevalence of heart failure (45.5% Vs. 32.7% Vs. 10.7%, $p<0.0001$) and recurrent falls (54.5% Vs. 12.2% Vs. 15.3%, $p<0.0001$). AF patients without OAC take more medications (6.23 Vs. 6.1 Vs. 5.1, $p=0.007$), with increased prescription of antiplatelet (72.7% Vs. 1.4% Vs. 22.6%, $p<0.0001$). Interestingly, clinical scores to assess thromboembolic and hemorrhagic risks were not helpful differentiating AF patients with and without OAC - CHADS₂VASC (0-9 points): 3.84 Vs. 4.14, $p=0.151$ and HAS-BLED (0-9 points): 3.06 Vs. 3.09, $p=0.349$. Patients without OAC had increased prevalence of a past history of upper gastrointestinal bleeding (9.1% Vs. 2%, $p=0.012$) and subdural hematoma (13.6% Vs. 2%, $p=0.015$).

Conclusion

Recurrent falls are the most important clinical factor related to OAC use in AF patients, besides expected contraindications related to gastrointestinal bleeding and subdural hematoma. On the other hand, clinical scores were not significantly associated with the decision to prescribe OAC in this population.

#501 - Abstract

COMPARISON OF HEMODYNAMICS AND PROGNOSIS BETWEEN DIFFERENT ETIOLOGY GROUPS WITH PULMONARY HYPERTENSION DUE TO LEFT HEART FAILURE

Ruilin Quan, Jianguo He

Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China

Background

Pulmonary hypertension due to left heart failure of different etiology can have different hemodynamics, prognosis and related prognostic predictors. The aim of this study was to identify the differences in hemodynamics and prognosis between two etiology groups.

Methods

We prospectively enrolled patients with pulmonary hypertension due to left heart failure whose etiology were hypertension or cardiomyopathy. Echocardiography, left and right heart catheterization (RHC) were performed at baseline and follow-up was performed every 6 months \pm 2 weeks. We compared baseline characteristics between two etiology groups and separately

performed survival analyses to evaluate prognosis and identify related prognostic predictors.

Results

In total, a cohort of 67 patients was enrolled and the etiology of 20 patients was hypertension while that of others was cardiomyopathy. At baseline, compared to patients with cardiomyopathy, patients with hypertension had a lower left ventricular end diastolic diameter (LVEDD) (59.55 ± 11.56 vs. 46.30 ± 7.97 mm, $P < 0.001$) and right ventricular diameter (RVD) (25.49 ± 8.33 vs. 23.05 ± 9.20 mm, $P = 0.034$) but higher left ventricular ejection fraction (LVEF) (38.85 ± 15.34 vs. $57.25 \pm 10.34\%$, $P < 0.001$) and mean right atrial pressure (RAP) (11.36 ± 6.08 vs. 15.63 ± 4.79 mmHg, $P = 0.009$). Diastolic pressure gradient (DPG) > 7 mmHg was a significant predictor for mortality in patients whose etiology of heart failure was cardiomyopathy (HR: 6.998, 95% CI: 1.357-36.092, $P = 0.020$) and the significance retained after adjusted for age, sex and LVEF in multivariate Cox model (HR: 8.354, 95% CI: 1.316-53.043, $P = 0.024$). However, DPG was not a significant predictor in patients with hypertension in neither univariate nor multivariate Cox analyses.

Conclusion

The hemodynamics and prognostic predictors in patients with pulmonary hypertension due to left heart failure of different etiology can be different. It is essential to find specific hemodynamic predictors and cut-off values in different etiology groups.

#503 - Abstract

REFRACTORY FINDINGS OF CONGESTION: PREDICTORS OF WORSE OUTCOME IN HEART FAILURE - FACTS FROM THE REFERENCE STUDY

Andreia Matos^{1,2}, Mário Teixeira Barbosa³, Manuel Bicho^{1,2}, Luís Menezes Falcão⁴

¹ Genetics Laboratory and Environmental Health Institute-ISAMB, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

² Instituto de Investigação Científica Bento da Rocha Cabral, Lisboa, Portugal

³ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisboa, Portugal

⁴ Department of Internal Medicine, Santa Maria Hospital, Lisboa, Portugal

Background

Hepatomegaly is a cardinal sign of refractory congestion; while the absence of inferior vena cava (IVC) inspiratory collapse is a well-known echocardiographic parameter of congestion.

These findings are indicative of lack of response to diuretics, a marker of reduced tissue perfusion and poorer outcome.

We investigated the association of hepatomegaly and the absence of IVC inspiratory collapse with early (defined as the period of 90 days post-discharge) all-cause mortality and long-term all-cause mortality in heart failure (HF) patients.

Methods

Hepatomegaly and IVC inspiratory collapse were evaluated in patients hospitalized, to an Internal Medicine ward, with acute decompensated HF in class III or IV of NYHA. Descriptive analysis was performed using t test or Wilcoxon Rank test as applicable. Categorical variables were compared using chi-squared test or Fisher's Exact test as applicable.

Results

In total, 65 patients were followed for a median of 13.7 (Q1-Q3 6.7-18.9) months. Mean age was 79.2 (SD 10.8) years and 56.9% were female. The mean left ventricular ejection fraction was $50.38 \pm 19.07\%$.

Hepatomegaly was observed in only 1.9% of the patients that survived the first 90 days post-discharge versus 25% of those who deceased in that period. The difference between the two groups was statistically significant (P -value=0.018).

As for long-term mortality, hepatomegaly was observed in 15.4% of the patients that died, but unremarkable in the survivors (P -value=0.022).

We acknowledged that the absence of IVC inspiratory collapse was far more frequent in the group that died during the first 90 days post-discharge (33.3%) than in the survivor group (9.4%). The difference between the two groups was significant (P -value=0.015). Regarding long-term mortality, the absence of IVC inspiratory collapse was observed in only 2.6% of the patients who survived compared to 30.8% of those who died during follow-up (P -value < 0.001).

Conclusion

Both hepatomegaly and the absence of IVC inspiratory collapse were predictors of short and long-term all-cause mortality. Swift identification of this high-risk group could contribute to improve HF prognosis.

#505 - Abstract

IS BUNDLE BRANCH BLOCK USEFUL IN HEART FAILURE RISK STRATIFICATION? DISCLOSURES FROM THE REFERENCE STUDY

Andreia Matos^{1,2}, Mário Teixeira Barbosa³, Manuel Bicho^{1,2}, Luís Menezes Falcão⁴

¹ Genetics Laboratory and Environmental Health Institute-ISAMB, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

² Instituto de Investigação Científica Bento da Rocha Cabral, Lisboa, Portugal

³ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisboa, Portugal

⁴ Department of Internal Medicine, Santa Maria Hospital, Lisboa, Portugal

Background

Although it has been reported that QRS prolongation ≥ 120 msec, in heart failure (HF) patients, is associated with increased all-cause mortality and even sudden death, there is conflicting data regarding

its direct impact on mortality. Ventricular dyssynchrony as an effect of anomalous conduction could justify the adverse outcome in the case of left bundle branch block (LBBB); while patients with QRS ≥ 120 msec with right bundle branch block (RBBB) morphology frequently have more severe bi-ventricular dysfunction. We analyzed the association of LBBB and RBBB with early (defined as the period of 90 days post-discharge) rehospitalization and all-cause mortality, and all-cause long-term mortality in HF patients.

Methods

Bundle branch block was assessed in adult patients admitted, to an Internal Medicine ward, with acute decompensated heart failure in class III or IV of NYHA.

Subgroup analysis was performed according to the left ventricular ejection fraction (LVEF) in light of the current European Society of Cardiology guidelines. Descriptive analysis was performed using t test or Wilcoxon Rank test as applicable. Categorical variables were compared using chi-squared test or Fisher's Exact test as applicable. Univariate Cox proportional hazard model was used to evaluate the relationship between variables and outcomes.

Results

In total, 65 patients were followed for a median of 13.7 (Q1-Q3 6.7-18.9) months. Mean age was 79.2 (SD 10.8) years and 56.9% were female. The mean LVEF was $50.38 \pm 19.07\%$. The presence of LBBB determined a short-term mortality risk 3.4 times superior in the general population study (HR: 3.444, 95% CI: 1.051-11.293, P-value=0.041). In the Heart Failure with Reduced Ejection Fraction (HFrEF) subgroup, LBBB increased the risk for long-term mortality 4.1 times (HR: 4.140, 95% CI: 1.021-16.790, P-value=0.047). Descriptive analysis showed that only 4.7% of the non-early readmitted patients presented RBBB versus 13.6% in the early readmitted patients (P-value=0.049).

Conclusion

In our study LBBB was a marker of short-term mortality risk in the overall population study. Regarding long-term survival, LBBB was also a predictor of worse outcome in the HFrEF subgroup. We were, also, able to detect a link between RBBB and early HF readmission in the general population study. Our findings suggest that bundle branch block implicates a worse outcome in HF patients, prompt recognition of this high-risk group could help to offer tailored treatment in order to improve prognosis.

#526 - Abstract

CAN WE REALLY HAVE CONTROL OVER ARTERIAL HYPERTENSION IN TRAIN CREW?

Yulia Venevtseva, Elena Kazidaeva, Aleksandr Melnikov

Medical Institute of Tula State University, Tula, Russia

Background

Some work demands are specific to train drivers: high emotional and mental demands, small amount of autonomy and skill

discretion. Beside this, train drivers are exposed to several cardiovascular disease risk factors that can result in sudden incapacity due to arterial hypertension (AH). Echocardiography (EchoCG) gives the opportunity to evaluate heart reaction to the antihypertensive therapy.

The study aimed to examine dynamics of EchoCG parameters in train drivers with mild controlled AH.

Methods

A 4-year prospective cohort study was conducted in 53 male workers (train drivers and their assistants) aged 25-59 years with mild controlled AH who received annual health check-ups at a Russian railway company.

15 males were included in 25-39 years' group, 23 - in 40-49 and 15 - in 50-55 years' group. EchoCG was made by Medison EKO 7 using standard M, D and Doppler mode.

Results

No differences between groups were found in 2013: end-diastolic left ventricular diameter was 50.1; 50.4 and 49.9 mm; interventricular septum (IVS) thickness - (M \pm m) 9.9 ± 0.9 , 11.0 ± 1.2 and 10.4 ± 1.0 mm, and posterior wall thickness - 9.4 ± 1.2 ; 10.2 ± 1.2 and 10.4 ± 1.0 mm. In 2017 right ventricle (RV) diameter in the young group got bigger (25.8 ± 1.9 vs 27.3 ± 2.0 mm, P<0.05) and IVS became thicker (9.9 ± 0.9 vs 10.7 ± 1.4 mm, P<0.05). In the 40-49 years' group only ejection volume have decreased from 83.5 ± 9.8 to 75.6 ± 9.9 ml (P<0.01). In the older group no dynamics was found.

To elucidate factors influenced on negative changes in Echo parameters all drivers were divided into 2 groups: 20 males with IVS thickening from 10.2 to 11.7 mm and 33 drivers without changes. Work experience in the first group was significantly bigger (17.3 ± 9.9 vs 13.0 ± 7.8 years), and age of work onset was lesser (25.9 vs 30.5 years). Despite the Echo parameters in 2013 did not differ, RV in the first group in 2017 was greater (28.3 ± 2.3 vs 27.0 ± 1.8 mm; p<0.05).

Total cholesterol level in the first group in 2013 was bigger (5.1 ± 0.7 and 4.6 ± 1.0 mmol/L; p<0.05), but was the same in 2017 (5.4 ± 1.0 and 5.0 ± 0.7 mmol/L). In the second group only total cholesterol has increased (p<0.05).

Conclusion

The main factors affecting negative Echo dynamics in train drivers were work experience, time of work onset and total cholesterol level. The most informative Echo parameters were RV diameter and IVS thickness. Thus, AH may be considered as a controlled risk factor using antihypertensive medication in train crew.

#531 - Abstract

BENEFIT OF SYSTEMIC THROMBOLYSIS IN PATIENTS WITH CHRONIC KIDNEY DISEASE AND PULMONARY EMBOLISM

Lukas Hobohm, Ingo Sagoschen, Thomas Münzel, Karsten Keller
Center for Cardiology, Cardiology I, University Medical Center Mainz,
Rheinland-Pfalz - Mainz, Germany

Background

Renal dysfunction is a well-established risk factor for fatal outcome in various cardiovascular diseases. Previous studies demonstrated that impaired renal function was associated with a poor prognosis in patients with acute pulmonary embolism (PE). Little is known about the use and the benefit of systemic thrombolysis in PE patients with chronic kidney disease (CKD).

Methods

Patients diagnosed with PE based on ICD-code I26 in the German nationwide database were stratified for presence of CKD and compared regarding adverse in-hospital outcomes. (source: RDC of the Federal Statistical Office of the federal states, DRG Statistics 2011-2015, own calculations).

Results

Between January 2011 and December 2014, 320,767 patients with acute PE (53.3% females) aged ≥ 18 years were included in this analysis; of those, 15.5% had a CKD. PE patients with acute kidney injury were excluded from the analysis. PE patients with CKD were older (77.0 vs. 67.0 years, $P < 0.001$), more frequently female (57.9% vs. 52.2%, $P < 0.001$), had more often comorbidities such as coronary artery disease (26.3% vs. 10.8%, $P < 0.001$) or heart failure (40.8% vs. 16.6%, $P < 0.001$) and presented more often with RV dysfunction (31.6% vs. 25.2%, $P < 0.001$) and shock (3.5% vs. 2.6%, $P < 0.001$). Overall, 41,226 (12.9%) patients died during in-hospital stay. PE patients with CKD had a higher mortality rate (16.6% vs. 12.2%, $P < 0.001$) compared to those PE patients without renal dysfunction and thus, a higher risk of in-hospital mortality in the univariate logistic regression model (OR, 1.4 [95% CI, 1.4-1.5], $P < 0.001$).

Systemic thrombolysis was less often administered in PE patient with CKD (3.5% vs. 4.1%, $P < 0.001$). In all PE patients with CKD, thrombolysis was accompanied by an reduced risk to die during hospitalization (OR 0.86, 95% CI, 0.82-0.90; $P < 0.001$). The favorable association between thrombolysis and CKD patients differs across CKD stages. Although, the highest mortality rates were found in PE patients with CKD stage 5 (38.6%), PE patients with CKD stage 5 demonstrated no benefit by thrombolytic treatment (in-hospital death: OR, 1.4 [95% CI, 1.2-1.7]; $P < 0.001$).

Conclusion

CKD is associated with an increased in-hospital mortality rate in PE patients. Overall, systemic thrombolysis was associated with a reduced in-hospital mortality rate in PE patients with CKD. However, in PE patients of CKD stage 5 systemic thrombolysis had no beneficial impact on survival.

#533 - Abstract

IN-HOSPITAL OUTCOMES AFTER PERCUTANEOUS LEFT ATRIAL APPENDAGE (LAA) CLOSURE - 5-YEAR EXPERIENCE IN GERMANY

Lukas Hobohm, Karsten Keller
Center for Cardiology, Cardiology I, University Medical Center Mainz,
Rheinland-Pfalz - Mainz, Germany

Background

The safety and efficacy of percutaneous left atrial appendage (LAA) closure has been demonstrated in randomized trials and prospective cohort studies, while results from large samples are missing. Thus, we aimed to evaluate 5-years experiences of in-hospital trends and safety outcomes of LAA closure in the German nationwide inpatient sample.

Methods

We analyzed data on patients' characteristics and in-hospital safety outcomes for all percutaneous LAA closures in Germany performed between 2011 and 2015 (source: RDC of the Federal Statistical Office and the Statistical Offices of the federal states, DRG Statistics 2011-2016, own calculations).

Results

Overall, 15,895 in-patients were included. Annual number of LAA occlusions increased from 1,347 in 2011 to 4,932 in 2015 (β 1.00 [95%CI 0.95 to 1.01; $p < 0.001$) with a non-significant uptrend of in-hospital mortality (0.5% in 2011 to 0.9% in 2015; β 0.01 [95%CI -0.09 to 0.32; $p = 0.271$). Non-survivors were older than survivors (78 [IQR, 73-78] vs. 76 [71-80] years, $P < 0.001$) and showed more frequently important comorbidities including cardiovascular diseases such as heart failure (59.1% vs. 29.8%, $P < 0.001$) and coronary artery disease (58.4% vs. 45.0%, $P = 0.001$), but also cancer (3.2% vs. 1.3%, $P = 0.050$), chronic renal insufficiency (50.6% vs. 27.9%, $P < 0.001$) and COPD (22.1% vs. 10.4%, $P < 0.001$). Important independent predictors of in-hospital mortality were cancer (OR 2.49 [95%CI 1.00-6.12], $p = 0.050$), heart failure (OR 2.42 [95%CI 1.72-3.41], $p < 0.001$), stroke (OR 5.39 [95%CI 2.76-10.53], $p < 0.001$), acute renal failure (OR 13.28 [9.08-19.42], $p < 0.001$), pericardial effusion (OR 5.65 [95%CI 3.76-8.48], $p < 0.001$) and shock (OR 45.11 [95%CI 31.01-65.58], $p < 0.001$).

Conclusion

The use of percutaneous LAA closures increased 3.6-fold from 2011 to 2015 with a non-significant uptrend of in-hospital mortality rate in this real-world setting. Important predictors of in-hospital death were acute renal failure, pericardial effusion and ischemic stroke during hospitalization.

#535 - Case Report

FOR THE FIRST TIME REGISTERED COMPLETE LEFT BUNDLE-BRANCH BLOCK: THE DIFFICULTY OF DIAGNOSTICS ON THE EXAMPLE OF A CLINICAL CASE

Kristina Pereverzeva, Sergey Yakushin, Anastasia Novoselova
Ryazan State Medical University, Ryazan, Russia

Introduction

Identified on an electrocardiogram (ECG), a complete left bundle-branch block (LBBB) in the presence of ischemic symptoms is a basis for suspecting myocardial infarction (MI) in a patient. The tactics of management of such patients is similar to the management of the patients with myocardial infarction with ST-segment elevation.

Purpose

To demonstrate the difficulty of determining the cause of development of LBBB in patients with chest pain.

Case description

Patient C., aged 45, applied on 09/09/18 at 18:30 to the central regional hospital with complaints of general weakness and oppressive, compressive pain behind the sternum, which proceeded at rest, lasting for about 30 minutes. ECG: sinus rhythm, LBBB. On examination: the frequency of respiratory movements is 20 per minute, heart rate (HR) 65 beats/min, blood pressure (BP) is 120/80 mm Hg Art. A alteplase thrombolytic therapy (TLT) was performed according to the scheme. After TLT on an ECG: sinus rhythm, LBBB is not detected. Troponin T 10/09/18 - 0.987 ng/ml. Transferred to the regional clinical hospital for percutaneous coronary intervention. On presentation the state a moderate. SpO₂ 90%. The heart rhythm is correct. HR 60 beats/min, BP: right arm 84/50 mm Hg Art., left arm 120/70 mm Hg Art. On ECG: sinus rhythm, the electrical axis of the heart is rejected to the left. In history: hypertensive disease with max BP 180/100 mm Hg Art during the year; not treated. In blood biochemistry troponins I 0.00 ng/ml → 0.06 ng/ml → 0.00 ng/ml. With coronary angiography: atherosclerotic lesions of the coronary arteries were not detected. On the computed tomography of the chest with a contrast the is of the aneurysm of the ascending aorta with signs of dissection to the level of the arc. An ultrasound examination of the aortic arch vessels on the right in the brachiocephalic stem determines the intimal detachment until its bifurcation, 2 lumens are formed: one, partially thrombosed, has the form of a blind bag, the other takes less than 20%. 13/09/18 at 6:30 - the patient is unconscious, he has bradycardia, turning into asystole, and hypotension; resuscitation is without effect; at 7:00, biological death is attested.

Discussion

ECG changes and increased troponin level typical for MI should not be absolute criteria for excluding other alternative diagnoses. The asymmetry of blood pressure on both arms allowed to suspect dissecting aneurysm in the patient: 84/50 mm Hg Art on the right arm, 120/70 mm - Hg Art. on the left arm.

ACUTE PERICARDITIS AND PARTIAL PERICARDIUM AGENESIS: CASE REPORT AND LITERATURE REVIEW

Carlota Tuñón De Almeida, Jose Antonio Ortiz De Murua López, Sara Muñoz Alonso, Victor Madrid Romero, Victoria Palomar Calvo, Juan José Torres Ramos, Carlos Aldasoro Frías, Montserrat Chimeno Viñas, Luis Miguel Palomar Rodriguez
Complejo Asistencial de Zamora, Zamora, Spain

Introduction

Congenital partial absence of pericardium is an unusual disorder often found incidentally in thoracic surgery, imaging studies or postmortem examinations, because patients are generally asymptomatic. We here present a case of partial pericardium agenesis which was initially diagnosed of acute pericarditis. We aim to report healthcare providers about this rare condition to reduce misdiagnosis and take into account for further differential diagnoses.

Case description

A 46-year-old male with a history of unidentified congenital heart disease was referred to our institution for acute onset of pleuritic chest pain and was diagnosed with acute pericarditis. Symptoms resolved rapidly with non-steroidal anti-inflammatory drugs. Physical and analytical exploration did not show any relevant data. The 12-lead electrocardiogram demonstrated sinus rhythm with right bundle branch block and hourly rotation. The chest X-ray showed a displaced cardiac silhouette on the left, and echocardiogram showed normal right ventricle dilation without other interesting data. In view of the findings, suggestive of possible agenesis of pericardium, a cardiac magnetic resonance imaging (MRI) was performed. Cardiac MRI showed right-sided pericardium but no pericardium present over the lateral wall of the left ventricle and heart apex displaced to the left.

Discussion

We briefly review the literature about this rare congenital anomaly, since approximately 400 cases have been published, and the diagnosis is often necropic. Chest x-ray and echocardiography are important for suspicion, but CT and cardioresonance are essential to assess the location of agenesis and predict probable future complications, such as herniation of cavities through apical myocardial constriction defects. This is so because the deadly cases published presented agenesis in that area. Most defects go unnoticed for years and are not symptomatic. Only a small group of them should be treated by the closure of the defect or pericardiectomy.

MASSIVE PULMONARY THROMBOEMBOLISM- MEDICAL IMAGES

Paulo Ferreira¹, Vanessa Machado¹, Cristina Ramalho¹, Hilda Freitas², Natalia Oliveira², Antonio Cabral²

¹ TrofaSaude Hospital Braga Centro, Braga, Portugal

² TrofaSaude Hospital Braga Sul, Braga, Portugal

Clinical summary

A 28 year-old woman with a history of asthma and anxiety came to our hospital with wheezing and anxiety. She presented with tachycardia (sinus). After bronchodilator and anxiolytic therapy, tachycardia remained without dyspnea. We suspected of pulmonary embolism (EP). It was confirmed, with the presence of exuberant massive EP, bilateral, with dilated right cavities at echocardiogram. Adequate therapy was done, with clinical improvement. Currently asymptomatic. The mother of the patient, a nurse at a Central Hospital of our country, thanked us for the care to the daughter and was convinced that another hospital may have considered asthma and anxiety as the only problems she presented, thanking us for saving her daughter's life. An exhaustive study did not detect etiology, yet.

#605 - Case Report

HEMOLYTIC ANEMIA FOLLOWING MITRAL VALVE REPAIR: A LATE PRESENTATION

Shalini Sri Kumaran

Singapore General Hospital, Singapore, Singapore

Introduction

Mitral valve repair (MVR) has been widely regarded as the optimal surgical procedure to treat mitral regurgitation (MR). Hemolytic anemia is a rare complication following MVR and is often under-recognized. It usually manifests within the first 6 months of the

procedure. We report a case of hemolytic anemia that presented 6 years post MVR.

Case description

A 60-year-old male presented to the hospital with new onset gross hematuria. His medical history was significant for a previous subdural hematoma for which he had undergone a right decompressive craniectomy in 2012 and a MV annuloplasty in 2013 for severe MR. In 2017, he had evidence of mild anterior MV prolapse seen on an echocardiogram. Clinically he appeared lethargic, but his vital signs were stable. He had conjunctival pallor. He was not jaundiced. Cardiovascular examination revealed normal heart sounds and a grade 3/6 pan-systolic murmur over the apex. The rest of his physical examination was normal. Frank hematuria was draining into the urine bag. Investigations revealed anemia with a hemoglobin (Hb) of 7.5 g/dL (baseline 11.5 g/dL) and he received a blood transfusion. His creatinine was normal at 58 umol/L. An extensive urological work-up only revealed candiduria repeatedly. He was started on oral fluconazole, which resolved his hematuria, however, his Hb continued to drop. A hemolytic anemia work-up showed an elevated lactate dehydrogenase (LDH) of 9682 U/L, decreased haptoglobin of < 0.1 G/L, elevated bilirubin of 34 UMOL/L, and a peripheral blood film of fragmented cells in varied sizes and shapes and increased polychromatic cells. The direct antiglobulin test and the Donath Landsteiner test were negative. A bone marrow aspirate and trephine done was also normal. An echocardiogram revealed severe MR with multiple regurgitation jets and very turbulent flow arising from the sub-annular plane which was new. Given the results, he was diagnosed with hemolytic anemia secondary to his now failed MVR. The hematuria was a red herring and he is now awaiting surgery.

Discussion

This report illustrates a case of hemolytic anemia which was initially in doubt as a complication of MVR, not only because of its infrequency, but due to its late presentation and the presence of a red herring. The mechanism of hemolysis has been reported to stem from mechanical trauma due to turbulence of outflow and current literature implies that the optimal treatment remains surgical with re-repair or replacement of the valve as resolution is unlikely on its own.

#624 - Abstract

EMBOLIC RISK STRATIFICATION AND PROGNOSTIC IMPACT OF EARLY SURGERY IN LEFT-SIDED INFECTIVE ENDOCARDITIS

Valentina Scheggi, Bruno Alterini, Lorenzo Roberto Suardi, Filippo Bartalesi, Nicole Ceschia

Azienda Ospedaliero-Universitaria Careggi, Firenze, Italy

Background

In patients with left-sided infective endocarditis and heart failure associated with large vegetations, early surgery has a definite

indication and prevents embolic events. However, optimal timing of surgery for other indications is still unresolved particularly when the presence of large vegetations represents the only indication.

Methods

We retrospectively analyzed 195 consecutive patients admitted to our department between 2013 and 2017 with definite left-sided infective endocarditis according to the modified Duke University criteria. Long-term follow-up was systematically obtained by structured telephone interviews on July 2018.

Available international guidelines were followed to plan diagnostic procedures and treatment strategies. Of the 195 patients, 151 (77%) underwent cardiac surgery, 29 low-risk patients received medical treatment, 10 were not operated due to prohibitive surgical risk and five refused surgery.

We compared surgical to medical therapy, and early to delayed surgery. In addition, we analyzed factors associated with embolic risk. All-cause mortality represented the study end-point.

Results

Overall survival was 78% at 4 years. Patients not operated because of risk or refusal had the worst prognosis, while outcome in high-risk operated patients was comparable to that of low-risk patients treated medically. Early (<2 weeks from diagnosis) surgery was associated with similar survival compared to delayed surgery. Embolic events were detected in 35% of cases, and *Staphylococcus Aureus* etiology was the main risk factor associated with embolism (OR 4, $p < 0.05$). Vegetation size >10 mm was also independently associated with embolic risk ($p = 0.033$) whereas renal failure, age, gender, endocarditis, type of valve, perivalvular extension and degree of valve regurgitation were not.

Conclusion

Compared to low-risk infective endocarditis patients treated medically, those at high-risk showed comparable survival when managed surgically, whereas a conservative approach was associated with an adverse prognosis. *Staphylococcus Aureus* infection and size of vegetations >10 mm were the best independent predictors of systemic embolism. Our data support aggressive surgical management of high-risk IE patients and highlight the importance of etiological characterization in clinical decision-making.

#628 - Abstract

HEART FAILURE: BETWEEN HEART AND PERIPHERAL SKELETAL MUSCULATURE

Paola Paolicelli, Francesca Passerini, Fabiana D'Onofrio, Lucia Donatella Grimaldi, Enrica Settimo, Anna Belfiore, Stefania Pugliese, Piero Portincasa, Vincenzo Ostilio Palmieri

Clinica Medica, Bari, Italy

Background

Congestive heart failure is characterized by dyspnea and reduced

exercise tolerance. The severity of the functional limitation has poor correlation with the degree of left ventricular dysfunction at rest, while peripheral alterations (blood flow, pulmonary, endothelial, neuroendocrine, muscular) can become the limiting factor of the effort.

Aims of the work are: to evaluate the morphological, dynamic and biohumoral alterations of skeletal muscle in patients with chronic heart failure. Secondary objectives are: to evaluate the modifications of these parameters during therapeutic treatment and with some parameters (NYHA class, lower limb edema, degree of stasis liver, skeletal muscle mass).

Methods

The study was conducted on 31 patients (13 males and 19 females, with an average age of 82 ± 8.9) hospitalized for "acute heart failure" and evaluated at the time of hospitalization (T0) and at discharge (T1). The following were performed: clinical evaluation, biohumoral examinations, echocardiography, thoracic, abdominal and muscular ultrasound, elastosonography (2D Share Wave with Logiq E9 XDClear GE ultrasound, stiffness value expressed in m/sec) hepatic, splenic and muscular.

Results

The stiffness of the muscle: at rest it does not differ significantly in the muscle of patients with heart failure compared to that of the control subjects (2.14 ± 0.5 vs 2.1 ± 0.3 , n.s.); in the contracted muscle it increases progressively from patients with decompensation to time 0 (lower limb right 5.03 ± 1.3), to that of patients with decompensation to time 1 (lower limb right 5.8 ± 1.3), to that of normal subject (lower limb right 6.5 ± 0.6 ; ANOVA $p < 0.001$); in the muscle contracted at time T1 is lower in subjects in class NYHA 4 (5.4 ± 1.4) compared to those in class NYHA 3 (6.3 ± 1.1 , $p < 0.04$). Muscle stiffness does not differ with FE values. It correlates negatively with hepatic vein diameter, hepatic stiffness, inferior cava vein dilatation, PAPs (Pearson correlation analysis).

Conclusion

By mean of muscular elastosonography we can hypothesize that the reduction of asthenia (and therefore of the NYHA class) is associated with greater muscular strength and efficacy; in these patients, the involvement of the skeletal muscular apparatus can be a determining factor for the onset of asthenia and reduced tolerance to physical effort. Elastosonography can be an accurate mean of recognizing the presence of deficits in muscle contraction in patients with heart failure.

#630 - Abstract

INCIDENCE AND OUTCOME OF PATIENTS WITH ACUTE PULMONARY EMBOLISM AND PREGNANCY

Lukas Hobohm, Karsten Keller

Center for Thrombosis and Hemostasis (CTH), University Medical Center Mainz (Johannes Gutenberg-University Mainz), Mainz, Germany, Mainz, Germany

Background

Pulmonary embolism (PE) is the leading cause of maternal mortality. Clinical diagnosis of pulmonary thromboembolism in pregnancy remains difficult because of pregnancy associated (physiological) symptoms and signs mimicking PE. We aimed to investigate the incidence, risk factors and outcomes of pregnant women with acute PE.

Methods

Women aged between 18 and 50 years diagnosed with PE based on ICD-code I26 in the German nationwide database were stratified for presence of pregnancy and compared regarding incidence, treatment and outcomes (source: RDC of the Federal Statistical Office and the Statistical Offices of the federal states, DRG Statistics 2005-2016, own calculations).

Results

Between January 2005 and December 2016, 63,246 women with acute PE aged between 18 and 50 years were included in this analysis; of those, 2.9% were pregnant. The in-hospital mortality rate was considerably lower in pregnant women compared to those females without pregnancy (3.5% vs. 7.3%, $P > 0.001$).

Pregnant women with acute PE were younger (31.0 (IQR 27.0/35.0) vs. 41.0 (IQR 32.0/46.0) years, $P < 0.001$), had less often comorbidities such as coronary artery disease (0.4% vs. 1.3%, $P < 0.001$), cancer (0.7% vs. 13.3%, $P < 0.001$), renal insufficiency (0.2% vs. 1.1%, $P < 0.001$), diabetes mellitus (1.1% vs. 5.6%, $P < 0.001$) or heart failure (4.3% vs. 7.0%, $P < 0.001$).

Interestingly, pregnant women with acute PE presented less often with deep venous thrombosis (6.0% vs. 38.5%, $P < 0.001$), RV dysfunction (12.6% vs. 24.4%, $P < 0.001$) and syncope (0.8% vs. 1.5%, $P < 0.001$), but were more often tachycardic (4.2% vs. 3.3%, $P = 0.001$). Notably, presence of shock (3.6% vs. 2.9%, $P = 0.052$) and cardiopulmonary resuscitation (5.5% vs. 5.1%, $P = 0.455$) were not different between pregnant and not-pregnant woman.

Conclusion

The diagnosis and management of PE in pregnant women are aggravated by the physiological changes of pregnancy and the paucity of studies done in pregnant patients. Signs of hemodynamic compromise such as RV dysfunction or syncope were less prevalent in pregnant women with acute PE than in those without pregnancy. Female PE patients aged between 18 and 50 years without pregnancy had a significant higher mortality rate indicating for an outstanding relevance of RV dysfunction,

syncope and important comorbidities such as cancer and heart failure for in-hospital prognosis.

#639 - Abstract

PREVALENCE OF VENTRICULAR ARRHYTHMIAS IN POST-MYOCARDIAL INFARCTION PATIENTS AND THE INFLUENCE OF ELECTROLYTE IMBALANCE

Luis Benjamin Godínez, Gabriel Antonio Rios, Cesar Gerardo López

Instituto Guatemalteco de Seguridad Social, Guatemala, Guatemala

Background

Several studies have shown that the presence of ventricular arrhythmias is an independent risk factor for subsequent mortality in patients recovering from acute myocardial infarction. There is also evidence that the imbalance of magnesium and potassium can influence the development of ventricular arrhythmias. However, this has not been well studied in our population. The aim of the present study was to establish the prevalence of ventricular arrhythmias in post-myocardial infarction patients and the influence of electrolyte imbalance.

Methods

Twenty-four-hour Holter recordings obtained before discharge from the hospital in 147 post-myocardial infarction patients were analyzed for the presence of ventricular arrhythmias. Levels of potassium, magnesium and peak troponin were obtained, and multivariate analyses were calculated.

Results

Ventricular arrhythmias were present in 78.2% of the patients, more than 10 premature ventricular beats per hour were recorded in 4.1% of the patients, and nonsustained ventricular tachycardia was present in 3.4% of the patients. The presence of ventricular arrhythmias was not statistically significant when compared with Holter recordings obtained from patients for reason other than myocardial infarction. In patients older than 75 years old, levels of potassium greater than 5 mmol/l and magnesium lower than 2 mg/dl predicted a 35.2% appearance of multifocal premature ventricular beats and in the same age group levels of potassium lower than 4 mmol/l and levels of magnesium lower than 2 mg/dl predicted a 58% appearance of one premature ventricular beat per hour.

Conclusion

This study shows that approximately 22% of patients recovering from acute myocardial infarction presented with less than one premature ventricular beat per hour in Holter recordings obtained before discharge from the hospital, and only around 5% of patients showed frequent (more than 10 premature ventricular beats per hour) ventricular arrhythmias. The electrolyte imbalance was associated with both more complex ventricular arrhythmias and more frequent premature ventricular beats.

EMBOLIC STROKE AS INITIAL PRESENTATION OF INFECTIVE ENDOCARDITIS - DUKE CRITERIA REVISITED

Mariana Fidalgo, Tiago Gregório

Centro Hospitalar Vila Nova Gaia / Espinho, Vila Nova De Gaia, Portugal

Introduction

Infective endocarditis (IE) refers to infection of one or more heart valves. It can present as an acute and rapidly progressive infection or have an insidious evolution with nonspecific symptoms. Complications of IE are mostly due to septic embolization, which can present in the form of embolic stroke.

Case description

A 20-year-old male patient presented to the ER with sudden onset of imbalance and facial asymmetry after physical exertion. He reported occasional fever and fatigue in the previous months and a history of dental treatments in the preceding year.

At presentation he was febrile (40°C), tachycardic (165 bpm) and normotensive (109/64 mmHg). Neurologic examination showed an aphasia, right homonymous hemianopia, right-sided hemiparesis with facial involvement and right-sided hypoesthesia, with a NIHSS score of 10. Blood tests showed an elevated C-reactive protein (4.4 mg/dL) with normal WBC. A cerebral CT scan with angio CT showed an occlusion of the left middle cerebral artery. The patient underwent thrombolysis and thrombectomy, with complete recanalization and neurologic improvement (NIHSS of 4).

Blood cultures were collected and sent for microbiology, along with the thrombus retrieved from thrombectomy. A transesophageal echocardiogram revealed a vegetation in the mitral valve suggestive of endocarditis with associated severe valve insufficiency. An empiric course of antibiotics was started (vancomycin plus gentamicin).

Microbiology of both blood cultures and thrombus isolated a *Streptococcus anginosus*. A definite diagnosis of IE was established based on modified Duke criteria and antibiotics were switched to ceftriaxone plus gentamicin, according to susceptibility tests. The patient underwent valve replacement surgery and had a complete recovery, with no neurological deficits.

Discussion

The modified Duke criteria are an important diagnostic tool in infective endocarditis. Positive blood cultures are one of the major criteria, but, as this case report demonstrates, it is also possible to isolate the pathogenic organism from septic embolus sent to the brain. Therefore, it is reasonable to send clots retrieved from thrombectomy for microbiological culture if the patient presents with fever or any other sign or symptom suggestive of septic embolization due to infective endocarditis.

HEART RATE VARIABILITY, QT INTERVAL DISPERSION AND TPEAK-TEND INTERVAL IN PATIENTS ON LONG-TERM HORMONE THERAPY FOR ADVANCED PROSTATE CANCER

Andrei Cristian Dan Gheorghe, Gabriela Silvia Gheorghe, Ana Ciobanu, Andreea Simona Hodoroagea, Ioan Tiberiu Nanea

Prof Th Burgele Hospital, Bucharest, Romania

Background

The antiandrogenic hormonal therapy is very useful in the treatment of advanced prostatic cancer but there are not data about their possible cardio-vascular effects.

Aim

To evaluate the effects of direct androgen receptor inhibitor enzalutamide in advanced prostate cancer on the cardiac electrical parameters in patients (pts) in sinus rhythm (SR)

Methods

We evaluated 40 men (pts) with advanced prostate cancer treated by orchiectomy and enzalutamide. We noted clinical history and excluded pts with atrial fibrillation, NYHA III and IV class heart failure (HF), acute myocardial infarction (AMI) within the last 6 months, chronic renal disease stages IV-V. We performed ECG, Holter ECG and evaluated QT interval dispersion (QTd), Tpeak-Tend interval (Tpe) in V5 lead, heart rate variability (HRV) using standard deviation of normal-to-normal interval over 24 hours (SDNN-24h), the square root of the mean squared differences of successive NN intervals (rMMSD) and the rate low frequency/high frequency (LF/HF) at the beginning of the treatment (V1) and 6 months later (V2). We noted in each pts the variations of the QTc, QTd, Tpe, SDNN 24 h, rMS-SD, LF/HF between V1 and V2 and Lown class of ventricular premature beats (VPB) on Holter ECG. Statistical analysis was performed using Epi Info 8: paired t-test for comparing the differences and correlation test.

Results

Pts were 71.8 +/-10 years old. 77.5% pts had arterial hypertension, 52.5 % stable angina, 25 % old myocardial infarction, 22.5% diabetes mellitus, 20 % chronic renal disease grade I-IIIb. They were stable throughout the study. Mean LVEF was 60+/-5%, and did not vary. Between V1 and V2 67.5% pts had a statistical significant increase of the QTd (+ Δ QTd) and 25 % pts a non significant increase of Tpe (ΔTpe). Mean +ΔQTd was 93+/-10 ms, mean +ΔTpe was 11+/-6 ms. 60 % pts had a significant decrease of SDNN-24. 50 % of them having concomitant increase of QTd. There was no change of the rMMSD and LF/HF ratio between V1 and V2. We did not note an increase in the number or severity of VPB between V1 and V2.

Conclusion

67.5% pts with advanced prostate cancer receiving enzalutamide

for 6 months had a significant prolongation of QTd and 60 % a significant decrease of SDNN-24 suggesting an increase of the myocardial electrical instability. During this period there was no change in the number or severity of VPB.

OBSERVATIONAL CASE-SERIES STUDY OF ANTICOAGULANT THERAPY IN NON-VALVULAR ATRIAL FIBRILLATION IN A NON-SELECTED COMMUNITY POPULATION

Andrei Cristian Dan Gheorghe¹, Gabriela Silvia Gheorghe², Cristina Elena Georgescu², Alina Stefania Luiceanu², Andrei Georgian Florescu², Andreea Simona Hodoroagea², Ioan Tiberiu Nanea²

¹ Prof Th Burgehele Hospital, Bucharest, Romania

² Prof Th Burgehele Hospital, Bucuresti, Romania

Background

New oral anticoagulants (NOAC) are increasingly prescribed for stroke prevention in patients with non-valvular atrial fibrillation (NVAF).

Purpose

The objective of this study is to provide a view on anticoagulant therapy in an unselected, real-world, population of patients with NVAF, treated in a community setting.

Methods

Retrospective, observational case-series study of NVAF patients using antithrombotic K antagonists (AVK) (acenocumarol) or NOAC (apixaban, rivaroxaban or dabigatran) for stroke prevention, as recorded in our specialized-care center. The study includes consecutive patients that presented between Jan 1st and Dec 31st 2018, who were assessed for stroke risk using CHA₂DS₂-VASc score and for bleeding risk using HAS BLED score.

Results

A total of 186 patients diagnosed with NVAF (mean age 72.2 ± 9.7 years, 53.8% women, 71% from urban areas) were evaluated in a cardiac ward. Upon admission, 85 patients (45.7%) had received no anticoagulant therapy, 36 (19.4%) were treated with NOAC and 63 (33.9%) with AVK. 24 patients (38.1%) treated with AVK were within therapeutic international normalized ratio range (INR of 2-3). 146 patients (78.5%) were assessed with an increased risk of stroke (CHA₂DS₂-VASc score ≥1 for men and ≥2 for women) of which, 64 (43.8%) had no previous stroke prophylaxis; 20 patients (51.3% of total low-risk patients) were treated with either AVK or NOAC. Following reassessment, 163 patients (87.6%) received prophylaxis with OAC of which, 58.9% with NOAC. While 33 patients (17.7%) with low risk received OAC, 16 patients (10.9%) with medium and high risk remained untreated because of HAS BLED risk ≥ 3. 16 patients (9.8% of total treated) developed a minor hemorrhage when administered AVK (4.6%), NOAC (10.9%).

Conclusion

Our study shows that in the real world nearly one in two patients with NVAF remains untreated and two thirds of those receiving AVK are not therapeutically controlled in the community. Upon reevaluation in a cardiac ward, 90% of moderate and high-risk patients received oral anticoagulant medication, without serious bleeding events. We observed the increased use of NOAC, with more minor bleeding than with AVK.

#668 - Abstract

INFERIOR VENA CAVA FILTER: RETROSPECTIVE ANALYSIS IN A THIRD LEVEL HOSPITAL

Sergio Moragón Ledesma, Laura Abarca Casas, Lucía Ordieres Ortega, Christian Mario Amodeo Oblitas, Irene García Fernández-Bravo, Jorge Del Toro Cervera, Francisco Galeano Valle, Pablo Demelo Rodríguez

HGU Gregorio Marañón, Madrid, Spain

Background

The role of anticoagulation in venous thromboembolism has been broadly documented in the last decades. Preventing the migration and extension of the thrombus is the main therapeutic goal; however, in certain situations anticoagulation is either contraindicated or ineffective. In this scenario, inferior vena cava filters (IVCF) may be useful to prevent the thrombus from reaching pulmonary circulation.

Methods

From a cohort of patients with venous thromboembolism, we selected those who required introduction of IVCF in a third level hospital. Demographic data of the patients and characteristics of each filter were collected. A descriptive retrospective analysis was obtained through our local database.

Results

The sample included 1956 patients with VTE; 57 patients (2.9%) required IVCF placement. Median age of IVCF patients was 68.84 years, with relative predominance for masculine gender. Among cardiovascular risk factors, arterial hypertension was registered in 50.9% of the sample, diabetes mellitus (14%), dyslipidemia (24.6%) and smoking (10%). 5.3% had suffered from ischemic heart disease and cerebrovascular disease. Ongoing cancer was involved in 36.8%, and 1.8% had peripheral arteriopathy. On the previous month, 33.3% had suffered a severe bleeding event, and 19.3% had a recent surgery. Thrombocytopenia (<50.000/mm³) was shown in 3.5%. Furthermore, 54.4% of patients presented pulmonary embolism (with or without deep vein thrombosis), and 45.6% had only deep venous thrombosis. Concerning filter characteristics, the most frequent type was Celect®, nevertheless the data was not collected in 72% of the cases. 50.9% of the implanted filters were permanent, and 49.1% retrievable, of which approximately half were removed. Finally,

complications were registered in 19.3% of patients, being inferior vena cava thrombosis the most frequent one, followed by filter obstruction or inclination.

Conclusion

Although anticoagulation is the mainstay of treatment for venous thromboembolism, inferior vena cava filter might be a useful alternative when anticoagulation is not a choice. However, due to the lack of evidence regarding this procedure and the risk of complications, confronting risks and benefits must always be taken into account. New prospective randomized trials are required to broaden the current knowledge about IVCF.

A RARE CASE OF “NON-RHEUMATIC” GIANT LEFT ATRIUM

Maria João Castro¹, Filipa Cordeiro², Sofia Carvalho², Sara Borges², Pedro Carvalho², Márcia Souto², José João Monteiro², Fernando Gonçalves², José Pedro Guimarães², Miguel Móz², José Ilídio Moreira²

¹ ULSNE, Bragança, Portugal

² CHTMAD, Vila Real, Portugal

Introduction

Giant left atrium (GLA) is a rare condition with a reported incidence of 0.3%, and following mainly rheumatic mitral valve disease. Rheumatic heart disease represents the main cause of giant left atrium, but other etiologies have been reported. GLA has significant hemodynamic effects and requires specific management.

Case description

A sixty-seven-year-old Caucasian woman was admitted for progressive exertional dyspnea. She had a history of mitral valve replacement with a Starr-Edwards prosthetic valve twenty-eight years before due to rheumatic mitral stenosis, atrial fibrillation, pacemaker implantation nine years earlier and chronic kidney disease. The chest X-ray revealed a marked cardiomegaly with a cardiothoracic ratio of 0.95. Computed tomography revealed a giant left atrium (GLA), causing compression of other cardiac chambers and lungs. Transthoracic echocardiography confirmed the striking dilation of left atrium (LA), which measured 78 mm in anteroposterior diameter and 1500 ml in three-dimension volume. There was also severe pulmonary hypertension, pressure overload of the right ventricle and normal systolic function of both ventricles. Transesophageal echocardiography revealed no prosthetic valve dysfunction and marked spontaneous echo contrast in LA, although adequate hipocoagulation. Pulmonary function tests revealed severe restrictive and obstructive pattern.

Discussion

The patient was diagnosed with GLA, a rare condition mainly associated with rheumatic heart disease that can cause embolic

events, sudden cardiac death and symptoms related with compression of the adjacent structures. It was considered that dyspnea was associated with the compression of the lungs and airways and with severe pulmonary hypertension. The management of this entity is not well established, particularly the role of LA reduction in the absence of mitral native valve disease or prosthesis dysfunction. Since it was decided the surgical risk was very high, the patient was discharged with medical therapy.

#681 - Abstract

CORRELATIONS BETWEEN VITAMIN D DEFICIENCY AND VASCULAR RIGIDITY PARAMETERS IN HYPERTENSIVE PATIENTS

Ovidiu Cosmin Iancu¹, Daniela Adina Moteli², Petru Bucuras³, Abhinav Sharma⁴, Florina Buleu⁴, Simona Dragan⁴

¹ Regina Maria Private Clinic, Timisoara, Romania

² Fresenius Nephrocare Clinic, Timisoara, Romania

³ Emergency County Hospital Pius Brinzeu, Timisoara, Romania

⁴ University of Medicine and Pharmacy Victor Babes, Timisoara, Romania

Background

In adults, low levels of vitamin D have been reported to be associated with hypertension. The aim of this study was to evaluate the relationship between vitamin D levels and vascular rigidity parameters in hypertensive patients.

Methods

145 patients were selected from a database of 680 hypertensive subjects addressed to our clinic in 2018. We obtained informed consent for participation in the study. Mean age was 63.6±6, 24.4% female and 75.6% male, under antihypertensive treatment, without confirmed coronary artery disease. Diabetic patients were excluded from the study. Blood pressure was measured according to the 2018 ESC/ESH Guidelines: 20% were stage 1, 43% stage 2 and 37% stage 3. We recorded anthropometric parameters (BMI). Echocardiographic measurements were taken in M-mode, 2D, continuous and colour Doppler using VIVID7 GE ultrasound. Serum levels of 25-OH vitamin D3 (25-OH D3) were determined by ELISA. Aortic pulse wave velocity (PWVAo) was determined using the Arteriograph device. Carotid intima-media thickness (CIMT) was measured using high resolution ultrasound and RRI by duplex Doppler in the intrarenal segmentary arteries. Ankle-brachial index (ABI) was measured using the standard Doppler technique. Albuminuria was measured in urine samples with dipstick. Glomerular filtration rate (GFR) was calculated using CKD-EPI formula. The Pearson correlation test was used for interpretation of results.

Results

Mean values: SBP was 146.6±18.8mmHg, DBP 86±12mmHg, GFR 51.95±10.7ml/min/1.73m², IVS 12.8±2.2mm, LVPW 12.4±1.78mm, EF45.9±6.7%, 25-OH D3 24.57±4.49ng/mL. Pearson linear correlation model: 25-OH D3 significantly correlated

with BMI ($p < 0.003$), albuminuria ($p < 0.031$), CIMT ($p < 0.0001$), ABI ($p < 0.0001$), PWVAo ($p < 0.0001$) and RRI ($p < 0.0001$).

Linear regression model: significant predictors considering 25-OH D3 as dependent variable were GFR ($p < 0.001$), CIMT ($p < 0.004$), ABI ($p < 0.011$) and RRI ($p < 0.0001$).

Association between 25-OH D3 deficit and gender did not establish a significant correlation (Mann-Whitney U Test, $p = 0.428$).

Two by two comparisons between HT stages revealed significant differences between stages 1 and 3 ($p < 0.001$) and 2 and 3 ($p < 0.001$) regarding 25-OH D3 deficit.

Conclusion

The results of this study are suggestive for a potential contribution of 25-OH D3 deficit to vascular rigidity in hypertensive patients. Future studies should clarify the consequences of correcting this deficit on the improvement of vascular rigidity parameters according to the stage of hypertension.

#703 - Abstract

INCIDENCE OF UNKNOWN VENOUS THROMBOEMBOLISM IN PATIENTS ADMITTED IN INTERNAL MEDICINE DEPARTMENT FOR DYSPNOEA AND / OR RESPIRATORY FAILURE

Mattia Bellan¹, Bonometti Ramona¹, Emma Avitabile¹, Silvia Strada¹, Micol Giulia Cittone¹, Elena Boin¹, Eleonora Rizzi¹, Azzurra Re¹, Flavio Bobbio², Mauro Campanini², Margherita Girino³, Giulia Comola¹, Mario Pirisi¹

¹ Department of translational medicine, Università del Piemonte Orientale, Novara, Italy

² Internal Medicine Department, AOU Maggiore della Carità, Novara, Novara, Italy

³ Internal medicine Department, Ospedale Santo Spirito, Casale Monferrato, Italy

Background

The diagnosis of pulmonary embolism (PE) is notoriously underestimated. Compression ultrasound (CUS) is a simple, cheap and safe diagnostic tool, characterized by a sensitivity > 90% and an approximate 95% specificity for symptomatic deep vein thrombosis (DVT).

Methods

In the present study we plan to evaluate, in patients hospitalized in internal division for dyspnoea and/or respiratory failure, with a diagnosis of acceptance other than PE, the additional diagnostic power of CUS. 218 patients were consecutively recruited and underwent to CUS within 72 hours from hospital admission. In case of positive result, a lung CT scan was performed to rule out PE, when not contraindicated.

Results

We recruited 218 patients (109 females; 50.2%); the median

age was 84 [75-88] years. We reported a positive CUS in 24 (11.0%) patients. Out of them 23 patients showed a proximal vein involvement, while 1 patient had solely bilateral paraneoplastic distal thrombosis. The Wells score for PE indicated an unlikely diagnosis (≤ 4) in 18/24 patients (72.0%).

Following the positive result of CUS, 8 patients underwent a CT scan which confirmed PE in 7 subjects (3.2% of the whole population). The Wells score for PE indicated an unlikely diagnosis in 6/7 patients (85.7%).

Conclusion

This study confirms that the prevalence of PE in patients admitted for dyspnea/respiratory failure is largely underestimated and suggests that the current risk scores are probably inadequate when applied in clinical practice.

The routine use of CUS in respiratory failure might significantly contribute in improving the diagnostic accuracy.

#739 - Abstract

HAEMOGLOBIN: ANOTHER FACTOR FOR CONSIDERATION TO SELECT PATIENTS WITH ACUTE PULMONARY EMBOLISM FOR OUTPATIENT TREATMENT?

Diogo Raposo André, Fabiana Gouveia, Rafael Nascimento, Teresa Raposo André, António José Chaves, Maria Luz Brazão
Hospital Central do Funchal, Funchal, Portugal

Background

Acute Pulmonary Embolism (PE) results from occlusion of the pulmonary circulation whose clinical condition depends on the existence of previous cardiopulmonary pathology, the size of the thrombus, the number of embolic episodes and the neurohormonal response to the event. The HESTIA (cH) criteria, developed by Zondag, identify which patients with right ventricular dysfunction have a low risk of developing an adverse event in the outpatient setting, allowing them to perform the treatment safely at home. In this study, similarly to cH, we sought to determine if haemoglobin (Hb) values at admission may be helpful in identifying low-risk patients who are able to comply with outpatient therapy earlier.

Methods

A retrospective study of patients diagnosed with PE at a Central Hospital from January to December 2017. Of the 117 patients with a diagnosis of acute PE, only 68 had a complete blood count at admission and no indication according to cH for early outpatient therapy. The data obtained were treated by IBM SPSS Statistics® Version 25 and the Pearson Chi-Square, Spearman's Rho and Logistic Regression tests were used.

Results

Of the 117 patients, 68 had no criteria cH for outpatient treatment (42 women), with a mean age of 70.35 years (± 15.34). Of these, it was found that the group with lower Hb levels had longer

hospitalizations with an average of 13.95 days (\pm 10.70). The existence of a 30-day mortality / re-hospitalization risk ratio was observed when there was a low Hb value (Pearson Chi-Square test, $p = 0.035$). It was found that in this group of patients there is an inverse relation of Hb values with mortality / re-hospitalization at 30 days ($\rho = -0.276$; $p = 0.023$). Logistic regression complements the above results, noting that higher levels of Hb provide a lower 30-day mortality / re-hospitalization risk (OD 0.699, CI 95% 0.506 to 0.967, $p = 0.030$)

Conclusion

Hb at admission is an analytical data to consider since it may help in increasing the sensitivity and specificity of cH, identifying patients with or without indication for early ambulatory therapy. It was found that patients with reduced levels of Hb on admission had a higher mortality / re-hospitalization risk at 30 days and that high levels of Hb are associated with a lower risk of death or re-hospitalization.

STROKE AND PULMONARY EMBOLISM: WHEN LEFT AND RIGHT ARE NOT APART

João Barbosa Martins, Mariana Formigo, Magda Costa, Sandra Barbosa, Jorge Cotter

Hospital Senhora da Oliveira, Guimarães, Portugal

Introduction

Atrial septal defects are the third most common type of congenital heart disease, however the overall incidence of stroke due to these defects still remains unknown.

Case description

A 73-year-old man presented at the emergency room with dysarthria, labial commissure deviation to the left side, facial right side paresis, strength reduction on the right upper and lower limb, with more than 6 hours of development. The only relevant background he presented were a prostatic neoplasia formerly treated by surgery and radiotherapy, epilepsy secondary to infection and dyslipidemia. His vital signs were significant for blood pressure of 170/87 and his physical examination revealed the previously reported deficits and a normal heart auscultation. Electrocardiogram presented sinus rhythm and head and neck computed tomography (CT) with contrast administration revealed a focal occlusion on the left Sylvian segment, with no possibility of mechanical intervention. Laboratory test were significant for elevated c-reactive protein and thus a chest X-ray was performed, revealing mediastinal congestion. After admittance and at early deficits recovery, the patient complained of 2 months lasting dyspnea and consequently, a thoracic contrast CT was briefly asked. This exam revealed a voluminous thrombus present at the right pulmonary artery and other at the left lower lobe pulmonary artery. A transthoracic echocardiogram, later confirmed by a transesophageal echocardiography revealed an aneurysmatic

movement of the interatrial septum with a patent foramen ovale and spontaneous right-to-left interatrial shunt. Anticoagulation and the remaining etiological study were promptly initiated. At discharge the patient almost totally recovered from the deficits and continued home anticoagulation, while waiting for cardiac atrial septum repairing procedure.

Discussion

In this case atrial septal aneurysmatic movements with a patent foramen ovale seemed to have a significant contribution to the thromboembolic phenomenon.

#761 - Abstract

THE USE OF DIRECT ANTICOAGULANTS AND ANTI-VITAMIN K DRUGS IN SCHEDULED ELECTRICAL CARDIOVERSION: A STUDY OF DAILY CLINICAL PRACTICE

David González Calle, Ana Elvira Laffond

Hospital Universitario de Salamanca, Salamanca, Spain

Background

In the past few years, several randomized trials comparing efficacy and security of direct anticoagulants (DOACs) and of anti-vitamin K (AVK) before scheduled electrical cardioversion in FA have been published. Notwithstanding, the differences found were not statistically significant. Therefore, it is important to record and analyze the results of these treatments in real daily practice.

Methods

Scheduled electrical cardioversions performed under treatment with either DOACs or AVK during a period of 24 months were retrospectively analyzed. Baseline clinical characteristics of both groups of treatment were compared. Results in terms of efficacy (stroke, transient ischemic attack, myocardial infarction or systemic embolism) and security (bleeding) were registered up to two months after electrical cardioversion. Time of anticoagulant therapy prior to electrical cardioversion was also compared.

Results

During the period of study 320 electrical cardioversions were performed, 32% under treatment with acenocoumarol ($n = 104$), 30% with rivaroxaban ($n = 94$), 23% with apixaban ($n = 73$), 8% with dabigatran ($n = 26$) and 5% with edoxaban ($n = 17$). There were statistically significant differences in certain baseline clinical characteristics between the patients treated with DOACs and with AVK, such as age (60.1 years old vs 66.1 years old, $p \leq 0.001$), creatinine serum levels (0.94 vs 1.12 mg/dl, $p = 0.01$), CHA₂DS₂VASc (1.94 vs 2.74 points, $p = 0.001$) and HAS-BLED (2.19 vs 2.61 points, $p < 0.01$). Incidence of thromboembolic events was low in both groups: one event in the group of rivaroxaban and three non-fatal strokes in the group of acenocoumarol. Bleeding episodes were also infrequent in both groups: one major digestive bleeding with rivaroxaban and three major bleedings

with acenocoumarol, including one fatal bleeding ($p = \text{NS}$). Time of anticoagulant therapy prior to electrical cardioversion was significantly lower in the group of DOACs (27.3 days vs 39.9 days, $p = 0.001$). Spontaneous cardioversions were more frequent in the group of DOACs (27 patients, 12.8%) than in the group of AVK (4 patients, 3.8%, $p < 0.01$).

Conclusion

Treatment with DOACs in scheduled electrical cardioversion is an effective and safe alternative to conventional treatment with AVKs, with the advantage that time until electrical cardioversion is reduced. Our results show that AVKs are still routinely used, in spite of cardioversion delay and the worse results shown in clinical trials and clinical registers.

#762 - Abstract

PALPITATIONS: DIAGNOSTIC VALUE OF KARDIA MOBILE DEVICES

Jospeh Kazibwe, Sarah Halmer, Michael Coupe, David Ferguson
Furness General Hospital, Barrow-In-Furness, United Kingdom

Background

Palpitations are amongst the top ten reasons for medical admissions in the NHS (National Health Service). Kardia devices may provide a symptom-rhythm diagnosis for patients with paroxysmal palpitations that are not associated with syncope. We set out to assess the diagnostic value of Kardia mobile devices in this population.

Methods

Data were collected from patients given devices from 27th July 2017 to the 3rd September 2018 at Furness General Hospital. Both univariate and bivariate analyses were done using SPSS. Non-parametric statistical analyses were carried out as the data were not normally distributed. The level of significance was 0.05.

Results

Only two patients could not use the devices due to software incompatibility. There were twice as many females as were males ($N=60$ and $N=30$ respectively). The median age was 47 years (19-77). The median number of days patients had the Kardia device was 57 (6-133). The median number of ECGs sent for analysis was 5 (0-102).

The main diagnoses were; Sinus Tachycardia $n=16$ (18%), Normal Sinus Rhythm $n=33$ (37%), Supra Ventricular tachycardia $n=9$ (10%), Atrial Fibrillation $n=9$ (10%), Atrial Ectopics $n=21$ (23%), Sinus Bradycardia $n=2$ (2%).

Younger patients appeared to stay with the devices for a longer time (Spearman's correlation, P value 0.005). However, there was a correlation between the patient's age and number of ECGs they sent out (P value 0.117). Similarly, there was no correlation between the number of ECGs sent out by the patient and the days they stayed with the device (P value 0.534).

Conclusion

Mobile Kardia devices are a valuable tool in the diagnosis of paroxysmal palpitations without associated syncope.

#765 - Case Report

AORTIC DISSECTION: AN UNUSUAL PRESENTATION

Rosário Eça, João Alves Teixeira, Pedro Duarte Mesquita, Cláudia Janeiro, Raquel Mesquita, Inês Santos

Centro Hospitalar Lisboa Central, Lisbon, Portugal

Introduction

Aortic dissection is relatively uncommon although it is the most common acute aortic condition requiring urgent therapy. It is a serious condition that can have catastrophic consequences if not detected and managed early. The classification of aortic dissection is based on the anatomical location and duration of symptoms. The Stanford system is more widely used and classifies aortic dissections as type A, involving the ascending aorta and its arch, and type B, involving the descending aorta. Aortic dissections can also be classified as acute, when presenting with <2 weeks symptoms or chronic (>2 weeks). The typical presentation of type A dissections include severe acute chest pain, frequently radiating to the upper back (more than 80% of the patients), occasionally accompanied by dyspnoea, syncope or stroke. Although most patients present with an acute onset, rarely aortic dissections can have a painless course and be accompanied by systemic disease symptoms like malaise, fever and weight loss.

Case description

This is a case report of a 48-years-old man, smoker, without history of hypertension, presenting to the emergency department with thoracic pain but had medical release with the diagnosis of anxiety. In 2 months the pain disappeared. However he developed persistent low-grade fever, night sweats, malaise, weight loss. These symptoms were associated with elevated acute phase biomarkers, like ferritin and c-reactive protein. He denied other symptomatology, most importantly pain and respiratory complaints. A CT scan was ordered, after an initial abnormal chest radiography, revealing slight mediastinal adenopathy, a small pericardial effusion and an unexpected type A aorta dissection. Patient underwent surgical intervention with replacement of the resected aortic by a graft with full recovery. Pathological investigation of the aortic specimen demonstrated intense inflammation with neutrophilic infiltrati.

Discussion

Chronic aortic dissection manifested with features of systemic disease in absence of the more typical symptoms has been rarely reported. Such atypical presentation can make the diagnosis of an aortic dissection particularly challenging, especially when no typical signs are present. In these cases, cross sectional imaging is of crucial importance. Differential diagnosis of aortic dissection

associated with a systemic clinical scenario should include, among many causes, isolated ascending aortitis, infectious aortitis in the setting of a known inflammatory disorder as giant cell arteritis.

#777 - Case Report

FROM RENAL FAILURE TO AMYLOIDOSIS THROUGH HEART FAILURE

Andrea Boccatonda, Giulio Cocco, Cosima Schiavone

Università degli studi G.d'Annunzio Chieti, Chieti, Italy

Introduction

Cardiac amyloidosis is a clinical condition that previously went undiagnosed and thought to be uncommon, but, recently, it is increasingly recognized as reason of heart failure. Moreover, advances in cardiovascular imaging techniques and newer modalities of treatment lead to early diagnosis, thereby limiting further amyloid deposition and modifying disease course. In this case report, we discuss a 76 years old male admitted for acute renal failure and cardiogenic shock with subsequent workup confirming a diagnosis of cardiac amyloidosis.

Case description

A 76 years old Caucasian male presented to our Internal Medicine department with diffuse bone pain and sudden onset shortness of breath. His medical history was notable for benign prostatic hypertrophy and recent removal of a colic polyp.

On initial physical examination, he had a blood pressure of 90/60 mmHg with pulse rate of 82 beats per minute (bpm). He had bilateral rales on lung examination and normal heart sounds with no murmurs or gallops on auscultation. His lower extremities were cool to touch with mild pitting edema bilaterally. Electrocardiogram (ECG) showed LBBB and low voltages in the limb leads. Chest radiograph demonstrated bilateral patchy opacities consistent with pulmonary edema.

Given the clinical finding of congestive heart failure, high-dose diuretic therapy was initially attempted. Due to the persistently high levels of urea and creatinine, and the poor response to diuretic therapy, the patient underwent dialysis with resolution of the picture of pulmonary congestion.

Subsequently, patient performed an echocardiogram that showed a dilated left ventricle (LV) with severe left ventricular hypertrophy and reduced LVEF of 30%-35%. Due to the discordance between the degree of LV thickness and QRS voltage on ECG, cardiac amyloidosis was considered as a possible etiology of the cardiomyopathy.

Cardiac magnetic resonance (MR) revealed greater late gadolinium enhancement at the base than at the apex, highlighting a base-to-apex gradient. The patient underwent to biopsy of abdominal fat that demonstrated advanced systemic light-chain amyloidosis.

Discussion

Our case demonstrates how cardiac involvement is fundamental in the pathophysiology of amyloidosis. Furthermore, the

discrepancy between the echographic finding and the ecg allows to place a strong diagnostic suspicion, so as to direct the patient to the biopsy.

#787 - Case Report

RECURRENT DVT AND THROMBOCYTOPENIA IN A YOUNG PATIENT

Ana Alwina Stan

MCA HEALTH CARE, Tirgu-Mures, Romania

Introduction

Deep venous thrombosis (DVT) is a manifestation of venous thromboembolism (VTE). DVT most commonly involves the deep veins of the leg or arm, often resulting in potentially life-threatening emboli to the lungs or debilitating valvular dysfunction and chronic leg swelling. Early recognition and appropriate treatment of DVT and its complications can save many lives. The goals of pharmacotherapy for DVT are to reduce morbidity, prevent post-thrombotic syndrome, and prevent pulmonary embolism.

Case description

We present the case of a 45 year old patient with a history of right hemicolectomy and segmentary resection of the descending colon post abdominal trauma and a vertebro-basilar stroke. He was first admitted in the Internal Medicine Department in Nov 2017 for DVT of the right femoro-popliteal-calf axis (total occlusion), confirmed by ultrasonography. At that time he also presented pancytopenia, which was investigated: bone marrow analysis (hyperplastic red series, macroblastic and erythroblastic cells), upper digestive endoscopy (gastritis and esophagitis), abdominal ultrasound (possible lesion adjacent to the left inferior renal pole). Anticoagulation with LMWH was started and later switched to acenocoumarol. A vitamin B12 deficiency was later established, followed by supplementation and consequent improving of hemoglobin and leukocyte levels. Throughout the year 2018 the patient also complained of fatigue and weight loss (aprox 6 kg), so neoplastic causes were investigated: abdominal and pelvis CT, colonoscopy (no pathological findings). In January 2019 he complained of swelling of the left calf, which was confirmed as DVT of the left popliteal, posterior tibial and fibular veins. Recent blood work still shows thrombocytopenia.

Discussion

Considering the recurrent DVT and history of stroke in this patient, a primary thrombophilia was taken into account, especially since a low platelet count does not seem to protect against VTE (testing is ongoing). If confirmed, appropriate measures will be implemented- indefinite anticoagulation, possibly switching to NOACs.

#801 - Abstract

CARDIAC ARRHYTHMIAS IN PREGNANT WOMEN WITH STRUCTURALLY NORMAL HEART: MANAGING AND PERINATAL OUTCOMESAliya Smagulova¹, Ayan Abdrakhmanov^{1,2}, Bayan Ainabekova¹¹ NpJSC «Astana Medical University», Nur-Sultan, Kazakhstan² JSC National research cardiac surgery center», Nur-Sultan, Kazakhstan**Background**

Normal physiologic changes during pregnancy may trigger arrhythmias. Risk of arrhythmias during pregnancy is relatively higher in patients with structural heart disease or a prior history of arrhythmias. However, data on pregnant women with structurally normal heart is limited.

Purpose

We aimed to evaluate the fate of arrhythmias and perinatal outcomes in pregnant women with structurally normal heart in this study.

Methods

50 pregnant women with structurally normal heart and identified cardiac arrhythmias were enrolled in the study (one center, prospectively collected data). Mean age of patients: 28.9±5.7 years, mean gestation age 22.9±6.9 weeks. Baseline clinical characteristics, maternal and fetal events during pregnancy and postpartum were investigated.

Results

Supraventricular tachycardia (n=20; 40%), atrial (n=5; 10%) and ventricular (n=16; 32%) premature beats were the most frequent arrhythmia in this study. Ventricular tachycardia was identified in 3 (6%) patient, third degree atrioventricular block – in 6 (12%) cases. Arrhythmia was first documented in 30 (60%) pregnant women. Arrhythmias were most frequently happened during the 2nd trimester (n=36; 72%). In 31 (62%) cases of intolerable symptoms of tachyarrhythmias cardioselective β -blockers were required. Catheter ablation was needed for 22 (44%) patients with drug refractory and hemodynamically significant arrhythmias. All ablation procedures were performed without fluoroscopy. Acute success was in all of the 22 patients. Permanent pacemaker was implanted for 6 (12%) patients with complete heart block. In one case was documented a procedural complication (ileofemoral venous thrombosis). Inferior vena cava filter and anticoagulation were used in this patient, follow-up period was without complications. Obstetric outcomes: preterm delivery was none declared, spontaneous vaginal delivery was in 31 (62%) cases, vaginal-assisted was in 6 (12%) women, Cesarean delivery was in 13 (26%) patients. Intrapartum hemorrhage was 325.9±214.3 ml. In one case (2%) developed pre-eclampsia. Neonatal outcomes: birth weight was 3421±711 grams, 5 minute Apgar's score was 8.4±1.4. Congenital malformations in newborns was not documented. There were no maternal and neonatal death.

Conclusion

the most common arrhythmias in pregnant women with structurally normal heart are supraventricular tachycardia and premature beats. It is associated with good pregnancy and neonatal outcomes

#803 - Case Report

NON CARDIOGENIC ACUTE PULMONARY EDEMA

Alejandra García García, Eva Cervilla Muñoz, Neera Toledo Samaniego, Irene García Fernández- Bravo, Ana Torres Do Rego, Elena Bello Martinez

Hospital General Universitario Gregorio Marañón, Madrid, Spain

Introduction

We present the case of a 74-year-old woman with diagnosis of hydrochlorothiazide -induced pulmonary edema.

Case description

We present the case of a 74-year-old woman with a personal history of permanent atrial fibrillation under treatment with acenocumarol, pacemaker carrier, rheumatic valvular heart disease (moderate aortic stenosis, mitral mechanical prosthesis and tricuspid regurgitation), chronic hepatitis B viral infection and autoimmune hypothyroidism. She had had previous severe adverse reactions with antihypertensive combined drugs in two occasions: with hydrochlorothiazide/valsartan and amilorid/ hydrochlorothiazide.

The patient was derivated to the emergency room from the Allergy Day Hospital. While performing an allergy provocation test with hydrochlorothiazide she rapidly developed hypotension, fever (37.8 °C), dyspnea and desaturation with congestive symptoms. The patient required intensive care management with non invasive mechanical ventilation and vasoactive support. She evolved favorably with rapid improvement of the congestive symptoms after supportive management and diuretics.

Blood analyses revealed transient leukopenia 700/ μ L (Neutrophils 300/ μ L; Lymphocytes 300/ μ L), eosinophilia was not observed. Hemoglobin and platelets were within normal range and no renal, hepatic or ionic alterations were observed. C-reactive protein and Nt-proBNP were mild elevates (5.4 mg/dL and 2686 ng/L respectively). Chest X-ray showed bilateral pleural effusion and vascular redistribution without consolidation images. Blood and urine cultures were negative. An echocardiogram was performed without changes in the left ejection fraction, valvulopathies or contractility compared to the previous one performed a few months earlier ambulatory.

Discussion

There have been sporadic reports of hydrochlorothiazid causing noncardiogenic pulmonary edema as an idiosyncratic reaction. The onset of symptoms typically occurs quickly after ingesting the medication, often within an hour. Due to the rare incidence of this reaction, the diagnosis of HCTZ-induced pulmonary

edema is often made only on re-exposure to the medication and may masquerade as septic shock and acute respiratory distress syndrome from a pneumonia. The possible mechanisms of the pulmonary edema still remain unknown.

TAKOTSUBO SYNDROME (TTS) VS ACUTE MYOCARDIAL INFARCTION (AMI): AN ATYPICAL CASE OF CARDIAC ARREST

Ana Catarina Trigo¹, Marta Vilaça¹, João Caiano Gil¹, Ana Sofia Correia², Nuno Moreno², Liliana Carneiro¹

¹ Medicine Department/Internal Medicine Service, Hospital Pedro Hispano, Matosinhos Local Health Unit, Matosinhos, Portugal

² Medicine Department/Cardiology Service, Hospital Pedro Hispano, Matosinhos Local Health Unit, Matosinhos, Portugal

Introduction

A myocardial infarction with nonobstructive coronary arteries (MINOCA) is a “working diagnosis” that must fill out the acute myocardial infarction (AMI) criteria, the presence of non-obstructive coronary arteries on angiography and the absence of other explicative clinical entities. Differential diagnosis from Takotsubo syndrome (TTS) and myocarditis can be challenging. TTS is a transient ventricular contractile dysfunction, more common in postmenopausal women, usually triggered by physical/emotional stress. Left ventriculography, echocardiography and cardiac magnetic resonance imaging (MRI) are crucial diagnostic tools. TTS and AMI have been considered mutually exclusive, but they can coexist and lead to each other.

Case description

A 54-year-old postmenopausal woman, without cardiovascular diseases, collapsed at home after a sudden thoracic pain. A history of emotional stress was reported on the days before, with no previous episodes of chest pain or viral illness. Immediate basic life support was performed by her family, followed by advanced life support by the prehospital emergency medical service. The initial cardiac arrest (CA) rhythm was ventricular fibrillation (VF). ECG after recovery demonstrated sinus rhythm, cardiac rate of 89 QRS complexes per minute, QRS interval of 0.088s, QTc interval of 0.483s, abolition of R waves in leads V1 to V3, with no alteration of ST segment or any arrhythmia. Emergent angiography showed normal coronary arteries, and ventriculography revealed extensive left ventricular contractility disorder typical of TTS. Subsequent studies showed substantial recover of ventricular function in 24h. MRI revealed ischemic late gadolinium enhancement pattern on distal anterior and lateral segments consistent with AMI. No prothrombotic conditions were found. An implantable cardioverter-defibrillator (ICD) was inserted, and the patient was discharged with bisoprolol, statin and dual antiplatelet therapy.

Discussion

Our patient fulfilled the European Society of Cardiology criteria

for both AMI and TTS; we still do not know which occurred first. Both can be complicated by VF and CA, with a frequency of 3% and 4-6% respectively for TTS. There are no clinical guidelines regarding electrophysiologic studies nor ICD therapy for long-term management of patients with TTS who experience CA. Notwithstanding this, our patient remains asymptomatic six months after the event, and no arrhythmias, shocks or antitachycardia pacing therapies were recorded on her ICD.

AN UNUSUAL CAUSE OF PERICARDITIS

Cátia Costa Oliveira¹, Catarina Quina Rodrigues¹, Isabel Durães Campos¹, Carla Maria Marques Pires Rodrigues¹, Paulo Medeiros¹, Luís Dias¹, Jorge Marques¹, João Maciel²

¹ Hospital de Braga, Braga, Portugal

² Centro Hospitalar de S. João, Porto, Portugal

Introduction

In the current era of antibiotic therapy, purulent pericarditis (PP) is a rare entity.

Case description

A 75-year-old woman went to the emergency department for retrosternal pain of pleuritic features with dorsal irradiation with about 1 week of evolution. The patient had sustained hypotension associated with poor peripheral perfusion and had initiated vasopressor support with noradrenaline. The electrocardiogram showed sinus bradycardia and a slight ST segment elevation with superior concavity in DI and aVL. She performed AngioTC that excluded acute aortic syndrome and pulmonary thromboembolism. Analytically, there was elevation of C reactive protein (400 mg/dL), Pro-BNP (10000 pg/ml) and creatinine (2.1 mg/dL). Transthoracic echocardiography (TTE) showed preserved biventricular function and moderate-volume pericardial effusion with fibrin appearance. Due to hemodynamic instability, pericardiocentesis was performed with initial output of 300 cc and then 650 cc of purulent fluid. Its analysis showed normal triglyceride counts and Gram staining showed the presence of bacterial colonies (later confirmed the presence of *Streptococcus anginosus* and *intermedius* strains) and started piperacillin/tazobactam and linezolid. Repeated thoracic CT showed findings suggestive of mediastinitis and a subcarinal foreign body image (patient with a history of accidental ingestion of fishbone days before the onset of symptoms). After oral contrast administration, there were no signs of extravasation into the mediastinum. The patient presented an improvement in her condition and was transferred to the cardiothoracic surgery department with the diagnosis of purulent mediastinitis/PP. It was performed a chest exploration and mediastinal/pericardial lavage. She repeated TTE showing a thin layer of pericardial effusion and the thoracic CT showed bilateral pleural effusion, and a multiloculated consolidation at the right lung, associated with subsegmental atelectasis of the adjacent lung parenchyma. Despite the initial clinical improvement, the patient eventually

evolved with respiratory septic shock with the isolation of a multiresistant strain of *Klebsiella pneumoniae* in the sputum, eventually dying.

Discussion

PP occurs more frequently in individuals with previous pericardial manipulation or disease, alcoholism, immunosuppressed patients or patients on a regular hemodialysis program. Its rapid diagnosis is essential since, although rare, in the absence of proper treatment can be lethal.

DISRUPTION OF BALANCE OF OXIDATIVE STRESS-ASSOCIATED ANGIOGENESIS IN HEART FAILURE

Andreia Matos^{1,2}, Mário Teixeira Barbosa³, Manuel Bicho^{1,4}, Luíz Menezes Falcão⁵

¹ Genetics Laboratory and Environmental Health Institute-ISAMB, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

² Instituto de Investigação Científica Bento da Rocha Cabral, Lisbon, Portugal

³ Department of Internal Medicine, Hospital Lusíadas Lisboa, Lisboa, Portugal

⁴ Instituto de Investigação Científica Bento da Rocha Cabral, Lisboa, Portugal

⁵ Department of Internal Medicine, Santa Maria Hospital, Lisboa, Portugal

Background

Hypoxia may be a concomitant state in heart failure patient, inducing the disruption of the balance of oxidative stress-associated angiogenesis. Soluble fms-like tyrosine kinase-1 (sFlt-1 or VEGFR1) and erythropoietin (EPO) activates neovascularization and reduces apoptosis. We investigated the role of these biomarkers in heart failure (HF) patients.

Methods

In the total of 59 hospitalized patients with acute decompensated heart failure in class II or IV of NYHA were assessed the biomarkers of sFlt-1 and EPO. These biomarkers were determined by ELISA. Subgroup analysis was performed according to the left ventricular ejection fraction in light of the current European Society of Cardiology guidelines. Mann-Whitney test, Spearman correlation, and ANCOVA analysis were applied. Statistical significance was considered for $P < 0.05$.

Results

Mean age 80.66 (SD 10.78) years and 52.9% were female. Mean ejection fraction was $48.45 \pm 17.68\%$, with 28.1% presenting HFrEF < 40%, 21.1% HFmEF 40-49% and 50.9% HFpEF. Higher levels of sFlt-1/sVEGFR1 were associated to patients with HFrEF comparing with HFmEF (HFrEF: 118.35 ± 63.47 pg/mL versus HFmEF: 79.13 ± 27.39 pg/mL, $P = 0.033$). EPO and sFlt-1/sVEGFR1 were directly correlated ($r = 0.856$, $P = 0.034$).

Conclusion

In our study, higher levels of sFlt-1/sVEGFR1 were found in patients with HFrEF, which may untangle a possible role of hypoxia status in the angiogenic profile of heart failure patients.

#830 - Case Report

A CASE OF SEVERE PLATIPNEA ORTHODEOXIA SYNDROME, SECONDARY TO PATENT FORAMEN OVALE IN AN ELDERLY WOMAN

Felice Crudele, Costanza Marchiani, Giulia Bandini, Maria Grazie D'Alfonso, Fabio Mori, Alberto Moggi-Pignone

University of Florence, Florence, Italy

Introduction

The Platypnea-Orthodeoxia syndrome (POS) is a rare clinical manifestation characterized by dyspnea with arterial blood desaturation (drop of $Pao_2 > 4$ mmHg or $Sao_2 > 5\%$), which occurs when the patient is sitting or standing up and regresses in the supine position. The main cause of this syndrome is an intra-cardiac shunt and other causes reported in the literature are pulmonary shunts and hepato-pulmonary syndrome.

Case description

An 87-years-old Italian woman was transported to the emergency room because of fever and flu symptoms for a few days. At the entrance, she was alert, hemodynamically stable, with only bibasilar inspiratory crackles on chest auscultation and no cardiac murmurs. She was former smoker and was on treatment for arterial hypertension. She suffered from orthostatic hypotension and was recently visited by a pneumologist for episodes of dyspnea, without evidence of respiratory impairment. During ER hospitalization, arterial desaturation was detected with the digital pulse oximeter, confirmed by arterial blood gas analysis (Pao_2 45mmHg), in the absence of dyspnoic symptoms, for which oxygen (FiO_2 60%) was administered via Venturi mask and a lung angio-CT was performed to exclude a pulmonary embolism. A transthoracic echocardiogram showed normal global function, without valve pathology or pathological shunts. Due to the persistence of severe arterial desaturation (up to Sao_2 60%), with the appearance of dyspnea, the patient underwent non-invasive ventilation (NIV) and, once stabilized, transferred to our department. It was therefore progressively tried to wean the patient from the NIV and during these attempts, it was shown that the patient maintained excellent values of Sao_2 in the supine position and instead bad values of saturation in orthostatism. Therefore, POS was diagnosed and a contrast echocardiogram was performed showing interatrial shunt, exacerbated in sitting position. So the patient was subjected to a transesophageal echocardiogram and to percutaneous closure of patent foramen. In the following days of hospitalization, the patient remained hemodynamically stable and with good saturation values even in a sitting position.

Discussion

We report the case of an elderly woman in whom patent foramen ovale diagnosis was made associated with platipnea orthodeoxia syndrome. This case shows that although rare and difficult to diagnose, POS can be detected with a careful physical examination, followed by an adequate diagnostic and therapeutic iter.

#847 - Case Report

EFFUSIVE (AND VIRAL) COINCIDENCES

Filipa Rodrigues, Carmen Valdivieso, Eugénia Madureira, Pedro Verão, Andreia Diegues, Ana Rita Silva

ULSNE, Bragança, Portugal

Introduction

The causes for pericarditis and pericardial effusion are multiple, usually divided into inflammatory and non-inflammatory and, in most cases, the cause of the effusion is determined with a thorough history and physical exam.

In developed countries, this condition is, not surprisingly, most often idiopathic or due to viral infection although neoplastic, tuberculosis or myxedema should be considered.

Case description

Presenting a case of two males admitted to medical ward during the same period:

First, a 56 year-old with medical background of aortic stenosis, presented with severe abdominal pain in the upper quadrants and chills of 1 week, with no other findings. Lab results revealed GGT: 121 U/L with normal ALT and AST levels, and a normal EKG. Abdominal CT scan and echocardiogram showed a 35 mm pericardial effusion. Pericardiocentesis was performed with hematic fluid outlet and negative BK in sputum and hemocultures. Further lab tests showed EBV VCA IgG: 14.39; EBV VCA IgM: 5.67 and EBV EBNA IgG: 19.76, being this the most probable etiology. The patient improved with colchicine and aspirin and was discharged with a follow up consult.

The second case: a 32 year-old male, with past medical history of autism, presented with dyspnea, fever and productive cough of 3 days. Lab tests showed hs-CRP: 19.25 mg/dL. A CT scan revealed a subacute 40 mm pericardial effusion. Pericardiocentesis was performed with 900 mL of serous fluid outlet with negative BK in sputum and hemocultures. More detailed lab tests revealed, EBV VCA IgG: 59.40; EBV VCA IgM: 0.20 and EBV EBNA IgG: 16.15, furthermore confirming the EBV infection as the most probable etiology. This patient also improved with colchicine and aspirin and was discharged.

Discussion

Viral pericarditis does not have a well-known frequency, although some studies point up to a number from 30% to 50%, most of them connected to the coxsackie viruses, with some studies identifying EBV as a close second.

Even though EBV is highly prevalent, affecting more than 90%

of individuals worldwide, cardiac involvement of this virus is seldom reviewed in the literature, since it is a very uncommon presentation, particularly pericarditis with sizable effusion.

The course of EBV induced pericarditis, although rare, is usually benign and uncomplicated, but this case serves as an example that we should think with an open mind when making a diagnosis.

#849 - Case Report

DRESSLER SYNDROME – BECAUSE AN ACUTE MYOCARDIAL INFARCTION IS NOT ENOUGH!

Tiago Pais, Cláudia Diogo, Bruno Cabreiro, Ana Ponciano, Joana Leite, Catarina Faria, José Leite, Célio Fernandes

Department of Internal Medicine, Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

After an acute myocardial infarction (MI), there is a high risk of cardiac complications: mechanical (rupture of the papillary muscle and ventricular wall), immunological or iatrogenic. Dressler syndrome (DS) occurs in <4% of patients with MI and typically occurs 1 to 6 weeks after the event. The hallmarks are pleuritic chest pain, fever, pericardial friction and elevation of inflammatory markers. It is thought to be associated with hypersensitivity reaction, in which the antigens released by the injured myocardial muscle produce antibodies against the pericardium, pleura and lungs. An important differential diagnosis is peri-infarct pericarditis, which usually occurs within the first four days after MI and is usually transient.

Case description

We present the case of a 55-year-old male with known cardiovascular risk factors such as arterial hypertension, type 2 diabetes mellitus, smoking habits and obesity (body mass index=35.4). He had history of non-ST segment elevation MI 12 days ago with a subocclusion of the right coronary artery submitted to angioplasty with placement of 2 stents. In the emergency department, he presented a sharp chest pain, not relieved with rest, without irradiation and associated with nausea and dizziness. At admission he was afebrile, with normal cardiac sounds and the remaining examination was unremarkable. Blood tests revealed elevation of inflammatory markers (C-reactive protein (CRP 67.8mg/dL), with no increase in myocardial necrosis markers and an NTproBNP <70pg/mL. The EKG showed inversion of T waves in V5-V6, DII, DIII and aVF and on echocardiogram he had an estimated preserved ejection fraction, inferior hypokinesia and inferior pericardial hyperechogenicity. He initiated lysine acetylsalicylate and colchicine with clinical improvement.

Discussion

Although the patient did not present the typical symptoms or signs, the conjunction of chest pain, elevated CRP, pericardial hyperechogenicity after 2 weeks of the MI let us conclude that is most probably a DS case. Although the incidence of

post-myocardial injury syndrome has been decreasing due to improvement of the methods of coronary reperfusion, the relapses are frequent (about 10-15% in the first 6 months). Larger MI, marked troponin elevation, minor ejection fraction, anterior infarct location correlate with worse outcomes and a poor prognosis.

AORTIC DISSECTION - THE DEMAND OF A HIGH INDEX OF SUSPICION

Leonor Naia¹, Flávio Pereira¹, Tiago Rabadão¹, Margarida Eulálio¹, Elsa Rocha²

¹ Baixo Vouga Hospital Center - Internal Medicine Department, Aveiro, Portugal

² Baixo Vouga Hospital Center - Emergency Department, Aveiro, Portugal

Clinical summary

An 88-year-old woman, admitted for muscle strength deficit in the upper limbs and backache with 5 hours of evolution. Medical history of arterial hypertension and ascending aortic aneurysm. At admission: normotensive, without further changes. Blood tests, 12-lead ECG and cranioencephalic CT scan without changes; thoracic radiography with enlargement of the mediastinum and dilation of the aortic arch. She entered in cardiorespiratory arrest. The echocardiography showed pericardial effusion associated to aortic dissection with cardiac tamponade; pericardiocentesis was attempted, without success. Aneurysms are usually asymptomatic, constituting an incidental diagnosis. Aortic dissection requires a high index of suspicion, as its prognosis is closely related to timely diagnosis and treatment.

DYSPNEA, A SYMPTOM TO INVESTIGATE

Isabel Maria Dias Martins Freitas, Tatiana Salazar, Ana Lima Silva, Pedro Rodrigues, Cláudia Maio, Jorge Salomão, Ana Luísa Cruz, Augusto Duarte

CHMA- Famalicão, Famalicão, Portugal

Introduction

Chronic thromboembolic pulmonary hypertension (CTEPH) is an uncommon but well-recognized cause of pulmonary hypertension (PH). It is characterized by intra-luminal thromboembolism and subsequent vascular remodeling of pulmonary arteries, causing stenosis. It is observed in 2-4% of patients after acute pulmonary embolism (PE) and related with significant morbidity and mortality. We aim to alert for CTEPH as an important cause of PH.

Case description

A 75-year-old female with a history of restrictive syndrome, dyslipidemia and arterial hypertension presented to the emergency department with a six-month progressively worsening dyspnea at rest. There was no history of deep vein thrombosis or PE. Pertinent physical exam findings included a pulse rate of 112 beats/minute, respiration rate of 26 breaths/minute and pitting edema in both lower extremities. Labs were significant for D-dimer >4400 ng/mL and pro-BNP of 10421 pg/mL. The electrocardiography presented with Q1T3S3 pattern and artery blood gas (FiO₂ 0.21) revealed type 1 respiratory failure. Chest computed tomography angiography (CTA) excluded signs of thromboembolism in the main pulmonary arteries but could not exclude thrombus in the sub-segmental arteries. For this reason, anticoagulant therapy was initiated. Transthoracic echocardiogram suggested signs of severe pulmonary hypertension with a normal left ventricular ejection fraction. The ventilation/perfusion scan confirmed peripheral pulmonary thromboembolism. Prothrombotic workout was unrevealing and other causes of pulmonary hypertension were excluded. Right heart catheterization revealed a mean pulmonary artery pressure of 39 mmHg, pulmonary vascular resistance of 8.38 mmHg, cardiac index of 2.95 l/min/m² and pulmonary wedge pressure of 6 mmHg confirming the diagnosis of CTEPH. An antagonist of endothelin receptor associated with rivaroxaban was the treatment of choice with patient referral to thromboendarterectomy.

Discussion

CTEPH is an important cause of pulmonary hypertension and should be specifically considered in the diagnostic workup. The prognosis is poor, with progressive pulmonary hypertension, right ventricular failure, and ultimately death, in the absence of treatment. CTEPH can occur in patients without an history of thromboembolic event. Dyspnea can be the first manifestation, emphasizing the importance of its etiologic investigation, since CTEPH is potentially treated by pulmonary thromboendarterectomy.

WHEN THROMBOLYSIS IS CONTRAINDICATED IN HIGH-RISK PULMONARY EMBOLISM

Isabel Maria Dias Martins De Freitas Freitas, Tatiana Salazar, Ana Lima Silva, Patrícia Rocha, Sara Pereira, Ana Luísa Cruz, Augusto Duarte

CHMA- Famalicão, Famalicão, Portugal

Introduction

Pulmonary embolism (PE) is the most severe form of venous thromboembolism and is associated with high morbidity and mortality rates. Its presentation is variable and non-specific, making its diagnosis a real challenge. Rapid intervention and reestablishment of pulmonary flow reduce mortality.

Case description

82-year-old male admitted for a wake-up stroke, with neurological deficits clinically compatible with the territory of the right middle cerebral artery, of probable cardioembolic etiology. Evidence of occlusion of a large vessel (M1) and with reperfusion criteria, for which he was submitted to thrombectomy, with clinical improvement, with residual neurological deficits persisting. At the 15th day of hospitalization the patient evolved with hemodynamic instability and shock. He underwent computed tomographic pulmonary angiography, which confirmed bilateral acute PE. Transthoracic echocardiography revealed again severe right ventricular systolic dysfunction, assuming high-risk PE. Given the absolute contraindication for thrombolysis, he underwent percutaneous pulmonary embolectomy, with improvement of bilateral perfusion and decrease of pulmonary arterial pressure from 81 mmHg to 55 mmHg. After hemodynamic recovery, vasopressor support was suspended, with no immediate complications of the procedure.

Discussion

This case aims to highlight the importance of PE in the differential diagnosis of shock, as well as the need to recognize percutaneous interventions as a valid alternative therapeutic option for surgical embolectomy, although not always available, in patients with high-risk PE and with a formal contraindication for thrombolysis.

#889 - Case Report

"UNDER PRESSURE". AN UNUSUAL CASE OF PULMONARY HYPERTENSION DUE TO BILATERAL DYSFUNCTION OF DIAPHRAGM

Carolina Defendini

Sapienza University, Internal Medicine Unit, Rome, Italy

Introduction

We present a case of a 74 years old man with an acute respiratory failure associated with bilateral dysfunction of diaphragm.

Case description

On day 4 after a laparoscopic prostatectomy the patient was admitted to our department for a type II respiratory failure with hypoxemia and hypercapnia. A chest X-ray showed elevation of both hemidiaphragms. The patient, never a smoker and without any occupational exposure, ten years earlier underwent a quadruple CABG with good residual left ventricular performance. A non-invasive ventilatory support failed in normalization of the arterial blood gas values, therefore he was intubated and ventilated for 24 hours. A transthoracic echocardiography showed a systolic pulmonary artery pressure estimated at 80 mmHg, a dilated right section with lowered performance of right ventricular wall. A thoracic CT angiography excluded pulmonary embolism but showed elevation of both hemidiaphragms and atelectasis of pulmonary bases. Autoimmune pathologies were also ruled out. Pulmonary function test showed both obstructive and restrictive pulmonary lung disease with FEV1 36%, FVC 32%, DLCO 35% ERV 200ml of predicted values in sit. Lung perfusion scintigraphy showed low perfusion at both lung bases. Right heart catheterization confirmed severe precapillary pulmonary hypertension with a RAP10 mmHg, mean PAPm 75 mmHg, PAWP 12 mmHg and a cardiac output 4.15 L/min. EMG and ENG confirmed signs of neurogenic damage of right phrenic nerve and decreased amplitude of cMAP of both phrenic nerves. The patient started therapy with Tadalafil and respiratory rehabilitation; was discharged 20 days after the normalization of arterial blood gas values.

Discussion

Unilateral weakness of one hemidiaphragm is more common and can be asymptomatic, while bilateral paralysis can cause significant respiratory failure. The mechanism responsible of pulmonary hypertension is the chronic alveolar hypoventilation with hypoxia and hypercapnic vasoconstriction. In our patient we can hypothesize that an idiopathic unilateral phrenic paralysis existed before CABG surgery for the presence of right side elevation in a preoperative chest X-ray. The contralateral nerve might have been damaged during the cardiac surgery, considered as the most common of all traumatic causes. This condition was clinically silent until laparoscopic prostatectomy during which air was blown into the abdomen, pushing the diaphragm upwards and reducing the expansion of the chest, thus causing acute respiratory failure.

#908 - Case Report

PATENT FORAMEN OVALE AND STROKE: ON THE SUBJECT OF TWO CLINICAL CASES

Ana Barbosa, Olinda Miranda, Inês Fonseca, Margarida Rocha, Helena Sarmento, Jorge Cotter

Hospital da Senhora da Oliveira, Guimarães, Portugal

Introduction

The patent foramen ovale (PFO) is the most common congenital heart defect affecting the adult population, being present in

25% to 30% of the individuals. Although most patients are asymptomatic, a variety of clinical manifestations may occur, including cryptogenic stroke (CS).

Case description

Case 1

Woman, 46 years old, history of dyslipidemia and stroke for 1 year with left hemiparesis (4+) and dysmetria in the finger-to-nose test. Admitted to the emergency department due to headache, dizziness and paresthesia in the left hemiface. At the end of the examination, hemihypoesthesia of the face and left central facial paresis were observed. In the head computerized tomography (CT): "...small cerebellar sequelar hypodensity...". No other alterations were documented in the initial study. Transesophageal echocardiogram (TEE) showed PFO, with right-to-left shunt documentation. Given the occurrence of two cerebrovascular events, she was targeted for PFO closure.

Case 2

Male, 41 years old, with no relevant past medical history, travelled to the emergency department due to acute vertigo syndrome. Head CT without changes. On admission, the patient also underwent head magnetic resonance imaging: "... a lesion in the upper slope of the left cerebellar hemisphere, translating a recent ischemic lesion." No other alterations were documented in the initial study, except in TEE which revealed PFO with a right-to-left shunt at rest.

Both cases have Internal Medicine outpatient follow-up to control cardiovascular risk factors.

Discussion

With these clinical cases the authors seek to emphasize the importance of excluding PFO in patients with cryptogenic stroke.

EXTENSIVE TYPE B AORTIC DISSECTION INVOLVING FEMORAL ARTERIES

José Eduardo Mateus¹, Gabriel Atanásio², João Valente²

¹ Internal Medicine Department, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

² Internal Medicine Department, Centro Hospitalar Vila Nova de Gaia / Espinho, Vila Nova De Gaia, Portugal

Clinical summary

A 58-year-old man presented to the emergency department with intense abdominal pain lasting for two hours. He had a history of hypertension, smoking and previous cocaine abuse. On observation he was hypertensive. Computed tomographic angiography of the thorax and abdomen revealed type B aortic dissection extending from the left subclavian artery to both femoral arteries. There were no signs of malperfusion, thus the patient was medically managed. One week later, despite using five different classes of antihypertensive drugs, blood pressure remained uncontrolled, motivating a thoracic endovascular aortic

repair with clinical improvement. The 10 year survival of patients with acute dissection ranges from 30–60%, which highlights the need of a high index of suspicion.

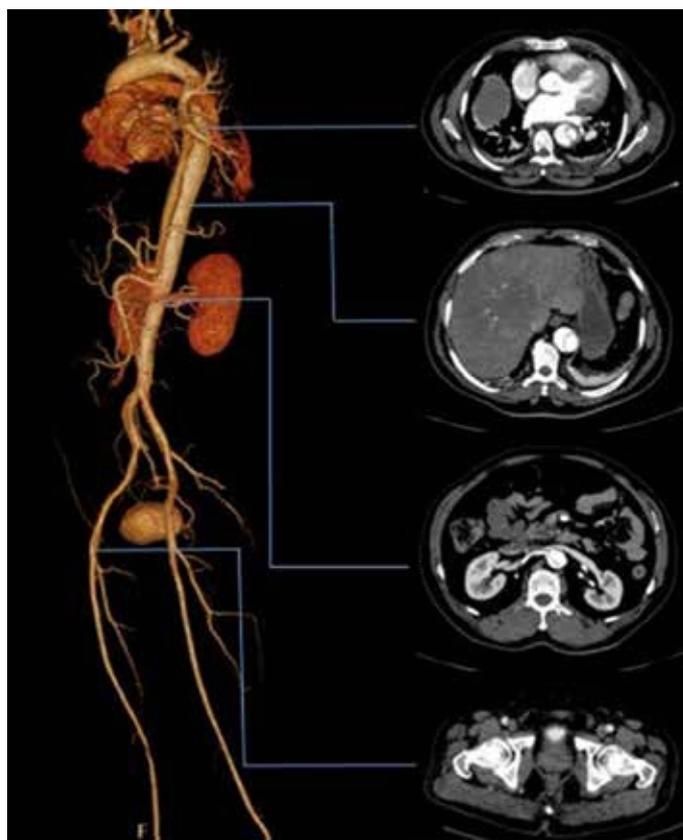

Figure #910. CT three-dimensional reconstruction of aortic dissection extending from left subclavian artery to femoral arteries (lateral incidence and four transverse plane sections).

#917 - Abstract

HEART FAILURE WITH REDUCED EJECTION FRACTION – IS THERE ANY DIFFERENCE IN BEING A WOMAN?

Ana Neto, Daniel Seabra, Inês Oliveira, Aurora Andrade, Paula Pinto

Tâmega e Sousa Hospital Center, Penafiel, Portugal

Background

Heart failure (HF) with reduced ejection fraction (HFrEF) affects more men than women but with several sex differences in the underlying disease. Women are more likely to have hypertension and valvular disease, but less coronary artery disease. Sex-specific data focused on cardiovascular (CV) disease have been increasing steadily, yet is not routinely collected nor translated into practice.

Purpose

Characterize a cohort of patients (pts) with HFrEF admitted in a HF Clinic (HFC) and identify gender-related features of HF, regarding clinical findings and prognosis.

Methods

Unicentric retrospective analysis of pts followed in a HFC since 3/2011. Included pts with reduced ejection fraction (EF) (<50%) and previous diagnosis for at least 6 months; they were divided in two groups: male (G1) and female gender (G2). Peripartum cardiomyopathy pts were excluded. Clinical, demographic, analytical, electrical and echocardiographic characteristics and major CV events - HF hospitalization (HFhosp) and mortality (from CV cause (CVm) and non-CV cause (nCVm)) were analysed.

Results

Included 374 pts with a mean age of 60.6 ± 13.2 years. G2 consisting of 93 pts (25%). The mean age of G2 was higher (63.5 ± 13.4 vs 59.7 ± 13.4 years, $p=0.015$) with predominance of non-ischemic etiology (76 vs 54%, $p<0.001$). Regarding non-ischemic cardiomyopathy, G2 presented less frequently with alcoholic etiology (6 vs 54%, $p<0.001$). There were no significant differences in CV risk factors prevalence, except for hypertension (71 vs 59%, $p=0.041$) and smoking (4 vs 49%, $p<0.001$).

The female group correlated negatively with the presence of atrial fibrillation (AF) (20 vs 40%, $p<0.001$), presented with higher EF at admission and during follow-up (FU) in the HFC ($p<0.001$). During the FU, G2 had lower number of clinical events - HFhosp ($p=0.032$) and mortality ($p=0.008$). No differences between NYHA class at admission and FU.

Conclusion

In this cohort, women with HFREF were older, had more hypertension but with lower prevalence of AF. Regarding etiology, female gender presented higher prevalence of non-ischemic etiology, particularly non-alcoholic cardiomyopathy, with higher EF at admission and FU. Concerning clinical events, they had less HFhosp and lower mortality rate comparing with men.

#920 - Abstract

IMPACT OF SYSTEMIC ATHEROSCLEROSIS ON CLINICAL CHARACTERISTICS AND SHORT-TERM OUTCOMES IN PATIENTS WITH DEEP VENOUS THROMBOSIS

Mir Abolfazl Ostad, Lukas Hobohm, Thomas Münzel, Karsten Keller

University, Mainz, Germany

Background

Venous thromboembolism (VTE) and arterial thrombotic disorders were considered as separate disease entities for a long time. This differentiation of thrombotic disease with regard to arterial and venous origin is based on anatomical differences and differences in clinical presentation. Venous thrombi are mainly composed of red blood cells and fibrin while arterial thrombi are mainly composed of platelets. Despite these differences, a large body of evidence in recent years questioned this oversimplification of separated diseases. Atherosclerosis and VTE

are accompanied by cardiovascular mortality and links between both entities were reported. We aimed to investigate the impact of systemic atherosclerosis on adverse outcomes in patients with deep venous thrombosis and thrombophlebitis (DVT) and to identify differences in DVT patients with and without systemic atherosclerosis.

Methods

The German nationwide inpatient sample was used for this analysis. Patients admitted for DVT were included in this study and stratified by systemic atherosclerosis (composite of coronary artery disease, myocardial infarction, ischemic stroke, and/or atherosclerotic arterial diseases). We compared DVT patients with (DVT+Athero) and without (DVT-Athero) systemic atherosclerosis and analysed the impact of systemic atherosclerosis on adverse outcomes.

Results

Overall, 489,679 patients with DVT (55.7% females) were included in this analysis. Among these, 53,309 (10.9%) were coded with concomitant systemic atherosclerosis with age-dependent incline. Concomitant PE (4.1% vs. 3.8%, $P=0.001$) was more frequently in DVT-Athero and risk for PE in DVT patients was independently associated with absence of systemic atherosclerosis (OR 0.87 [95%CI 0.83-0.91], $P<0.001$). In-hospital mortality (3.4% vs. 1.4%, $P<0.001$) and adverse in-hospital events (2.2% vs. 0.8%, $P<0.001$) were more prevalent in DVT+Athero compared to DVT-Athero; both, in-hospital mortality (OR 1.52 [95%CI 1.41-1.63], $P<0.001$) and adverse in-hospital events (OR 1.49 [95%CI 1.40-1.58], $P<0.001$) were affected independently of sex, age and comorbidities by systemic atherosclerosis.

Conclusion

DVT patients with concomitant systemic atherosclerosis were associated with poorer outcomes. Systemic atherosclerosis was associated with isolated DVT (without concomitant PE) indicating for a link between atherosclerosis and VTE.

#922 - Abstract

IMPACT OF ATRIAL FIBRILLATION/FLUTTER ON THE IN-HOSPITAL MORTALITY OF ISCHEMIC STROKE PATIENTS

Mir Abolfazl Ostad, Lukas Hobohm, Philip Wenzel, Thomas Münzel, Christine Espinola-Klein, Karsten Keller

University, Mainz, Germany

Background

Stroke is the second leading cause of death worldwide. The enormous morbidity of this condition results of an interplay between the caused neurological impairment going along with emotional and social consequences, and a high risk for stroke recurrence. In the United States of America more than 690,000 adults suffer from an ischemic stroke each year.

Ischemic strokes, which are caused by atrial fibrillation/flutter (AF) are frequently more devastating than those without AF. The purpose of our study is to investigate the impact of AF on adverse events in hospitalized ischemic stroke patients and estimate the elevated impact of AF for occurrence of these adverse events.

Methods

The nationwide German inpatient sample of the years 2005-2015 was used for this analysis. Ischemic stroke patients were identified by ICD code I63 and stratified by AF (source: RDC of the Federal Statistical Office and the Statistical Offices of the federal states, DRG Statistics 2005-2015, own calculations). Logistic regression models were used to investigate the impact of AF on adverse in-hospital events and adjusted for age, sex and comorbidities to prove the independence of the associations.

Results

Overall, 2,958,697 hospitalized ischemic stroke patients (50.5% females, 65.4% aged >70 years) were included in the analysis. Of these, 849,466 patients (28.7%) were diagnosed with AF. Overall, 9.0% of the stroke patients died in-hospital. The case fatality rate increased with growing age and was higher in stroke patients with than without AF (13.0% vs. 7.3%, $P<0.001$).

AF was an important predictor for in-hospital death (OR 1.30 [95%CI 1.28-1.31], $P<0.001$) and adverse events during hospitalization independently of age, sex and comorbidities. Deterioration of patients' prognosis due to AF was especially pronounced in younger patients.

Conclusion

AF in ischemic stroke patients is associated with higher in-hospital mortality and higher rate of adverse events during hospitalization independently of age, sex and comorbidities.

#924 - Abstract

PREDICTORS OF IN-HOSPITAL MORTALITY IN PATIENTS WITH COPREVALENCE OF PULMONARY EMBOLISM AND ISCHEMIC STROKE – BENEFIT OF SYSTEMIC THROMBOLYSIS

Mir Abolfazl Ostad, Lukas Hobohm, Thomas Münzel, Karsten Keller

University, Mainz, Germany

Background

Pulmonary embolism (PE) is a frequent complication in immobile stroke patients and an important cause of death. Without prophylaxis for venous thromboembolism (VTE), approximately 75% of the stroke patients with hemiplegia develop a deep venous thrombosis and 20% a PE, which is fatal in 1-2% of the patients. Remarkably, the risk for occurrence of deep venous thrombosis correlate strongly with the degree of paralysis with predilection in the paralyzed leg. We aimed to identify factors and comorbidities,

which are different between PE patients with (PE+Stroke) and without ischemic stroke (PE-Stroke), investigate predictors of in-hospital death and evaluate, whether systemic thrombolysis in these critical ill patients is beneficial.

Methods

Patients were selected by screening the nationwide sample for PE (ICD-code I26) and were stratified by ischemic stroke. In PE+Stroke patients, we compared survivors with non-survivors and examined predictors of in-hospital death as well as the benefit of systemic thrombolysis (source: RDC of the Federal Statistical Office and the Statistical Offices of the federal states, DRG Statistics 2011-2014, own calculations).

Results

The nationwide sample comprised 346,586 hospitalized PE patients (53.3% females) in Germany between 2011 and 2014; among these, 6,704 (1.9%) patients had PE+Stroke. PE+Stroke revealed a substantially higher in-hospital mortality than PE-Stroke (28.9% vs. 14.5%, $P<0.001$). While age, cancer, chronic lung diseases, renal insufficiency, coagulation abnormalities, atrial fibrillation/flutter and diabetes mellitus (DM) type 2 were independent predictors of an increased case-fatality rate, female sex, obesity and arterial hypertension (AHT) were connected with better survival. Systemic thrombolysis was not connected with a survival benefit in PE+Stroke in general (35.5% vs. 27.9% in-hospital deaths, $P<0.001$), but led to improved survival in PE+Stroke patients, who had to undergo cardio-pulmonary resuscitation (OR 0.548 (0.358-0.840), $P=0.006$).

Conclusion

Females, obese and hypertensive patients had a better survival PE+Stroke. Systemic thrombolysis was not connected with survival benefit in general, but might be beneficial in those, with cardio-pulmonary resuscitation.

#939 - Case Report

UPPER LIMB DEEP VEIN THROMBOSIS AT YOUTH: AN UNCOMMON CASE REPORT

Inês Pereira Oliveira, Filipa Leal, Luís Nogueira, Mari Mesquita, Paula Pinto

CHTS, Penafiel, Portugal

Introduction

Thoracic Outlet Syndrome (TOS) results from neurovascular compression at the thoracic outlet, being the neurogenic subtype is the most common (90%). Venous (vTOS) and arterial TOS are rare (7% and 3%, respectively).

We present a case report of a young patient with upper extremity deep vein thrombosis (UEDVT) in the setting of vTOS due to an anatomic variant: an uncommon clinical situation, which implies significant morbidity if not identified and timely treated.

Case description

A 19-year-old female patient with no relevant past medical history, no usual medication, repetitive physical activity, smoking habits or drug abuse, presented to the emergency room with pleuritic thoracic pain and right arm swelling. No previous similar symptoms.

Physical examination showed inflammatory signs of the arm, present bilateral radial pulse and no collateral circulation. Compression maneuvers were negative.

Increased d-dimers on blood analyses. Doppler ultrasound (US) revealed deep vein thrombosis of the right subclavian vein (SV). Thoracic CT showed signs of pulmonary embolism and identified a clavicular osteophyte compressing the SV. Anatomic similarities on the left, with no evidence of thrombosis.

She was diagnosed with UEDVT. Unsuccessful catheter-directed thrombolysis was performed and non-vitamin K oral anticoagulants were initiated.

Anti-phospholipid syndrome and thrombophilia were excluded later on medical appointment. Repeated doppler US revealed left arterial and bilateral venous compression. Surgical decompression with first rib resection has been planned for definitive therapy.

Discussion

Vascular TOS is infrequently encountered in clinical practice, namely with simultaneous venous and arterial compression, as reported.

VTOS in the setting of anatomical variants as osteophytosis at youth is particularly rare, since these are usually related to ageing and bone degeneration. Repetitive upper limb physical activity is a quite more common cause of vascular compression at the thoracic outlet, increasing the likelihood of thrombosis if associated with a hypercoagulability status, smoking habits or contraceptive medication. All these were excluded.

The approach of this pathology is defying due to the lack of randomized controlled trials concerning the issue and overall rarity of the syndrome. There is high risk of recurrence and post-thrombotic syndrome, leading to significant morbidity and highlighting the importance of a timely and appropriate diagnosis and intervention.

#944 - Abstract

USE OF FERRIC CARBOXYMALTOSIDE IN PATIENTS WITH HEART FAILURE AND IRON DEFICIENCY IN A MULTIDISCIPLINARY HEART FAILURE UNIT

Amalia Veronica Perez Papadopulos, Sara Hernandez Araque, Lucia Florio, Gabriela Ormaechea
Hospital de Clinical, Montevideo, Uruguay

Background

Heart failure (HF) is important cause of morbidity and mortality, with high impact on health costs due to hospitalization. Comorbidities such as iron deficiency should be considered in

the management of patients with HF since it can hinder patients prognosis. Evidence suggests that treatment of iron deficiency, despite the existence of anemia, improves symptoms, functional capacity and quality of life.

Our objective was to determine the clinical impact of intravenous iron administration in a population of patients with HF with reduced left ventricular ejection fraction (R-LVEF) who present iron deficiency with/without anemia in a Multidisciplinary HF Unit.

Methods

Prospective cohort study. Patients included: HF with R-LVEF, >18 years; stable clinical situation; informed consent. Patients who received iron/erythropoietin, transfused in the last 3 months, or history of anaphylaxis were excluded.

Iron deficiency was defined: ferritin <100ug/l or 100-300ug/l and transferrin saturation index <20%. Intravenous carboxymaltose iron was administered according to ferric metabolism and hemoglobin (Hb). Minnesota Quality of life test (MQLT) and 6-minute walk test (6MWT) were made. NTproBNP and NYHA class of initiation were controlled. Protocol: if Hb<14 mg/dl, 1000 mg of iron was administered; if Hb 14-15 mg/dl: 500 mg. Control 6 weeks with haemogram, NYHA class, NTproBNP, MQLT, 6MWT. Quantitative data were expressed in medians and interquartile ranges, were compared by Mann Whitney test before and after treatment with iron; qualitative variables were expressed in relative frequency and compared by Chi2 test. $p<0.05$ was considered significant.

Results

Thirty patients were included: 19 women; median age 73 years, ischemic etiology 14; baseline median Hb: 12.5mg/dL; basal ferritin 80.5 ug/l, LVEF 30% median; median MQLT value 62 points and median 6MWT 155 meters. After iron administration, significant improvement in quality of life was observed with median 43.7 points ($p=0.0001$), improvement in median 6MWT 210 meters ($p=0.0001$). NYHA improved in 10 patients and maintained it in 11 ($p=0.12$); NTProBNP: 14 patients decreased, 8 increased ($p=0.29$). No adverse effects were reported.

Conclusion

The experience with the use of ferric carboxymaltose in patients with iron deficiency in our Heart Failure Unit was significantly beneficial giving improvement in clinical parameters independent of the existence of anemia. It is the first experience in our country and supports international research.

#954 - Abstract

A NEW RISK ASSESSMENT MODEL FOR THE STRATIFICATION OF THE THROMBOEMBOLISM RISK IN MEDICAL PATIENTS: THE TEVERE SCORE

Manuel Monti¹, Sergio Timpone², Iginio Fusco Moffa³, Paolo Diego L'Angiocola⁴, Francesco Borgognoni¹, Giovanni Maria Vincentelli²

¹ Usl Umbria 1, Assisi, Italy

² Fatebenefratelli Hospital, Rome, Italy

³ USL Umbria 1, Perugia, Italy

⁴ Gorizia Hospital, Gorizia, Italy

Background

In hospitalized medical patients, the VTE risk is notable. Nevertheless, the available assessment model (TPF) is generally underused.

In this work, we propose an ex novo risk assessment model based on the elaboration of the clinical data exhibited by the TEV patients. Differently from previous studies, the proposed approach does not exploit pre-established models, resulting in a more valid and easy-to-use score.

Methods

We performed a double case-control observational study. For each case of VTE, we enrolled two consecutive patients without VTE of equal sex and age group (18–50, 50–55, 55–60, 60–65, 65–70, 70–75, 75–80, >80 years). The study involved both the EM and the IM Departments of 23 hospitals and universities in Lazio and Umbria (Italy).

Results

We analyzed the data of 1215 patients, 409 with VTE (50% – deep venous thrombosis (DVT), 9.9% – pulmonary embolism (PE), 40.1% – PE+DVT) and 806 case-control. 222 patients (30%) were in charge to the EM department while 520 patients (70%) to the IM one. The TEV risk factors with more statistical significance ($p < 0.01$) are: previous VTE, active cancer, known thrombophilic condition, immobilization, chronic venous insufficiency, hyperhomocysteinemia, central venous catheter, recent hospitalization. Obesity, recent surgery, family history of VTE, hormone therapy and treatment with drugs that stimulate hematopoiesis are resulted at intermediate statistical significance ($p < 0.05$ but > 0.01). A multiple logistic regression was used with robust standard errors and forward selection of the candidate variables using the Bayesian information criterion. A new score is developed, the “TEVere Score”, which shows an higher specificity and sensitivity (respectively 43.3 and 87.5, with accuracy 72.1) compared with the Padua, the Kuscer and the Chopard score. TEVere score also exhibits a greater predictive validity for thromboembolism risk (AUROC 0.7266; 95% CI, 0.71 to 0.73) than the Kuscer score (AUROC 0.6891; 95% CI, 0.67 to 0.70) ($p = 0.0093$).

Conclusion

The results obtained by this study show that information on

environmental risk factors, coagulation factors, and comorbidity lead to higher accuracy in the prediction of the VTE risk in medical area. In daily practice, our clinical model (TEVere score) may be the preferred one for its good predictive performance and since its factors are easier to be determined, especially in EM. These results may provide guidance for thromboprophylaxis and form the basis for a management study.

#962 - Case Report

MULTIPLE THROMBOTIC EVENTS IN A PATIENT WITH PATENT FORAMEN OVALE - A SUCCESSFUL CASE

Daniel Neves Sebaiti, Alexandra Briosaa, Filipa Ferreira, Ana Rita Pereira, Ana Marques, Isabel João, Prof Dr Helder Pereira
Hospital Garcia de Orta, Almada, Portugal

Introduction

Patent foramen ovale (PFO) is an anatomical interatrial communication that persists into adulthood. Closing the PFO is controversial, particularly in older patients, and the results of the studies have been contradictory.

Case description

We present a rare case of a 69 years old male, Caucasian, with history of hypertension and diabetes and several thrombotic events in a short period of time (from March 2015 to July 2015) which included 8 transient ischemic attacks, one stroke with hemorrhagic transformation, and one episode of pulmonary thromboembolism. Etiological investigation was negative, therefore the thromboembolic events were considered to be cryptogenic. The later thrombotic events occurred despite anticoagulation therapy. The transcranial Doppler showed a “shower-curtain” pattern, suggesting the presence of a right-to-left shunt. Transesophageal echocardiography (TOE) showed PFO with spontaneous right to left shunt visible with color Doppler, no other abnormalities were found, pulmonary venous return was normal, left ventricle had normal chamber size and systolic function and normal thoracic aorta. Considering the recurrent episodes of thrombotic events even under effective anticoagulation and attending to the characteristics of the foramen ovale (spontaneous significant shunt) the patient was considered for percutaneous PFO closure.

Under general anesthesia, cardiac catheterization was performed, guided by transesophageal echocardiography and radiology, confirming PFO dimensions (6.99 mm x 24 mm, using sizing balloon), and proceeded with PFO closure using Amplatzer 25mm device, but due to significant mismatch between the septum primum and septum secundum, a significant residual shunt was observed in TOE with bad apposition of the device in the septum primum. Considering the significant number of paradoxical thrombotic events, it was important to have absence of residual significant shunt, therefore the device was replaced by a larger sized one, Amplatzer 30 mm, with significant reduction of residual shunt, without obstruction of adjacent valves our veins.

Discussion

Echocardiographic follow-up showed no residual shunt and maintaining good apposition of the device. No thrombotic event was documented during almost six years of follow up. This case illustrates the importance of patient selection, besides the controversy around percutaneous closure of PFO. Aneurysmatic atrial septum is usually seen as a risk factor for stroke, but in this case the septum was normal.

#963 - Abstract

THE IMPACT OF PRO-THROMBOTIC, ATHEROGENIC AND ANTIOXIDANT PLASMA STATUS ON LONG TERM PROGNOSIS IN YOUNG PATIENTS AFTER ACUTE CORONARY SYNDROME (ACS)

Daniel Neves Sebaiti, Alexandra Briososa, Paula Fazendas, Filipa Ferreira, Ana Rita Pereira, Ana Marques, Helder Pereira
Hospital Garcia de Orta, Almada, Portugal

Background

Free radicals have an important role in tissue lesions pathogenesis in different pathologies, including in atherosclerotic plaque formation and, therefore, in thrombus formation, which may have a central role in developing acute coronary syndrome in young age. In a previous study, we observed that, the group of patients that had acute coronary syndrome in young age, presented a significantly lower total value of antioxidant plasma status compared with the control group and reference values.

Aims

Analysis of long-term influence of pro-thrombotic, atherogenic and total antioxidant states factors in patients that had an acute coronary syndrome in young age.

Methods

The study population included 23 patients admitted for acute coronary syndrome between January 1995 and June 1998. The male/female ratio was 87%/13% and mean age was 35 years (22-40 years). None of the patients had diabetes or diagnosis of familial hypercholesterolemia.

Blood samples were collected 16.5 (+/- 10.7) months after ACS. Laboratory tests: plasma antioxidant status (PAS) (colorimetric method measured in Trolox equivalent), Lipoprotein (a), Apolipoprotein A and Apolipoprotein B (Nephelometry technique), Apolipoprotein E (immune-electro-diffusion method), factors VII e VIII activity. None of the patients were lost on follow-up.

Results

Mean follow-up period 13.7 years; 3 deaths. Fifteen patients presented major cardiovascular events: heart failure 4 patients; new ACS 11 patients; 6 patients underwent percutaneous coronary intervention for stable coronary artery disease. PAS:

1.21 (0.1) mmol/L, Apo B 1.28 (0.37) g/L, Apo E 45.6 (17.3) mg/L, Homocystein 10.9 (2.87) μ mol/L, Lip (a) 0.24 (0.81) g/L, Apo A 1.14 (0.22) g/L, VII 114 (109)%, VIII 50 (42)%, vWF 99(40)%. Patients that had major cardiovascular events had significantly higher levels of Lip (a) e vWF (Mann-Whitney Test $p < 0.05$). The ROC analysis of this parameters presented an AUC of 0.84 and 0.79 respectively, with a cut-off for Lp (a) of 0.195 (73% sensitivity, 75% specificity) and vWF 90% (73% sensitivity, 75% specificity) (Fig 1). There was no statistically significant difference in PAS and in the other evaluated laboratory parameters.

Conclusion

Total plasma antioxidant status was lower in the ACS patients compared with the control group. Occurrence of MACE was not associated with a lower level of antioxidant activity. Higher values of pro-thrombotic and atherogenic factors such as Lip (a) e vWF were associated with a worst prognosis after the first ACS.

#966 - Abstract

ASSOCIATION BETWEEN TOBACCO CONSUMPTION AND SEVERITY OF ARTERIAL HYPERTENSION

Paola Sposito¹, Veronica Torres¹, Florencia Sacchi¹, Caroliona Acosta¹, Lucia Pomies¹, Lia Carlevaro², Mariana Drever³, Maximiliano Pereda⁴

¹ University of Uruguay, Montevideo, Uruguay

² CASMU, Montevideo, Uruguay

³ Hospital Maciel, Montevideo, Uruguay

⁴ MUCAM, Montevideo, Uruguay

Background

Smoking and hypertension (HTA) are two of the main cardiovascular risk factors (CVR). The association between smoking and hypertension determines a risk increase 4.5 times higher. Smoking could be linked to poor control of blood pressure and be modifiable if the patient stop smoking. Alterations in the circadian rhythm of blood pressure and fundamentally nocturnal hypertension have been postulated as predictors of cardiovascular risk.

Aim

To assess the association between smoking and cardiovascular risk in hypertensive patients based on circadian rhythm of arterial blood pressure.

Methods

Analytical, cross-sectional observational study, 3 hospital centers participated. Inclusion criteria: hypertensive older than 18 years who have undergone Ambulatory Blood Pressure Monitoring (ABPM) in a period of 3 months. Exclusion criteria: pregnant women. Variables: age, sex, smoker, Tobacco Year Package Index (IPA), diabetes mellitus and sleep apnea hypopnea syndrome, body mass index, chronotherapy, variability patterns and nocturnal

arterial hypertension in ABPM. Analysis by Chi square test or Fisher exact test, software used STATA v.12.0.

Results

Of a total of 245 ABPM, 202 patients with a diagnosis of hypertension were included in the analysis, average age 55.4 years, 144 women and 58 men. Current smokers: 16.3% Average IPA 38.4. In the total number of patients included, patterns of variability were observed Dipper (90/202) 44.5% and Non-dipper (60/202) 32.6%. Current smokers patients presented risk variability patterns 54% Non Dipper (30%) and Riser (24%) in greater proportion than non-smokers 47% Non Dipper (32%) and Riser (15%) although there was no statistically significant relationship $p=0.6295$. Nocturnal HTA was observed in a high percentage of patients regardless of their smoking status: 61% smokers, 66% non-smokers $p = 0.1354$. HTA nocturnal without chrono therapeutic treatment 71%. As for the gender, nocturnal HTA was observed in 83% of male smokers vs. 59% of women, obesity in 50% of male smokers vs. 39% of female and diabetes in 33% of male smokers vs. 17% of female.

Conclusion

In the studied population, the current smoker patient with hypertension had a tendency to present patterns of blood pressure variability of higher CVR as well as a relationship between male sex and the presence of nocturnal hypertension was observed. The cessation of tobacco consumption could be important in the control of hypertension. A large number of patients presented nocturnal hypertension.

A CASE OF TRICUSPID INSUFFICIENCY AND ANEURYSM

Duarte André Ferreira, Mauro Fernandes, Margarida Temtem, Tatiana Henriques, Maria Luz Brazão
Hospital Central do Funchal, Funchal, Portugal

Clinical summary

An 83-year-old woman, with a history of atrial fibrillation presented to the emergency department with a week history of orthopnea, chest pain and effort dyspnea. On examination she was afebrile. On auscultation: holosystolic murmur and decreased vesicular murmur at the bases with fervors. Considerable edema to the knees. Laboratory evaluation revealed troponinT 0.027 ng/mL, NT-proBNP 2114 pg/mL, d-dimers 1070 ng/mL. Postero-anterior chest radiography showed significant cardiomegaly. Computed tomography angiography presented exuberant dilation of the right atrium, pleural effusion bilaterally and some pericardial effusion. Transthoracic echocardiogram was also performed. The patient was admitted to cardiology for right heart failure, with severe tricuspid insufficiency and probable aneurysm.

Figure #975. Computed tomography showed a significant cardiomegaly and exuberant dilation of the right atrium.

#987 - Case Report

PAINFUL LEFT CERVICAL SWELLING IN A HEALTHY 44-YEAR OLD MAN – A CASE OF A COMPLETE LEFT INTERNAL JUGULAR VEIN THROMBOSIS

Diogo Santos Ferreira, Joana Andreia Cabrera, Cristina Almeida Pinto, Dulce Mendonça Pinheiro, Vitor Paixão Dias
Centro Hospitalar Vila Nova de Gaia/Espinho, Vila Nova De Gaia, Portugal

Introduction

Less than 5% of deep vein thrombosis is due to thrombosis of the internal jugular vein (IJV). It may be provoked by insertion of catheters or have an underlying genetic, malignant or inflammatory disease.

Case description

An otherwise healthy 44-year old man presented to his attending doctor because of a painful left cervical swelling, following strain with his left arm over the previous week. The swelling was of about 5cm in diameter, hard, non-tender superficially and slightly warm. Three days later, the cervical ultrasound showed a complete left IJV thrombosis with a central heterogenous thrombus and he was advised to be seen at the local Emergency Department. A Computed Tomography Angiography (CTA) confirmed the diagnosis and excluded pulmonary thromboembolism. He was admitted to the Internal Medicine ward for etiological study and treatment with subcutaneous low-molecular weight heparin 80 mg twice a day.

From his background, he was a smoker of half a pack since he was 20 years old and consumed half a bottle of wine during the

weekend (lunch and dinner). He denied any family history of thromboembolic diseases.

During the hospital stay, the swelling progressively responded to anticoagulant therapy and the patient improved symptomatically. The prothrombotic blood study was unremarkable. However, the image in the original CTA of a slight adipose tissue densification in the lesser gastric curvature led to an upper endoscopy study, with findings compatible with esophagus neoplasm. The biopsy confirmed the diagnosis of adenocarcinoma with little cohesion and presence of signet ring cells. The current stage is cT3N+M0 and he was proposed peri-operative chemotherapy with FLOP (5FU, Folinic acid, Oxaliplatin, Docetaxel).

Discussion

This case highlights the importance of a thorough study of IJV thrombosis and shows a rather unusual presentation of a rare neoplasm in a young smoker and otherwise healthy individual. In fact, paraneoplastic thrombosis may be found in about half the cases of IJV thrombosis. However, the most frequent location of the tumor is the ear, nose and throat region. Also, it enforces the fact that esophagus cancer can be very insidious symptomatically, as the subject presented with no esophageal or constitutional symptoms. This represents a rare case of an IVJ thrombosis caused by a tumor outside the head and neck region as the first symptom of the disease.

#988 - Case Report

AN UNUSUAL CASE OF "MASKED" HYPERTENSION AND THE IMPORTANCE OF A CORRECT BLOOD PRESSURE EVALUATION

Diogo Santos Ferreira, José Mário Bastos, Telmo Borges Coelho, Luís Silva Andrade, Vítor Paixão Dias

Centro Hospitalar Vila Nova de Gaia/Espinho, Vila Nova De Gaia, Portugal

Introduction

ESC/ESH latest arterial hypertension guidelines recommend that blood pressure (BP) should initially be measured in both upper arms. This case highlights the potential consequences of an incorrect BP measurement.

Case description

An otherwise healthy 75-year old man was sent to the Emergency Department (ED) after a routine evaluation by his attending doctor showing a marked asymmetry of BP between his two upper arms (190/108 mmHg right arm versus 132/74 mmHg left arm), which was confirmed in the ED. BP in both legs was 220/90 mmHg. The patient denied pain, paresthesia or weakness in both arms. All limbs were warm and well perfused. However, the left pulse was weaker and slightly delayed.

The patient had no relevant medical history and was not under any medication. He regularly assessed his BP in his left arm and denied any history of arterial hypertension. He was a heavy smoker (as much as 3 packs a day), active since he was 10. Previous data

showed LDL values of 160 mg/dL (2014) and 137 mg/dL (2017). Blood work was unremarkable. An electrocardiogram showed T-wave inversion in DII, DIII, aVF, V5-V6, with criteria of left ventricular hypertrophy and enlargement of left atria (Figure 1). Chest radiograph was unremarkable. Computed Tomography Angiography showed left subclavian artery stenoses of about 1,5-2 cm (Figure 2). He was discharged, scheduled follow-up with a Vascular Surgeon and prescribed acetylsalicylic acid, rosuvastatin-ezetimibe and azilsartan.

Discussion

This case underlines the importance of a correct measurement of BP, especially in both upper arms initially – as both the attending doctor's and self-evaluation was always made in his left arm, this arterial hypertension was probably "masked" for years. As a result, there were already signs of cardiac remodeling to this unrecognized hypertension. ESC/ESH guidelines indicate that a consistent and significant systolic BP difference between arms (i.e. >15 mmHg) is associated with an increased cardiovascular risk, most likely due to atheromatous vascular disease, and if there is a difference in BP between arms, the arm with the higher BP values should be used for all subsequent measurements.

Atherosclerosis is the most common cause of subclavian artery stenoses. Often patients present during their sixth or seventh decades of life, and they have associated peripheral arterial disease risk factors such as smoking, diabetes mellitus, hyperlipidemia and hypertension, some of which were present in this subject.

#991 - Abstract

HYPERKALEMIA, HEART FAILURE AND PATIROMER IN MULTIMORBIDITY PATIENTS

Raquel Rodil-Fraile¹, Gregorio Tiberio-Lopez²

¹ Clínica San Miguel, Pamplona, Spain

² Complejo Hospitalario de Navarra, Pamplona, Spain

Background

The objective of the present study is to evaluate Patiromer tolerance and effectiveness in a multimorbidity population.

Methods

Observational study. Multimorbidity patients with sintomatic chronic heart failure (CHF) and hyperkalemia in follow-up by the Internal Medicine of Complejo Hospitalario de Navarra since March to November 2018.

For data analysis student t-test for paired samples we were performed. All tests were performed using STATA version 9 (Texas, NC).

Results

We included 8 patients (M/W: 7/1) with an average age of 80 years. The Barthel index media was 90 points. The comorbidity index measured by the Charlson scale was 9 points. Six patients had HF with reduced ejection function (HFrEF) and two had HF

with preserved ejection function (HfpEF). 50% (4) of the patients had advanced chronic kidney disease (CKD) (stage 4), followed by 37% (3) with CKD with stage 3b. 75% (6) of the patients received ACE/ARB and 12.5% (1) received ARM treatment. The mean potassium levels before treatment were 5.7. All patients received treatment with resinalcio, with regular tolerance.

After adjustment of basal medication and initiation of Patiromer, follow-up of patients was performed. 75% (6) of the patients received treatment with sacubitril-valsartan at a dose of 24/26 mg twice a day, with good tolerance, and 88% of the patients (7) received treatment with ARM at a mean dose of 23 mg per day (12.5-25 mg). The potassium levels after the modifications was 4.7 ($p < 0.001$).

75% of patients received patiromer 8.4 g/day, with good tolerance and no side effects; the remaining 25% received Patiromer 8.4 g twice a day.

Conclusion

The treatment with Patiromer, apart from the good tolerance and palatability, is a good alternative for the optimization of the treatment of HF, as well as for the treatment of hyperkalemia secondary to CKD or pharmacological treatment.

#997 - Abstract

EARLY FOLLOW-UP VISIT BY A MULTIDISCIPLINARY HEART FAILURE TEAM AFTER HOSPITALIZATION FOR ACUTE HEART FAILURE – IMPACT IN THE OUTCOMES

Sofia Furtado¹, Rita Homem², Ana Rita Santos³, Joana Maurício⁴, Sérgio Maltês³, Inês Felizardo Lopes¹, Mariana Popovici¹, Inês Lopes Da Costa¹, Inês Egídio³, Inês Nabais⁵, Francisco Adragão⁶, Catarina Rodrigues³, Luís Campos³, Inês Araújo³, Cândida Fonseca³

¹ Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

² Hospital Garcia de Orta, Lisboa, Portugal

³ Centro Hospitalar Lisboa Ocidental, Lisboa, Portugal

⁴ Hospital Prof. Doutor Fernando Fonseca, Lisboa, Portugal

⁵ Hospital de Cascais, Lisboa, Portugal

⁶ Centro Hospitalar Universitário do Algarve, Portimão, Portugal

Background

An early follow-up visit within 7 to 14 days after hospitalization for acute heart failure (AHF) is associated with lower readmission rates and is currently the standard of care in the European Guidelines for HF. Our purpose was to describe the use of an early follow-up visit by a multidisciplinary HF team (combining specialized medical and nurse care) in the transition care of HF patients, after discharge from the hospital, and to analyze its association with early readmission for HF and all-cause mortality.

Methods

Retrospective cohort study of patients consecutively admitted to a HF Unit for AHF in one year (from 11/2017 until 10/2018). Exclusion criteria: death before discharge; transfer to another

hospital. We compared patients who were evaluated in a follow-up visit 7 to 14 days after discharge from the hospital, where treatment adjustments could be made by the HF specialist, with those who were not evaluated. Primary outcomes: readmission for AHF and all-cause mortality at 3 months after discharge. Cox proportional hazards regression was used.

Results

Of 181 admissions for AHF, 153 were analyzed. Patients were 77±11 years-old; 54% were male and 46% had reduced left ventricular ejection fraction. At discharge from the hospital, median NT-proBNP was 3258 (1429-5995) pg/mL. One-hundred and thirty-six (89%) patients were referred to a follow-up visit by the same multidisciplinary HF team within 7 to 14 days after discharge, of which 79% (n=107) complied. The mortality rate after 3 months was 6.5% (n=10) and the AHF readmission rate was 14.7% (n=22).

An early follow-up visit was independently associated with a lower risk of readmission for AHF at 3 months (crude HR 0.32, 95% Confidence Interval (CI): 0.14-0.75, $p=0.008$; adjusted HR 0.26, 95% CI: 0.10-0.66, $p=0.004$) and a lower combined risk of all-cause mortality or readmission for AHF at 3 months (crude HR 0.37, 95% CI: 0.18-0.78, $p=0.009$; adjusted OR 0.32, 95% CI: 0.13-0.72, $p=0.006$).

Conclusion

We found a high compliance with an early specialized follow-up visit after hospitalization for AHF. A multidisciplinary HF team visit in the vulnerable transition period after hospitalization for AHF is feasible and was associated with lower risk of HF readmission and death from all-cause at 3 months, mostly due to preventable readmissions.

#1004 - Case Report

AN EMERGENCY

Elsa Araújo, Manuel Barbosa, Marta Pereira, Vítor Costa, Bárbara Sousa, Helena Vilaça

Unidade Local de Saúde do Alto Minho, Viana Do Castelo, Portugal

Introduction

Hypertensive emergencies (HE) are characterized by acute, severe elevation in blood pressure (BP) associated with the presence or impendence of target-organ dysfunction. HE is uncommon, with an estimated population incidence of 1 to 2 cases per million per year.

Case description

A 50-year-old male, caucasian, with a history of recently diagnosed hypertension (HT), dyslipidemia and smoking habits presented to the emergency department (ED) because of headache and blurred vision with 24 hours of onset. Despite presenting a BP of 220/110 mmHg he was medicated with antihypertensive therapy and was discharged with a therapeutic adjustment.

He returned to the ED the next day with worsened complaints. His BP was 191/103 mmHg and ocular fundus examination showed bilateral papilledema and scattered hemorrhagic exudates, findings consistent with hypertensive retinopathy. His admission labs were significant for anemia, thrombocytopenia and acute kidney injury. Proteins and erythrocytes were detected in urinary sediment and the electrocardiogram presented criteria of left ventricular hypertrophy. Brain computed tomography, renal echography and renal arterial doppler were unremarkable.

The patient was admitted to the intensive care unit for HE with multiple target-organ dysfunction: hypertensive retinopathy and thrombotic microangiopathy with thrombocytopenia, hemolytic anemia and acute kidney injury. He was started on labetalol perfusion for 24 hours for BP control and, later, with oral antihypertensive therapy.

The remaining etiological study excluded other causes of HE and secondary HT.

The patient's BP profile was controlled using triple antihypertensive therapy (angiotensin-converting enzyme inhibitor, calcium channel blockers and β -blockers). The patient maintained vigilance in internal medicine consultation and nephrology. Currently, 1 year after the HE episode, the patient has progressed to chronic kidney disease (CKD) with estimated glomerular filtration rate at 50ml/min/1.73m².

Discussion

HE are acute and life threatening, so doctors need to recognize and treat them immediately so as to reverse the target organ injury. In this case, given the patient's delay in seeking help, as well as the delay in diagnosis and initiation of treatment, the patient maintained target-organ dysfunction, with progression to CKD.

#1016 - Case Report

CLINICAL-EVOLUTION PARTICULARITIES OF EBSTEIN'S ANOMALY

Nicoleta Dima¹, Elena Rezus¹, Roxana Ganceanu-Rusu¹, Andreea Clim², Minela Aida Maranduca¹, Viorica Ungureanu², Adelina Parlapan², Codruta Badescu¹, Ciprian Rezus¹

¹ "Grigore T. Popa" University of Medicine and Pharmacy, Iasi, Romania

² "Sf. Spiridon" Clinical Emergency Hospital, Iasi, Romania

Introduction

Ebstein's anomaly is a congenital heart defect characterized by an anomaly of the tricuspid valve apparatus. It consists in attaching apical septal and posterior tricuspid valve to the right ventricle wall, with subsequent atrialization of right ventricle. It is a rare condition that occurs in 1 out of 210 000 people, which represents less than 1% of all congenital heart malformations and may develop asymptomatic at many patients until the third and fourth decades of life, representing a significant public health problem.

Case description

59-year-old patient diagnosed at age of 26 with the Ebstein's

anomaly, delaying surgery, occupational exposure to respiratory hazards for about 30 years (metal powders environment), with recurrent episodes of bilateral ankle thrombophlebitis at the age of 37 when chronic oral anticoagulation was initiated, with a history of syncope episode, associating secondary polycythemia. The patient is hospitalized with serious overall condition in the context of global cardiac decompensation. Explorations carried out reaffirms cardiac malformation - atrial septal defect ostium secundum type, membranous ventricular septal defect with two-way shunt in left ventricle and right atrium, with dysplasia and reshuffle the tricuspid valve, the right ventricle atrialized 50%, tricuspid stenosis and tricuspid regurgitation grade III (gradient RA/RV 60 mmHg), with signs of moderate pulmonary hypertension. The presence of secondary polyglobulia required repetitive therapeutic phlebotomy.

Discussion

Ebstein's disease presents a survival rate of 5% to the 5th decade of life. Surgical treatment in our patient's replacement of the tricuspid valve would not be enough to correct developed ventricular dysfunction and increased operator risk. Congenital heart malformations require special attention, interdisciplinary approach and periodic clinical monitoring because of complications that can develop with impaired quality of life - pulmonary hypertension, hyperviscosity syndrome and arrhythmias.

#1034 - Abstract

CLINICAL DETERMINANTS OF THE PR INTERVAL DURATION IN SWISS MIDDLE-AGED ADULTS: THE COLAUS STUDY

Marylène Bay, Peter Vollenweider, Pedro Marques-Vidal, Federica Bocchi, Etienne Pruvot, Jürg Schläpfer

Lausanne University Hospital, Lausanne, Switzerland

Background

Prolonged PR interval is associated to adverse outcomes, such as atrial fibrillation or cardiovascular and all-cause mortality. However, data on determinants of the PR interval are scarce. We aimed to identify the clinical and biological determinants of the PR interval duration in the general population.

Methods

Cross-sectional study conducted between 2014 and 2017 in a representative sample of the Swiss population. PR interval duration was assessed by a 12-lead electrocardiogram and categorized into prolonged (≥ 200 ms) or normal (< 200 ms) for analysis. Covariates were obtained either by questionnaire, interview, physical examination or blood testing. Determinants were identified using stepwise logistic and results were expressed as multivariable-adjusted odds ratio (OR) [95% confidence interval]. A further analysis was performed after adjusting for antiarrhythmic drugs, P-wave contribution to the length of PR interval (P duration/PR duration*100 ratio), electrolytes (kalemia, calcemia, magnesemia) and previous history of coronary heart disease.

Results

Overall, 3668 participants with measurable PR interval duration were included (55.6% females; mean age 62±10 years). Prolonged PR interval was found in 365 (9.9%) participants. Stepwise logistic regression identified male sex (OR 1.49 [1.09-2.04], $p=0.012$); older age (65-74 years: OR 2.47 [1.78-3.43], $p<0.001$, and ≥ 75 years: OR 4.56 [3.13-6.64], $p<0.001$); increased height (per 5 cm, OR 1.16 [1.07-1.26], $p<0.001$) and hypertension (OR 1.45 [1.14-1.85], $p=0.003$) as positively associated and, at the opposite, current smoking (OR 0.64 [0.44-0.85], $p=0.015$) and high resting heart rate (≥ 70 beats/min, OR 0.46 [0.32-0.65], $p<0.001$) as negatively associated with prolonged PR interval duration. After further adjustment for the other covariates, male sex, older age and increased height remained positively, and high resting heart rate negatively associated with prolonged PR interval. Conversely, hypertension and current smoking were no longer associated.

Conclusion

In a sample of the Swiss middle-aged population, male sex, older age and increased height significantly increase the likelihood of a prolonged PR interval duration, whereas high resting heart rate significantly decreases it.

#1051 - Abstract

FEATURES OF NUTRITION IN YAKUTIA AND MORTALITY RATE FROM CIRCULATION SYSTEM DISEASES

Milana N. Petrova

M. K. Ammosov North-Eastern Federal University Institute of Medicine, Yakutsk, Russia

Background

The ability of the people to survive in difficult conditions, when in the winter - 50, in the summer + 40, and at the same time skillfully organizing their food is a special phenomenon in the material culture of the Yakut people. Yakut cuisine is based on national traditions, it absorbs the best elements of the northern kitchen tradition, includes a wide variety of dishes. Among the factors that have the greatest impact on the population's health indicators, the nature of nutrition plays an extremely important role: fatty foods that help survive in harsh climatic conditions contribute to the disturbance of lipid metabolism and the manifestation of circulatory system diseases.

Purpose of the study. To conduct a comparative analysis of mortality from diseases of the circulatory system in selected districts of the Republic of Sakha (Yakutia).

Methods

In July-August 2017, a survey was conducted using a sampling method for quota sampling ($n=870$), based on the structure of the general population by respondent employment. 745 questionnaires were distributed in 26 settlements of the Oymyakonsky, Tomponsky, Suntarsky, Namsky, Ust-Aldansky,

Verkhne-Vilyuysky uluses and Mirninsky districts, with a total population of 55,188.

Results

Mortality from circulatory system diseases has a certain tendency to decrease $y = -5,303x + 462.4$; $R^2 = 0.269$; from cerebrovascular diseases $y = -2.399x + 102.6$; $R^2 = 0.774$; from CHD slightly reduced $y = -1.066x + 177.0$, $R^2 = 0.059$; from AMI, negative dynamics have not been observed since 2000 $y = 0.497x + 29.41$, $R^2 = 0.344$. When analyzing the mortality of the population of the studied areas as a whole from diseases of the circulatory system in 2015-2016, most cases observed in Oimyakon ulus (1194.4-1354.2: 100000 population), from AMI (65.7-44.8: 100000 population) and from cerebrovascular diseases (219.1-179.1: 100000 population). There were more deaths from coronary heart disease in Tompon ulus (277.1-289.4: 100,000 population).

Conclusion

1. Given this situation, it is extremely important to pay attention to the diagnosis of circulatory system diseases in primary care facilities;
2. To conduct routine inspections among the nomadic peoples.

Acknowledgement. The abstract was published with the financial support of the Russian Foundation for Basic Research, the project "The Problem of Valorization and Popularization of Nutrition Culture of the Peoples of the North in Modern Conditions (on the Example of Yakutia)" No. 17-21-08001.

#1055 - Abstract

HEART FAILURE WITH MIDDLE-RANGED EJECTION FRACTION – A DISTINCT ENTITY OR AN INTERMEDIATE CLASS?

João Pedro Pais¹, Ana Sofia Matos¹, Ana Nascimento¹, Francisco Teixeira Da Silva¹, Miguel Romano¹, Rui Silva², Francisca Cardoso¹, Diana Guerra¹

¹ Unidade Local de Saúde do Alto Minho, Viana Do Castelo, Portugal

² Centro de Medicina de Reabilitação de Alcoitão, Alcoitão, Portugal

Background

Heart failure with middle-ranged ejection fraction (HFmrEF) is described as the presence of symptoms of HF, a left ventricular ejection fraction (LVEF) between 40% and 49%, high levels of natriuretic peptides and a structural heart disease or diastolic dysfunction. However, guidelines lack an evaluation of the differences between this new class and the two most known classes [HF with preserved ejection fraction (HFpEF) and HF with reduced ejection fraction (HFrEF)]. While some studies defend HFmrEF as a progression from one of the two existing classes, others present HFmrEF as a distinct entity, with specific clinical and demographic characteristics. With this work we intend to describe the clinical and demographic characteristics of patients with HF followed in an outpatient heart failure clinic.

Methods

The clinical files of all the patients followed in an Internal Medicine coordinated heart failure clinic, between April of 2014 and October of 2018 were collected. Patients without diagnostic criteria for heart failure were excluded. The demographic variables, comorbidities and clinical characteristics of heart failure were analysed. Statistical tests were performed using SPSS v25 software.

Results

A total of 315 clinical files were analysed. 63 patients were excluded for not meeting the criteria for diagnosis of HF. Of the remaining, 70 (27,8%) had a LVEF inferior to 40% (HFrEF), 33 (13,1%) had an LVEF between 40% and 49% (HFmrEF) and 130 (51,6%) had a LVEF over 50% (HFpEF). 18 patients (7,5%) were still being studied. In HFmrEF we observed a male predominance (60,6%), similar to HFrEF and higher than HFpEF. In HFmrEF, the median age at diagnosis was 83 years (being 73 years in HFrEF and 84 in HFpEF). HFmrEF patients had an intermediate prevalence of alcoholism, valvular disease, history of depression and smoking. HFmrEF patients had a significantly higher prevalence of coronary disease and a lower prevalence of chronic obstructive pulmonary disease as compared with HFrEF and HFpEF. When evaluating the etiology of HF, patients with HFmrEF had a significantly higher prevalence of ischaemic etiology.

Conclusion

Our results suggest that HFmrEF shares some characteristics with HFrEF and HFpEF, which favours the hypothesis that HFmrEF results from progression of one of the other types of HF, rather than representing a distinct entity. However, our work involves a small number of patients and further studies are required for a better understanding of this entity.

#1071 - Abstract

COULD RENAL MICROVASCULAR DAMAGE AND 25-OH VITAMIN D DEFICIT PREDICT PROGNOSIS IN HEART FAILURE?

Florina Buleu¹, Daniela Adina Moteli², Ovidiu Cosmin Iancu³, Ana-Maria Pah¹, Vladiana Turi¹, Petru Bucuras⁴, Ruxandra Maria Christodorescu¹, Simona Dragan¹

¹ University of Medicine and Pharmacy Victor Babes, Timisoara, Romania

² Fresenius Nephrocare Clinic, Timisoara, Romania

³ Regina Maria Private Clinic, Timisoara, Romania

⁴ Emergency County Hospital Pius Brinzeu, Timisoara, Romania

Background

Vitamin D deficiency, highly prevalent in heart failure (HF) patients increases arterial stiffness and has been associated with increased mortality risk. Renal resistive index (RRI) is a specific marker correlated with microvascular damage. The purpose of the study was to correlate arterial stiffness represented by vascular calcification biomarkers, 25-OH vitamin D3 levels, and RRI with parameters of left ventricular function in heart failure patients.

Methods

90 patients with a history of heart failure longer than 12 months, NYHA class II-III were selected from a database and divided into 3 groups based on left ventricular ejection fraction (LVEF): HF with preserved ejection fraction, group A (n=30), HF with mid-range ejection fraction, group B (n=30), and HF with reduced ejection fraction group C (n=30). Serum levels of 25-OH vitamin D3 were determined by ELISA. Left ventricular volumes (LVTSV, LVTDV) and LVEF were measured by echocardiography. Aortic pulse wave velocity (PWV) was determined using the Arteriograph device. Carotid intima-media thickness (CIMT) was measured using high resolution ultrasound and RRI was measured by duplex Doppler in the intrarenal segmentary arteries. Peak systolic velocity (PSV) and minimum end-diastolic velocity (EDV) were determined using angle correction and RRI was defined as (PSV-EDV)/PSV. The Spearman correlation test was used for the interpretation of the results.

Results

Serum levels of 25-OH vitamin D3 were significantly lower in group C compared to the other groups (17.35±4.51 vs 23.86±4.85 vs 26.29±4.97 ng/ml, p<0.0001).

25-OH vitamin D3 values were significantly correlated with cardiac parameters: LVTDV (r=-0.503, p<0.001), LVTSV (r=0.541, p<0.001), LVEF (r= 0.602, p<0.001), aortic PWV (r=-0.723, p<0.001) and also with IMT (r=-0.464, p<0.001).

RRI values were significantly correlated with cardiac parameters: LVTDV (r=0.355, p<0.001), LVTSV (r= 0.387, p<0.001), LVEF (r=0.534, p<0.001) aortic PWV (r=0.734, p<0.0001) and 25-OH vitamin D3 (r=-0.667, p<0.0001).

A significant association between serum vitamin D3 and RRI (Chi2 test, p <0.001) was established.

Conclusion

Measurement of arterial stiffness is a convenient, inexpensive and reliable method in heart failure patients.

RRI and 25-OH vitamin D3 deficit appear to be significantly correlated with the severity of the disease in HF patients.

Both markers might contribute to prognosis and treatment adjustments in these patients.

#1094 - Case Report

PERIMYOCARDITIS IN THE YOUNG - STILL A CHALLENGE

Estela Ferrão, Francisca Pulido Valente, Filipa Alves Santos, Maria José Grade, Luisa Arez

Algarve University Hospital Center - Hospital Portimão, Portimão, Portugal

Introduction

In the clinical practice we can find a spectrum of myopericardial syndromes whose classification depends on the degree of myocardium vs pericardium involvement, including pure

pericarditis and myocarditis, myopericarditis and perimyocarditis. However the terms are commonly misused.

The diagnostic and therapeutic approach is challenging, the etiology is mainly idiopathic and although the natural history is mainly benign, it can also evolve to a permanent cardiomyopathy.

Case description

A 19-year-old healthy man, presented to the emergency room with a 5 days history of headache, fever, productive cough, and a pleuritic chest pain since the day before. He referred a similar episode 3 weeks before, that had started with diarrhea, with spontaneous resolution.

Physical exam: Bibasal rales in the 2/3 of the right hemithorax.

Laboratory results: Total CK 1016 IU/L, 617 IU/L hs troponin T 1376 ng/l, proBPN 1479 pg/ml, CRP 205 mg/L. Serology, auto immunity and coagulation studies: negative. Negative pneumococcus and legionella urinary antigens

ECG: Inferolateral ST elevation and ST depression in V1.

Chest X ray: interstitial infiltrate in right pulmonary basis

Transthoracic echocardiography: reduced left ventricular global systolic function with left ventricular ejection fraction <40%, more marked hypokinesia in the posterolateral region.

He started empirical antibiotherapy directed to a possible atypical pneumonia. A cardiology evaluation was made. He was put on AAS, colchicine and medical therapy for heart failure with reduced ejection fraction and evolved clinical and analytically well.

Discussion

This case highlights the difficulty when diagnosing myopericardial syndromes since they can have a very variable clinical presentation, mimicking other clinical conditions including coronary acute syndromes, that must be ruled out because of their gravity.

Particular to the patient was that we could not exclude an atypical pneumonia as a rare cause of his perimyocarditis, despite the gastroenteritis history.

Because of the potential evolution to a dilated cardiomyopathy the optimal and timely diagnosis, treatment and follow up are crucial.

#1112 - Case Report

A 24-YEAR-OLD MAN WITH DEEP VEIN THROMBOSIS WITH NO APPARENT CAUSE

Ricardo De Los Rios De La Peña, Estefanía Martínez De Viergol Agrafojo, Ángela Soler Gómez

Hospital Universitario Puerta del Mar, Cádiz, Spain

Introduction

Deep vein thrombosis is a disease in which the blood fails to return from the peripheral venous system due to an obstruction of the vein that runs through an accumulation of platelets that form a thrombus. It is much more frequent in the lower limbs than in the upper limbs, as well as in women more than men. Among the possible risk factors for suffering this disease are smoking,

pregnancy, immobility, recent surgery, cancer or coagulation disorders, and others. Treatment involves anticoagulation full doses in acute disease and prophylaxis dose after a period of initial treatment, which can vary between 6 and 12 months.

Case description

A 24-year-old man attended the emergency department due to an enlarged left lower limb, with pain and redness. As an important background, it is important not to be a smoker, not to present cardiovascular risk factors, to have been operated on for intestinal obstruction with months of life and to have had a sedentary habit the previous month due to study reasons. In the emergency department, the patient is treated with analgesia and a first dose of anticoagulation, analytical is extracted with coagulation and a Doppler ultrasound of the affected limb is requested, where a thrombus that occludes the venous circulation of the left femoral and inguinal vein is discovered. Enter internal medicine for broader study. He is tested for coagulation disorders and serologies, being normal. To complete the study, thorax and abdomen CT angiography is requested, where a genetic venous malformation is found, an aplasia of the inferior vena cava, which causes the patient's thrombosis. Upon discharge, anticoagulation was prescribed with Edoxaban 60 mg for 6 months, being replaced by Rivaroxaban 10 mg, which should be taken for life.

Discussion

The duration of anticoagulation is not yet securely established. Most authors describe a minimum of 6 months of treatment, with subsequent revisions for suspension or change treatment. In cases of genetic malformation of blood vessels, as was our case, several studies have described the need for anticoagulation at prophylactic doses for life, since the recurrence of thrombosis has been proven in the majority of patients who stopped treatment.

ISCHEMIA-INDUCED PATTERN OR INCIDENTAL FINDING?

Paulo Duarte Medeiros, Ana Sá, Vanessa Palha, Teresa Pimentel, Narciso Oliveira, Carlos Capela

Hospital de Braga, Braga, Portugal

Clinical summary

This is the ECG of a 77yo woman with history of hypertension that presented to the emergency room with complaints of epigastric pain that started 2h before.

On her physical examination we highlight an irregular heart rhythm and a tender abdomen.

The ECG revealed a ventricular trigeminy pattern, HR 75/min. Myocardial necrosis markers were negative. We performed an abdominal ultrasound that revealed thickened mesoappendix fat, which helped us making the diagnosis of appendicitis.

Acute appendicitis is a common diagnosis, but in this case the patient lacked other symptoms and the pain was mainly epigastric;

thus, we also ruled out the possibility of atypical myocardial infarction presentation. Finally, we should know that ventricular trigeminy does not signify myocardial ischemia.

HIGH BLOOD PRESSURE DIFFERENCE BETWEEN BOTH UPPER LIMBS AS A DEBUT OF SUBCLAVIAN STEAL SYNDROME

Mario Salcedo¹, Sergio Palacios-Fernandez², María Sahuquillo¹, Jon Ortiz¹, Cristina Campo¹, Carmen Morata¹, Francisco Javier Salcedo Aguilar³

¹ Hospital Universitario y Politécnico La Fe, Valencia, Spain

² Hospital Clínico Universitario San Juan, San Juan De Alicante, Spain

³ Hospital San Pedro, Logroño, Spain

Introduction

A 53-year-old woman referred to external consultations of Internal Medicine for significant blood pressure difference between both upper limbs.

Personal background: smoking, arterial hypertension since one year ago, dyslipidemia and chronic ischemic heart disease (acute myocardial infarction with stent implantation 8 years before).

Case description

Physical examination revealed a blood pressure in the upper right limb of 140/90mmHg and 190/110mmHg in the left one.

Measurement of central arterial pressure was performed by flattening tonometry (Sphygmocor® system), which obtained a value of 160/100mmHg.

Subsequently, the following study was carried out:

- Echocardiogram showed slight septal hypertrophy without evidence of aortic coarctation;
- CT-angiography of supra-aortic trunks revealed a proximal focal critical stenosis in the right brachiocephalic trunk;
- Arteriography confirmed this stenosis. There was a retrograde (reversed) blood flow in the right vertebral artery. The right arm was supplied by blood flowing in a retrograde direction down the right vertebral artery at the expense of

the vertebrobasilar circulation. This is called subclavian steal syndrome;

- A brain MRI showed cortico-subcortical infarcts in areas of border zone, which suggested previous episodes of cerebral hypoperfusion.

Given the cerebral repercussion of this stenosis, and the risk of hypoperfusion with antihypertensive treatment, the patient is awaiting revascularization, despite the haemodynamic complexity of this procedure.

Discussion

In the initial diagnostic evaluation of a patient with hypertension, blood pressure should be systematically measured, and determinations should be made in both arms. When there is a blood pressure gap higher than 10mmHg between both upper limbs, a vascular study of the supra-aortic trunks must be carried out, ruling out stenosis of the subclavian artery, aortic coarctation or less common problems, such as brachiocephalic trunk stenosis. The most frequent etiology is the presence of arteriosclerotic lesions.

The measurement of central blood pressure can assist with the intensity of pharmacological treatment in these patients, until the defect is corrected.

#1131 - Abstract

VASCULAR RISK IN ELDERLY

Sara Muñoz Alonso, Victor Madrid Romero, Victoria Palomar Calvo, Carlota Tuñón De Almeida, Ana Isabel Rodrigo Martín, María Esther Fraile Villarejo, Montserrat Chimeno Viñas
Complejo Asistencial De Zamora, Zamora, Spain

Background

The elderly, patients over 65 years old, are increasing population figures in developed countries. Vascular diseases are leading causes of mortality and disability in elderly people.

In this study we evaluated vascular risks factors (hypertension, dyslipidemia and diabetes) in patients hospitalized in internal medicine and whether there are differences between elderly, very elderly and great elderly.

Methods

Observational descriptive retrospective study.

Patients were divided into three age groups: elderly (65-79 years), very elderly (80-89 years) and great elderly (more than 90 years). We analyzed vascular risk factors (hypertension, dyslipidemia and diabetes) in each age group as well as the percentage of total dependency measured by the Barthel scale.

Results

304 patients admitted to internal medicine were obtained, of which 50 were excluded because they were under 65 years old, hence n= 254 patients.

22.8% were elderly (total dependency 13.8%), 56.3% were

very elderly (total dependency 45%) and 20.9% were great elderly (total dependency 58.5%). Differences were found in the proportion of hypertensive patients according to their age range ($X^2=7.6$, $p<0.05$), the very elderly and great elderly had higher blood pressure (76.9% and 77.8%) than the elderly (58.6%). In the rest of the vascular risk factors evaluated (diabetes, dyslipidemia) they were not found in greater proportion in the very elderly and great elderly patients.

Conclusion

It is clear that high blood pressure and age are directly related. We need to be cautious and individually evaluate the start or maintenance of drugs for vascular risk control. The main factors to be taken into account in this population group are life expectancy, comorbidity and functional capacity.

Since more than half of the very elderly are totally dependent in this study, perhaps vascular risk control drugs should not be used in this population group.

#1137 - Abstract

ASSOCIATION WITH NEW-ONSET ATRIAL FIBRILLATION AND CANCER: A RETROSPECTIVE STUDY

Alda Tavares¹, Sara M. Pinto², Mário Bibi², Rute Ferreira², Cristina Rosário²

¹ Department of Medical Oncology, Hospital Pedro Hispano, Matosinhos Local Health Unit., Matosinhos, Portugal

² Department of Internal Medicine, Hospital Pedro Hispano, Matosinhos Local Health Unit., Matosinhos, Portugal

Background

An association between atrial fibrillation (AF) and cancer has been reported, likely because of systemic inflammation, shared risk factors, and common disease states underlying both conditions in ageing populations. Recent studies suggest that cancer increases the risk of new-onset AF (NOAF). The aim of this study was to describe clinical characteristics associated with NOAF in cancer patients.

Methods

A retrospective study was conducted, among patients (pts) admitted with AF in our Internal Medicine Ward, between April of 2014 and June of 2015. The pts with a cancer diagnosis in the last 60 months were selected and epidemiological and clinical data were collected. Active cancer was defined for diagnosis of cancer or any anti-cancer treatment within 6 months before admission. Statistical analysis was performed with SPSS® software v25; values $p<0,05$ were considered statistically significant.

Results

Among 214 pts admitted with AF, 19 (8.8%) had a diagnosis of cancer in the last 60 months. Of whom, 14 (33.7%) had active cancer. Breast (21.1%), colorectal (21.1%), lung (15.8%) and

prostate cancer (15.8%) were the more frequent types of cancer. Metastatic disease presented in 5 pts (26.3%).

NOAF was diagnosed in 7 pts (36.8%) with a diagnosis of cancer in the last 60 months and 6 (42.9%) with active cancer. Comparing clinical characteristics between the groups with/without a new-onset AF, no significant differences were found concerning age, sex, and comorbidities. Attended to a type and metastatic cancer, only pts with active lung cancer had a higher rate of new-onset AF with significant difference ($p=0.036$).

The median interval of diagnosis AF and cancer was 23 months (1-147). No significant differences were found concerning the rates of NOAF between groups with a diagnosis of cancer in the last 24, 12, 6, and 3 months.

Anti-cancer therapy in the last 6 months was executed in 8 pts (42.1%): surgery in 4, chemotherapy in 4, radiotherapy in 4, and hormonotherapy in 4 pts. A NOAF was more frequent in the group submitted to treatment, but not statistical significance.

Conclusion

In this retrospective study, only active lung cancer was associated with NOAF. Larger studies for evaluating the association with AF and cancer are needed, to identify cancer parameters associated with NOAF.

#1157 - Abstract

TROPONIN TRENDS IN PATIENTS WITH MYOCARDITIS: A CASE SERIES

Vera P Sarmiento, Bruno Piçarra, João Pais, Mafalda Carrington, Ana Rita Santos, Margarida Massas, Diana Coutinho, Tereza Veloso, José Aguiar

Hospital do Espírito Santo de Évora, Évora, Portugal

Background

It is generally understood that patients with myocarditis present with a descending troponin curve, unlike patients with acute coronary syndromes, though the evidence for this belief is not clear. We designed this study to determine the troponin trends in patients with myocarditis.

Methods

We have identified all patients admitted with MRI-confirmed myocarditis to the Cardiology ward of a central hospital, from 2014 to 2016. We registered socio-demographic and clinical variables, including the individual troponin values obtained for each patient. We analysed the data descriptively, comparing the groups in relation to the different troponin trends found. Patients with less than three troponin measurements were excluded.

Results

There were 54 patients admitted with myocarditis to the Cardiology ward, from which 42 (78%) were men, median age 33 (IQR 24,5-48), 42 had at least one cardiovascular risk factor, more frequently hypertension, and two patients had previous

episodes of myocarditis. There were 35 patients (65%) reporting an infection in the previous 30 days. All patients, except one, presented with pain, 20 patients had documented fever, 30 (56%) patients presented with ST elevation in the 12-lead EKG. We included 42 patients in the troponin trend analyses (the remaining 12 had less than three troponin values measured). For 25 patients (62%) the troponin increased in the first hours to days of presentation, and then began its descending curve (inverted U-shaped curve). Most of these patients had a maximum troponin value at 6-24h of presentation. In 16 cases, the troponin followed a descending-only curve. In one case, there was a second increase in troponin at 72h of presentation, followed by a decrease of its value.

Conclusion

The troponin trends of patients with myocarditis is varied. In our series, more than half of the patients presented an inverted U-shaped curve, similar to that of acute myocardial infarction patients. Therefore, the troponin trend does not seem a reliable tool to support the differential diagnosis between myocarditis and acute coronary syndromes, though larger studies are needed in order to confirm our findings.

LIPODERMATOSCLEROSIS

Sara Braga, Joana Ribeiro

Hospital Sousa Martins, Guarda, Portugal

Clinical summary

Lipodermatosclerosis (LDS) is a skin inflammation occurring usually in the legs, caused when venous blood doesn't return to the heart. Increased blood pressure in the veins can cause diffusion of substances, like fibrin, out of capillaries, leading to ulceration. Recurrent ulceration and necrosis can develop LDS. In advanced LDS the proximal leg swells from chronic venous obstruction and the lower leg shrinks from chronic ulceration and necrosis resulting in the inverted coke bottle appearance of the lower leg. These legs belong to a 46-year-old man with a congenital pulmonary valve stenosis, whose treatment (after commissurotomy and tricuspid ring implantation) is based on medication and follow-up of heart failure, sometimes presenting severe decompensation which leads to hospitalization.

Figure #1162. Lipodermatosclerosis, male, 46 years old.

LIVING WITH A COMPLETE ABDOMINAL AORTA THROMBOSIS

Luisa Costa, Andreia Silva, Ana Rodrigues, Carolina Ferreira, Jesus Garrido, Carla Lima, Sérgio Lemos

Centro Hospitalar Tondela Viseu, Viseu, Portugal

Clinical summary

A 54-year-old man, presented to the emergency department with back pain and anuria. On examination, his blood pressure was 190/120 mmHg, no femoral pulse and collateral abdominal circulation. Laboratory evaluation identified serum creatinine of 9.9 mg/dL, hyperkalemia of 7.6 mmol/L and blood urea nitrogen level of 292 mg/dL, that motivated hemodialysis support. A contrasted abdominopelvic computed tomography revealed a mural thrombus causing total occlusion of the abdominal aorta immediately below the emergence of the superior mesentery artery, including renal, iliacs and femoral arteries, with exuberant collateral circulation. Treatment consisted of conservative measures and chronic hemodialysis. The patient died two years later, after a pancreatitis, remaining autonomous until that day.

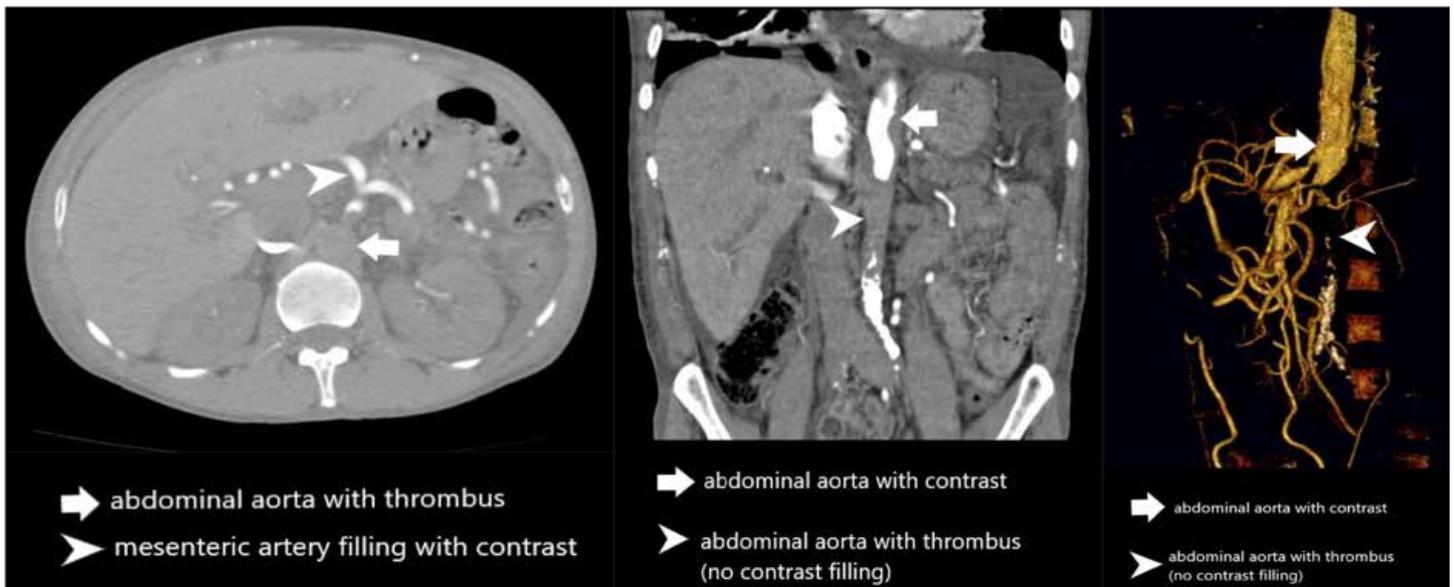

Figure #1163. CT scan - Abdominal aorta thrombus.

#1169 - Abstract

ATRIAL FIBRILLATION AND HEART FAILURE: A COMBINATION FOR DISASTER?

Sara Moreira Pinto, Alda Tavares, Mário Bibi, Rute Morais Ferreira, Cristina Rosário

Hospital Pedro Hispano, Oporto, Portugal

Background

Atrial fibrillation (AF) is the most common sustained arrhythmia. Its development and stability are directly related to the patients morbidity, such as Heart Failure (HF). If on one hand HF promotes AF, this one also influences the course and exacerbations of HF. We analysed patients admitted with AF and HF, in terms of demographic, treatment approach and risk of readmissions.

Methods

A retrospective study was conducted among patients admitted in an Internal Medicine Ward, between April of 2014 and June of 2015. The patients with AF were selected and epidemiological, clinical and analytical data were collected and analysed. Statistical analysis was performed with SPSS® software v25; values $p < 0,05$ were considered statistically significant.

Results

A total of 236 admissions and 214 patients were examined, with a median age of 77 years and 66% of women. A total of 41% of AF were classified as inaugural. Fifty percent of patients had the diagnosis of HF at admission, in which 53% were in class II of NYHA; 12% in class I; 22% in class III and 2% in class IV. Of these patients, only 65% were anticoagulated at discharge, mostly with vitamin K antagonists (75%), 9% with apixaban, 8% with dabigatran and 3% with rivaroxaban. Sixteen percent of patients had an ejection fraction lower than 35%. During hospital admission 8% of patients with AF and HF died and 17% died in the first year after discharge.

When it comes to anticoagulation and poor outcome, 10% of anticoagulated patients died in the first year compared to 39% of deaths in non-anticoagulated patients ($p=0.001$). In terms of readmissions in the first 6 months, there were 76 readmissions in AF and HF patients, compared to only 54 readmissions in patients without HF.

Conclusion

With population aging, HF and AF will be more prevalent, making the diagnosis, stratification and correct treatment more important. Only by acting on both, we can manage a better quality of life for our patients, free from exacerbations, hospital admissions and symptoms. We verified a worst outcome in patients that were not anticoagulated at discharge, as expected. According to several studies, catheter ablation is a possibility we need to consider in patients with ejection fraction lower than 35%. In our study, there were a significant percentage of patients (16%) that could had benefited from this treatment. More studies will be necessary in order to demonstrate efficacy and safety of this procedure, as well as the real impact in the lives of our patients.

#1170 - Abstract

ANTICOAGULATION IN PATIENTS WITH ATRIAL FIBRILLATION AND CHRONIC KIDNEY DISEASE: A RETROSPECTIVE STUDY

Sara Moreira Pinto, Mário Bibi, Alta Tavares, Rute Morais Ferreira, Cristina Rosário

Hospital Pedro Hispano, Oporto, Portugal

Background

Atrial fibrillation (AF) is the most common sustained arrhythmia and is directly dependent on patient morbidity, such as chronic kidney disease (CKD). There is a clear dichotomy between these

entities, being indispensable the evaluation of CKD and its stage before starting anticoagulation. If on one hand, in stages 3 and 4 of CKD the main concern is the thrombotic risk, in stage 5 the hemorrhagic risk is more substantial. As so, it became imperative to find alternative strategies for those patients.

Objective: Analysis of demographic data and treatment approach in patients with CKD and diagnosis of AF.

Methods

A retrospective study was conducted, among patients admitted in our Internal Medicine Ward, between April of 2014 and June of 2015 with AF. Epidemiological, clinical and analytical data was collected and analysed.

Results

A total of 236 admissions and 214 patients were examined, with a median age of 77 years and 66% of women. A total of 41% of AF were classified as inaugural. Twenty percent of patients had stage 3 CKD, 7% had stage 4 CKD and 1% had stage 5 CKD. Of these patients, just 57%, 56% and 67% respectively were anticoagulated at discharge, even with clear superior CHA₂DS₂-VASc (median of 4) when compared to HAS-BLED (median of 1). Vitamin K antagonists were the first choice in anticoagulation, prescribed in 70% of stage 3 CKD, 44% of stage 4 CKD and 100% of cases in stage 5 CKD. The preferred direct oral anticoagulant (DOAC) was apixaban in 15% of stage 3 CKD patients and 44% of stage 4 CKD. Rivaroxaban was used in 11% of patients in stage 3 CKD. No patient was proposed to closure of auricular appendix.

Conclusion

The presence of CKD in AF patients plays a big role in the decision of anticoagulation, being in many cases responsible for the decision of not anticoagulate. This may reflect the fact that fewer than 50% of patients with AF and CKD were anticoagulated at discharge in our cohort. On the other hand, vitamin K antagonists remain the preferred drugs, most likely because they are older and are able to be monitored through INR. There is a need for more prospective studies that show the efficacy of auricular appendix closure, as well as studies in the safety of DOACs. Even so, regarding DOAC, apixaban is the only currently approved by United States Food and Drug Administration in all stages of CKD, presenting with a low hemorrhagic risk.

#1216 - Abstract

INFLUENCE OF DISABILITY ON LONG-TERM PROGNOSIS OF HEART FAILURE PATIENTS WITH PRESERVED EJECTION FRACTION

Aicha Alaoui-Quesada, Aída Gil-Díaz, Yonay Ramírez-Blanco, Dolores Pérez-Ramada, Héctor Rosario-Mendoza, María Eugenia Arkuch-Saade, Alicia Conde-Martel

Hospital Universitario de Gran Canaria Dr. Negrín, Las Palmas De Gran Canaria, Spain

Background

Heart failure is a frequent syndrome seen in Internal Medicine, being predominant in our patients the advanced age, multimorbidity and preserved ejection fraction. The natural history and optimal treatment of these patients remains unclear. Recognition of prognostic risk factors is relevant to identify patients with advanced heart failure who could benefit from a closer follow-up and need of palliative referral.

Methods

We performed a prospective observational study of patients from Internal Medicine consultations with chronic heart failure and preserved ejection fraction. We collected demographic and clinical characteristics including functional capacity measured with the Barthel index, analytical and echocardiographic parameters, emergency visits and hospitalizations due to heart failure decompensation. We analyzed the association of mortality between categorical variables with Chi-square or Fisher test and T-Student or Mann Whitney test for the categorical and continuous variables. We obtained the predictive mortality variables with a Cox regression model.

Results

160 outpatients were studied with a follow up of 2 years, being 38.8% males with an average age of 79.35 and 61.2% women with an average age of 79.91. The most frequent comorbidities were: hypertension (98.1%), atrial fibrillation (73.7%), anemia (69.3%) and chronic renal failure (58.6%). The observed mortality was 45.6%. The main cause was a cardiovascular origin (63.3%), being 94.7% of them due to refractory heart failure. There were no sex differences. Variables associated with mortality were: age ($p=0.028$), ischaemic cardiopathy (OR 2.22, $p=0.026$), hyperuricemia (OR 2.25, $p=0.019$), frailty (OR 4.05, $p=0.002$), creatinine plasmatic levels ($p=0.005$), hemoglobin ($p=0.002$), sodium ($p=0.007$), Barthel index below 60 (OR 2.93, $p=0.014$) and more than 6 days of hospitalization during the previous year (OR 4.50, $p=0.002$).

Predictive mortality variables in the multivariable Cox regression were Barthel index <60 points (HR 3.32. IC95% 1.67-6.60. $p=0.001$), creatinine >2 mg/dl (HR 5.75. IC95% 2.17-15.19. $p<0.001$), sodium <140 mEq/L (HR 2.04. IC95% 1.06-3.95. $p=0.034$) and more than 6 days of hospitalization in the last year (HR 3.53. IC95% 1.28-9.76. $p=0.015$).

Conclusion

Patients with preserved ejection fraction had a high long-term death rate. Poor functional basal status determined by Barthel index, renal insufficiency, plasmatic sodium and hospital admission predicted mortality.

#1217 - Abstract

DYSLIPIDEMIE DURING DIFFERENT THERAPEUTIC DISEASE

Marina Noniashvili

Tbilisi State Medical University, Tbilisi, Georgia

Background

Study of lipid spectrum changes during different therapeutic pathologies.

Methods

Retrospectively was studied the history of 267 patients (181 women and 86 men, whose average age was 42+15,1 years). They were treated with different diagnoses: thyroid pathologies (97 patients), respiratory system diseases (106), kidney pathologies (20), pathology of joints (37), and gastrointestinal diseases (7). Age groups were allocated: under 40 years: -125 patients, above 40 years: -142 patients. The lipid spectrum indicators, the characteristics of dyslipidemia and the results of antilipid treatment were assessed.

Results

Lipid spectrum was examined in 89,7% with thyroid gland pathology. Dyslipidemia was revealed in 46%, and was treated 50%. During the respiratory system pathologies, the lipid spectrum detection was done 4 times less in 24% of patients, dyslipidemia was revealed in 46%, only 8,3% ($p < 0,05$) was treated by antilipid medicine. In kidney pathologies lipidogram was conducted in 40%, Dyslipidemia was detected only in 12.5%. The rate of lipid spectrum detection was the lowest in patients with joints diseases and was examined in 10.10%, dyslipidemia was revealed in 25% ($p < 0,05$). The lipid spectrum in patients with gastrointestinal system pathologies was investigated in 85,7%, and only in 16.6% was detected dyslipidemia.

In patients with thyroid pathologies according to the lipid spectrum, were revealed high rates of triglycerides and total cholesterol -32, 5% and 25% -isolated high rates of total cholesterol; Hypertriglyceridemia 15%, common cholesterol and low Density lipoproteins in 10%, all atherogenic fractions was increased in 17.5%. In patients with respiratory diseases increased total cholesterol have been reported in 41.6%; high rates of triglycerides and total cholesterol in 25.3%; all atherogenic fractions was increased in 25%; only in 8% high rates of triglycerides was revealed. ($p=0.5$).

Conclusion

Thus, patients with chronic pathologies of thyroid gland have high levels of dyslipidemia and treatment. Insufficient control of the lipid spectrum was revealed in patients with respiratory system diseases, kidneys, joints' and other pathologies. High frequency of lipid spectrum detection and low levels of dyslipidemia were observed during gastrointestinal pathologies. Thus, in patients with different therapeutic pathologies it is recommended to control lipid spectrum regardless of age, especially if you have a risk factors of CVS diseases.

#1220 - Abstract

IN-HOSPITAL MORTALITY IN HEART FAILURE NONAGENARIAN PATIENTS. RECANIC SUBANALYSIS.

Aída Gil-Díaz¹, Jose María García Vallejo¹, Elvira Sáez-Martínez¹, Iván Marrero-Medina¹, Melitón Dávila-Ramos², Alina Pérez-Ramírez³, Antonio García-Quintana¹, Alicia Conde-Martel¹

¹ Hospital Universitario de Gran Canaria Dr. Negrín, Las Palmas De Gran Canaria, Spain

² Hospital Universitario Nuestra Señora de La Candelaria, Santa Cruz De Tenerife, Spain

³ Hospital Universitario de Canarias, San Cristobal De La Laguna, Spain

Background

Heart failure is the first cause of admission in older patients. Age and multimorbidity are related. Nevertheless, some studies have suggested that geriatric components (frailty, cognition, nutrition or functional status) play a role in the prognosis of these patients. It is important to identify elderly patients with worse prognosis in order to improve the medical care and quality of life.

Methods

We performed a prospective multicenter observational study in the Canary Islands hospitals (RECANIC) with patients admitted in Cardiology and Internal Medicine departments due to heart failure. In this abstract we considered only patients older than 75 years. We collected demographic and clinical characteristics including functional capacity measured with the Barthel index, NYHA functional class, left ventricular ejection fraction (LVEF), analytical parameters, treatments and clinical evolution. We compared nonagenarian prognosis with older than 75 years with Chi-square or Fisher test for categorical variables and T-student or Mann-Whitney test for the categorical and continuous variables. We obtained the predictive mortality variables with a multivariable logistic regression.

Results

2200 patients were registered in the RECANIC study, out of which 1365 were older than 75 years old, with 193 nonagenarians. Nonagenarians were mostly women ($p < 0.001$), presenting more renal insufficiency ($p < 0.001$), cognitive impairment ($p < 0.001$), institutionalization ($p = 0.012$) and worse functional status in the Barthel index ($p < 0.001$) compared to 75-89 year old patients. Preserved LVEF was the most prevalent finding in both groups. Respiratory infections were the main cause of heart failure decompensation. Mortality of nonagenarians was greater (16.1 vs 9.6%) than patients within 75-89 years ($p = 0.009$). Variables associated with mortality in nonagenarians were: dyslipidemia ($p = 0.007$), cognitive impairment ($p = 0.012$), renal function measured by GFR (MDRD) below 30 ($p < 0.001$), NT-proBNP ($p = 0.007$) and potassium serum levels ($p < 0.001$). Predictive mortality variables of nonagenarian inpatients in the multivariable logistic regression were: masculine gender (HR 5.04. IC95% 1.54-16.51. $p = 0.008$), Barthel index < 60 (HR 3.44. IC95% 1.20-9.87. $p = 0.021$) and GFR < 30 (HR 14.36. IC95% 4.42-46.66. $p < 0.001$).

Conclusion

Nonagenarians constitute 8.77% of the total admissions due to heart failure. In-hospital mortality is superior to less elderly patients and is related to sex, poor functional capacity and renal insufficiency.

#1227 - Abstract

DIABETES AND CARDIOVASCULAR RISK - ANALYSIS OF PATIENTS FOLLOWED IN THE MEDICAL CONSULTATION OF DIABETOLOGY

Natália Teixeira Nunes Teixeira¹, Ana Rita Paulos¹, Ana Mestre², Marta Cerol¹

¹ Hospital Distrital Santarém, Santarém, Portugal

² Hospital Distrital Santarém, Santarém, Portugal

Background

Diabetes mellitus (DM) is closely associated with cardiovascular disease (CV), which is a huge challenge considering the prevalence, resources mobilized for treatment and inherent morbidities. Macrovascular complications continue to be one of the most common causes of death. Objectives - characterization of the cholesterolemic profile in a group of patients with DM, CV risk analysis and therapeutic strategies.

Methods

Retrospective study of patients with DM, followed in a Diabetology consultation in 2017. Data were collected between the first and last visit performed in the referred period, through SClinico and the statistical analysis performed in Excel.

Results

The total number of patients was 108. The mean disease duration was 17 years, the male gender predominated (51%), the most frequent age group was 61-70 years old, with a mean age of 64.5 years and 87% were type 2 diabetics. Mean hemoglobin A1C was 8%, and about 56% of patients were obese. Presence of hypertension in 76.4%, dyslipidemia in 61.4%, sedentary lifestyle in 38.7% and smoking in 8.7% of the cases. Regarding LDL cholesterol levels, 81.4% had values > 70 mg / dl and 78.3% had HDL <60 mg / dl. The mean overall cardiovascular risk (CVR) according to the ASCVD risk score was elevated by 31.2%. 62% had statins, 87.4% antihypertensive therapy, 39.8% antiplatelet aggregation and 7.6% oral hypocoagulation. The most commonly prescribed statins are simvastatin, followed by atorvastatin. The most common macrovascular complications were coronary disease (42.03%), peripheral arteriopathy (19.27%) and cerebrovascular disease (13.68%).

Conclusion

In view of the results obtained, the therapeutics directed to this area of the disease should be optimized and intensified, namely in the selection of the statin more appropriate to the RCV profile.

#1232 - Case Report

CONVOLUTED SIMPLICITY: A CASE OF ORTHOSTATIC HYPOTENSION, HIDING MULTIPLE UNRELATED CONTRIBUTORY CAUSES

Pietro Di Francesco, Alice Monti, Elisa Ceriani, Davide Villa, Giorgio Mantoan, Nicola Montano, Eleonora Tobaldini

Department of Internal Medicine, Fondazione IRCSS Ca Granda, Ospedale Maggiore Policlinico, and Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy

Introduction

Orthostatic hypotension is a clinical manifestation of an underlying disease that in older patients is commonly related to an autonomic nervous system dysfunction. While Occam's razor prompts us to look for a common origin, a single mechanism might hide multiple predisposing factors.

Case description

A 81 y.o. man presented to the emergency department (ED) after two pre-syncope episodes. Medical history included type 2 diabetes, colon cancer recently treated with an emicolectomy and previous history of pre-syncope episodes.

In ED, physical examination revealed a systolic murmur, ECG showed first degree AV block and blood test revealed acute pre-renal failure. The bed-side echocardiogram showed mild pericardial effusion without tamponade. Thus, we performed a chest CT, that was negative for aortic dissection but it revealed a right hemi-diaphragmatic elevation that causes a significant compression of the right heart and a left shift of mediastinum.

The patient revealed significant orthostatic hypotension while echocardiogram highlighted a moderate dynamic subaortic stenosis exclusively in orthostatic position.

The patient was treated with low dose bisoprolol and intravenous hydration for subaortic stenosis and pre-renal failure. No surgical options were available for hemi-diaphragmatic elevation.

After few days of treatment, the patient had no more orthostatic hypotension; the echocardiogram was repeated and it showed normal trans-aortic velocity even during standing.

Thus, this patient had three different factors that contributed to decrease cardiac output causing pre-syncope. First, cardiac subaortic stenosis, treated with beta-blockers. Second, the mechanical compression of the elevated diaphragm. Finally, hypovolemia, which worsened the pre-existing conditions and that was treated with fluid supplementation.

Discussion

A careful evaluation of all the possible mechanisms involved in the pathogenesis of a disease and an accurate use of echocardiography, not only in static but also in dynamic situation, helped finding the correct treatment in this tricky situation that could, at first glance, lead to a misinterpretation of the available data.

#1242 - Abstract

MARKERS OF CALCIUM METABOLISM IN CALCIFIC AORTIC VALVE DISEASE

Madina Khasanovna Baikulova¹, Elena Vital'Evna Shcheglova², Olga Igorevna Boeva²

¹ Regional Clinical Cardiology Centre, Stavropol, Russia

² Stavropol State Medical University, Stavropol, Russia

Background

Disturbances of mineral metabolism are common among elderly people and are potentially involved in the development of calcifying aortic valve disease. In particular, in chronic kidney disease, when electrolyte disorders are especially pronounced, high levels of calcium and phosphate significantly increase the risk of valvular heart disease. In addition, primary hyperparathyroidism is associated with the risk of aortic stenosis. These data suggest that some characteristics of calcium metabolism may determine susceptibility to calcific aortic valve disease in the general population of patients who do not suffer from severe concomitant pathology. The aim of the study was to test the hypothesis about the association of blood levels of calcium metabolism markers, such as parathyroid hormone, vitamin D and ionized calcium, with calcifying aortic valve disease.

Methods

The objects were 108 patients with tricuspid aortic valve calcification over the age of 65 years. Calcification and aortic valve stenosis were verified using transthoracic echocardiography. A comparison group consisted of 58 patients without signs of aortic valve pathology, comparable to the main group by sex, age, clinical features, anamnesis, structure of cardiovascular pathology and drug therapy. Serum concentrations of human intact parathyroid hormone and 25-hydroxy vitamin D were detected by ELISA.

Results

In patients with calcifying aortic valve disease, serum concentrations of parathormone and ionized calcium were significantly lower. The 25OH level of vitamin D was significantly lower in women of the both groups. The correlation analysis has shown no association of parathyroid hormone and 25OH vitamin D with echocardiography and laboratory parameters.

Conclusion

Thus, in patients with cardiovascular pathology, the presence of calcifying aortic valve disease is associated with lower serum concentrations of parathyroid hormone and ionized calcium, which may indicate their pathogenetic role in this disease.

STRESS CARDIOMYOPATHY

Claudemira Fernanda Pinto, Filipa Silva, Maria Inês Matos, Maria Teresa Brito, Joana Tender Vieira, Mariana Ferreira Almeida, Bruno Besteiro, Jorge Almeida

Centro Hospitalar de São João, Porto, Portugal

Introduction

Stress Cardiomyopathy (CMS) is characterized by transient systolic dysfunction of the left ventricle, and may sometimes mimic an acute myocardial infarction, in the absence of obstructive coronary artery disease.

Case description

We describe a case of an 87-year-old man, who was brought to the emergency department (ED) after a fall, without loss of consciousness, chest pain or palpitations, with right thoracic and temporal trauma. He had been lying down for several hours until was found by a relative. In terms of past medical history he had hypertension, heart failure with preserved ejection fraction, atrial fibrillation and epilepsy. On initial evaluation at ED he complained of chest compressive pain, was conscious, disoriented, blood pressure of 155/99 mmHg, pulse of 71/min, respiration of 16/min and oxygen saturation was 98% in room air. Cardiovascular and pulmonary examination was normal and his abdomen was soft without tenderness. No pain at palpation of the spine. The EKG showed left axis deviation, Q waves in the inferior leads, V1 and V2. The blood tests on admission showed anemia of Hb 10.6 g/dL, thrombocytopenia of 76,000x10⁹/L (already present in 2016), normal C-reactive protein, BNP level of 1088 pg/ml. INR 1.9. Chest X-rays did not show rib fractures, hemo/pneumothorax. Brain CT scan at admission and at 24 h without evidence of intra- or extra-axial traumatic or hemorrhagic lesions. There was an elevation of high sensitivity troponin I up to 758 ng/L. Was evaluated by Cardiology, who performed a transthoracic echocardiography that showed moderate to severe dysfunction of the left ventricular, mid-apical akinesia and vigorous contractility of the basal segments. In view of the typical findings previously described and the stress induced by the fall and, the hypothesis of Takotsubo syndrome was considered and the patient was admitted in the Internal Medicine Department. During the hospitalization, favorable evolution was observed; the patient remained asymptomatic, with hemodynamic stability and progressive reduction of troponin I (maximum value of 758.3 ng/L to 119.3 ng/L at the time of discharge). Repeated EKG revealed evolution with inversion of T waves in the anterior wall. Myocardial perfusion scintigraphy showed a left ventricular perfusion without changes.

Discussion

CMS is a diagnosis of exclusion in patients with suspected ACS, with favorable prognosis. This case is highlighted by its atypical characteristics with absence of cardiovascular symptoms and installation timing.

#1263 - Abstract

VENOUS RECANALIZATION AFTER A THROMBOEMBOLIC EVENT IN A TUNISIAN POPULATION

Mohamed Sami Zrida^{1,2}, Maroua Mrouki^{1,2}, Yosra Cherif^{1,2}, Fatma Ben Dahmen^{1,2}, Meya Abdallah^{1,2}

¹ Tunis El Manar University Faculty of Medicine of Tunis, Tunis, Tunisia

² Regional Hospital Ben Arous, Internal Medicine Department, Ben Arous, Tunisia

Background

The aim of this study was to assess the prevalence of recanalization in control imaging of patients followed for venous thromboembolic disease at the end of treatment with vitamin K antagonists (VKA) and to investigate the factors that may influence it.

Methods

A prospective, longitudinal and descriptive study involving patients with venous thromboembolic disease treated by VKA was conducted in an internal medicine department between January 2015 and December 2017. Control imaging was performed for each patient at the end of the agreed period of anticoagulation. The studied population was subsequently divided into two groups according to the absence or presence of venous recanalization in the control imaging in order to investigate its influencing factors.

Results

Sixty patients were included in this study whose average age was 56 years. Twenty-nine patients were male and 31 were female. Eighty percent (n=53) of patients lived in urban areas and 12% (n=7) lived in rural areas. Fifty (83%) patients had deep vein thrombosis (DVT), 9 (15%) had pulmonary embolism (PE), and one (2%) had superficial thrombophlebitis. Twenty one (35%) were smokers and 19 (32%) were obese. Two patients had a family history of venous thromboembolism (VTE) and 3 had a personal history of VTE. Seventeen percent of the studied population had varicose veins in the lower limbs. High blood pressure was noted in 18 (30%) patients, diabetes in 11 (18%) patients, dyslipidemia in 11 (18%) patients, cardiac pathology in 3 (5%) patients, hypothyroidism in 4 (7%) patients and active cancer in 2 (3%) patients. Twenty-two percent (n=13) of the total patients had recent surgery and 3 (5%) patients had an orthopedic cast. The agreed period of treatment was 6 months in 92% (n=55) of cases, 3 months in 6% (n=4) of cases and 1 month in 2% (n=1) of cases. At the control imaging, 65% (n=39) of the patients had totally recanalized and 33% (n=20) had partially recanalized. A complete absence of recanalization was noted in only one case (2%) after 6 months of treatment with AVK. Among the factors studied, only the urban / rural living environment had a statistically significant effect on venous recanalization.

Conclusion

VTE is a common and multifactorial disease. The determination of the optimal duration of anticoagulation remains a challenge

for clinicians. Control imaging is not common during therapeutic follow-up of VTE cases. However, it may help to optimize the duration of anticoagulation.

#1276 - Case Report

CHAGAS CARDIAC DISEASE, A DISEASE THAT MUST BE KEPT IN MIND

Irene Cortes Verdasca¹, Miguel Ferreira², Pedro Mota³, Nuno Cardim³

¹ Hospital São Francisco Xavier, Lisboa, Portugal

² Hospital Beatriz Angelo, Lisboa, Portugal

³ Hospital da Luz, Lisboa, Portugal

Introduction

The term Chagas disease is used for the general disease caused by *Trypanosoma cruzi*, a protozoan parasite. The disease is a heterogeneous condition with a wide variation in clinical course and prognosis. Although the majority of infected individuals remain asymptomatic throughout life, some develop only conduction defects and mild segmental wall motion abnormalities, others develop severe symptoms of heart failure, thromboembolic phenomena, and lifethreatening ventricular arrhythmias.

Case description

A 34-year-old woman natural from Argentina, living in Portugal for nine years, with history of Chagas' disease acquired by congenital transmission, presented to the outpatient clinic with a 2-week history of palpitations. There were no other symptoms or signs of disease at physical examination. Laboratory evaluation confirmed the diagnosis of Chagas' disease by positive IgG serologic test for *Trypanosoma cruzi*; the remaining laboratory evaluation as cardiac markers, thyroid function, inflammatory parameters were normal. The electrocardiogram, 24-hour Holter monitoring and cardiac event recorder showed no arrhythmia or no relationship between symptoms and changes in heart rate or rhythm. Further cardiovascular assessment by transthoracic echocardiogram documented left ventricle cavity at the upper limit of normal with non-hypertrophied walls, with normal ejection fraction and global longitudinal strain, but with infolateral hypokinesia and decreased regional longitudinal strain in this wall. Cardiac magnetic resonance imaging was performed and it revealed dilated left ventricle with segmental alterations (lower wall and apex) with preserved global systolic function; dilated right ventricle without evident changes in regional kinetics and increased T1 and T2 native to the left ventricle, although there was no late enhancement (possible fibrosis and diffuse inflammation). These findings were suggestive of chronic Chagas' myocardiopathy, an early form (indeterminate phase).

Discussion

Chagas disease is an important cause of heart failure. Assessment of cardiac disease in patients with confirmed infection by protozoan trypanosome *cruzi* is crucial to detect early cardiac

impairment and risk stratification before symptoms develop. Characterization of the indeterminate phase has been challenging and it is imperfect because early manifestations can be subtle.

#1280 - Abstract

UNATTENDED COMPARED TO ATTENDED OFFICE BLOOD PRESSURE AND TO 24-HOUR BLOOD PRESSURE MONITORING IN STABLE HYPERTENSIVE PATIENTS

Jan Filipovsky, Jitka Mlikova Seidlerova, Stepan Mares
Charles University Medical Faculty, Pilsen, Czech Republic

Background

Measurement of unattended automated office blood pressure (uAutoBP) may eliminate white-coat effect. This method was used in the recently published SPRINT study. We studied the relationships of uAutoBP to office blood pressure (OBP) measured by the physician and to 24-hour ambulatory blood pressure monitoring (ABPM).

Methods

Stable treated hypertensive subjects were included in this study which was performed in four Czech hypertension centres. uAutoBP was measured with the BPTru device (six measurements), after uAutoBP, OBP was measured six times in the office: three times with auscultatory method (auscOBP), followed by three oscilometric measurements (oscOBP). 24-hour ABPM was performed within one week from the clinical visit.

Results

Data on 172 subjects aged 63.7 ± 12.4 years with OBP $127.6 \pm 12.1/77.6 \pm 10.0$ mm Hg are reported. uAutoBP was by $8.5 \pm 9.0/3.0 \pm 6.1$ mm Hg lower than auscOBP and by $8.6 \pm 8.6/1.9 \pm 5.7$ mm Hg than oscOBP; these differences were relatively homogeneous in all the centres. The uAutoBP-auscOBP difference increased with the auscOBP level and it did not depend on any other factor (age, number of antihypertensive drugs, presence of diabetes, lipid disorders or kidney disease, interval from the morning drug intake). 24-hour mean BP was by $4.2 \pm 12.1/3.5 \pm 7.8$ mm Hg lower than auscOBP and by $4.3 \pm 11.0/0.5 \pm 6.9$ mm Hg higher than uAutoBP; the correlation coefficients of 24-hour mean BP with OBP and with uAutoBP did not differ (p for difference ≥ 0.13).

Conclusion

Compared to uAutoBP, OBP gives higher values, both when measured with auscultatory or oscillometric method. Contrary to some previous studies, we did not prove that uAutoBP would be associated to ABPM more closely than OBP.

As we have no prognostic data with uAutoBP and the inter-individual variability of the OBP – uAutoBP difference is large, uAutoBP cannot replace classic OBP.

#1290 - Medical Image

THE PHANTOM OF A WELL KNOWN PATHOLOGY

Sara Gomes, Francisco Gomes, Teresinha Ponte, Filomena Carneiro, Fatima Campante

Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Clinical summary

79-year-old man with history of heart failure presents with dyspnea and worsening limb edema. A posteroanterior chest radiograph showed an enlarged cardiac silhouette and a well-delineated, homogeneous rounded opacity, near the right horizontal fissure. The patient initiated diuretic treatment, with complete resolution of the opacity at discharge. Decompensated heart failure causes bilateral pleural effusion resulting in obliteration of the costophrenic sinus; sometimes there is accumulation in the minor fissure – the so called vanishing, pseudo or phantom tumor. Early recognition of this radiological finding is important to prevent unnecessary diagnostic procedures and therapeutic errors.

Figure #1290. Posteroanterior chest radiograph.

#1293 - Case Report

THE CURE AND THE CAUSE - ANTHRACYCLINE-INDUCED CARDIOTOXICITY, A CASE REPORT

Sara Gomes, Catarina Medeiros, Maria Loureiro, Otilia Simoes, Filipa Ferreira

Hospital Garcia de Orta, Almada, Portugal

Introduction

Anthracyclines are a very effective anticancer therapy with promising results, specially when administered in higher dosages. Unfortunately they are also associated with an increased risk of

heart failure (HF) leading to significant morbidity and mortality, which in light of the growing life expectancy of cancer patients might become an issue on the long term.

Case description

A 52 year-old woman presented in the emergency department complaining of shortness of breath and palpitations for 3 days. Two years before she was diagnosed with breast cancer, treated with neoadjuvant chemotherapy with doxorubicin, cyclophosphamide and paclitaxel, adjuvant radiotherapy and total left mastectomy. She denied previous history of chest pain, HF or other cardiovascular symptoms, and echocardiograms prior and after chemotherapy were unremarkable. At presentation the high sensitive T Troponin was 714 ng/L (rising to 2860 ng/L), the EKG showed left bundle branch block morphology (previously known) and the echocardiogram revealed a dilated left ventricle with global hypokinesia leading to a severely reduced ejection fraction. Acute coronary syndrome decompensating a previously unknown HF was the presumptive diagnosis.

The coronarography showed a large thrombus occluding the distal segment of the right coronary artery, which was treated with mechanical aspiration and anticoagulation. Cardiac MRI confirmed severely depressed left ventricle ejection fraction with exuberant apical hyper trabeculation, suspicious of a cardioembolic etiology for the infarction; there was no late gadolinium enhancement suggesting infarction scar. After diuretic and vasodilator therapy during hospital admission, the patient was asymptomatic at discharge.

Discussion

The decision to use anthracyclines is based on the baseline cardiac function. The toxicity of doxorubicin is related to its cumulative dose and is usually evident within 30 days of administration of the last dose, but it may occur 6 to 10 years after administration. Combination with other drugs, radiotherapy, preexisting cardiac diseases or other risk factors contribute to the severity of anthracycline induced cardiomyopathy. In this particular patient, she presented acutely in the ER with a complication of its previously undiagnosed cardiomyopathy. This case enlightens the crucial role of regular assessment to allow early detection of cardiac involvement and implementation of therapeutic measures.

#1297 - Abstract

RISK FACTORS FOR LONG-TERM MORTALITY IN PATIENTS WITH VERIFIED PULMONARY EMBOLISM OF HIGH AND INTERMEDIATE RISK

Valentin A. Kokorin¹, Elena A. Kochmareva^{1,2}, Vladimir A. Khlebnikov¹, Vladimir Yu. Titov¹, Varvara P. Rymberg¹, Valentin V. Malimon¹, Ivan G. Gordeev¹

¹ Pirogov Russian National research medical university, Moscow, Russia

² City Clinical Hospital #15 named after O.M. Filatov, Moscow, Russia

Background

Pulmonary embolism (PE) is a fearsome state with high incidence and mortality rate. Risk factors (RF) and scales in patients with acute PE are currently actively studied in terms of a short-term prognosis. However, in the long-term RF for negative outcomes are less examined.

We aimed to identify the risk factors for long-term mortality in patients with verified PE.

Methods

150 patients with PE of intermediate and high risk of lethal outcome were enrolled. PE was verified by computed tomographic pulmonary angiography and/or Echo. To assess further outcomes, the patients were contacted by phoned 36 months after discharge from the hospital. Contact was lost with 42 patients, so the final analysis included data from 118 patients aged from 25 to 92 years (mean age 66 years), of which 73 women (61.9%) and 45 men (38.1%). The patients were divided into the groups of favorable and unfavorable course of the disease. The IBM SPSS Statistics, version 23 program was used for statistical analysis.

Results

All-cause mortality rate at 36 months was 56 of 118 (47%). The following factors were associated with the fatal outcome: positive test for heart-type fatty acid binding protein (H-FABP) at admission (30,0% vs 39,7%, $p < 0,05$, OR 3,54, CI 95% 1,6-7,7), age >70 years (38,1% vs 58,2%, $p < 0,05$, OR 2,3 CI 95% 1,1-4,7), systolic blood pressure (SBP) <100 mmHg (41,9% and 68,0%, $p < 0,05$, OR 2,9 CI 95% 1,1-7,5), SpO₂ <90% (39,5% and 64,9%, $p < 0,05$, OR 2,8 CI 95% 1,3-6,3), history of atrial fibrillation (AF) (40,7% and 70,4, $p < 0,05$, OR 3,4 CI 95% 1,3-8,7), syncopal episodes at presentation (38,7% vs 62,8%, $p < 0,05$, OR 2,6 CI 95% 1,2-5,8), BOVA score ≥ 3 points (36,0% vs 55,9%, $p < 0,05$, OR 2,2 CI 95% 1,06-4,76), simplified PESI scale >2 points (22,9% vs 57,8%, $p < 0,05$, OR 4,6 CI 95% 1,8-11,4), creatinine clearance (Cr Cl) <60 ml/min (38,3% vs 56,9%, $p < 0,05$, OR 2,1 CI 95% 1,01-4,43), left ventricle ejection fraction (LVEF) <50% (40,8% vs 80,0%, $p < 0,05$, OR 5,8 CI 95% 1,8-18,6).

Conclusion

Thus, the following RF were associated with long-term mortality in patients with PE of high and intermediate risk: positive test for H-FABP at admission, age >70 years, SBP <100 mmHg, history of AF, syncopal episodes, BOVA score ≥ 3 points, sPESI scale >2 points, Cr Cl <60 ml/min and LVEF <50%.

⁴ PHO Dr.Biljana Ivanovska Bojadziev, Skopje, Macedonia, Former Yugoslav Republic of

⁵ PHO Dr.Shuperliski, Kocani, Macedonia, Former Yugoslav Republic of

⁶ PHO Polyclinic Manolev, Skopje, Macedonia, Former Yugoslav Republic of

Introduction

Massive ascites and recurrent pleural effusion of unknown origin is an uncommon condition, which represent a diagnostic and therapeutic challenge. Patient with delayed diagnosis and treatment may have a poor prognosis.

Case description

A 34-years-old male was referred to our department due to 12-months progressive abdominal distention with massive ascites and pleural effusion of unknown origin.

By thorough investigations, he was diagnosed as chronic calcified constrictive pericarditis. He received pericardiectomy and had an uneventful postoperative course.

He was doing well at 3-month follow-up and has returned to work.

Discussion

Extracardiac manifestations, such as massive ascites, recurrent pleural effusion and liver cirrhosis, were rare in patient with constrictive pericarditis. Pericardiectomy can be a radical solution for the treatment of chronic constrictive pericarditis. In order to avoid delayed diagnosis and treatment, physicians have to bear in mind this rare manifestation of chronic calcified constrictive pericarditis.

#1312 - Case Report

COULD ATRIAL FIBRILLATION LEAD TO HEMICOLECTOMY? A CASE REPORT

Deborah Blanca, Ludovico Furlan, Olivia Milani, Nicola Montano, Eleonora Tobaldini

Department of Internal Medicine, Fondazione IRCSS Ca' Granda, Ospedale Maggiore Policlinico and Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy

Introduction

Atrial fibrillation (AF) is the most common cardiac arrhythmia worldwide.

Physicians should consider the thrombotic and haemorrhagic risk before starting anticoagulant therapy.

Case description

A 75-year-old man presented to emergency department with haematochezia; esophagogastroduodenoscopy was negative for acute bleeding. The patient had a history of kidney failure in previous transplant and permanent AF, despite ablation, so he started anticoagulant therapy. Four months before hospital admission, he had acute anaemia due to gastric ulcer. Three months later, he underwent auricula closure using WATCHMAN device; anticoagulant therapy was discontinued and a dual antiplatelet therapy (clopidogrel + aspirin) was started.

When he was admitted to our department, antiplatelet therapy was discontinued. We performed colonoscopy, that showed colic blood oozing and haemostatic clips were positioned. After the recurrence of bleeding, colonoscopy was repeated; the procedure was complicated by iatrogenic gut perforation. An urgent abdominal cavity surgical toilet was therefore performed for a faecal peritonitis; surgeons crafted sigma terminal colostomy. In postoperative intensive care unit, calcium heparin for prophylaxis and aspirin were prescribed. After surgery, patient had a new episode of bleeding from colostomy; endoscopy was performed and two clips were placed for active bleeding.

Later, he was transferred to our internal medicine department for ventilator-associated pneumonia. Patient was discharged with single antiplatelet therapy after 28 days of hospitalization. Three days after discharge, the patient came back for recurrence of pneumonia and C.difficile enterocolitis.

Discussion

The patient had a CHA2DS2-VASc risk stratification score equal to 2 (only for age) with an annual stroke risk of 2.2%. He had a high risk of bleeding due to age, anticoagulant, kidney failure and recurrent gastrointestinal bleeding. The patient underwent the placement of WATCHMAN device, a procedure that requires anticoagulant and then dual anti-platelet therapy for several months, despite the higher bleeding risk. Any treatment should be tailored on patients, taking into account risks and benefits.

#1315 - Abstract

CARDIAC AUTONOMIC DERANGEMENT IS ASSOCIATED WITH WORSE NEUROLOGICAL OUTCOME IN THE VERY EARLY PHASES OF ISCHEMIC STROKE

Alice Monti¹, Roberto Maria Sacco², Serena Serafino², Michele Tassi², Gianluca Gallone², Giuseppe Torgano², Eleonora Tobaldini¹, Nicola Montano¹

¹ Department of Internal Medicine, Fondazione IRCSS Ca' Granda, Ospedale Maggiore Policlinico, and Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy

² Department of Emergency Medicine, Fondazione IRCSS Ca' Granda, Ospedale Maggiore Policlinico, Milan, Italy

Background

Acute ischemic stroke (AIS) is associated with autonomic dysfunction whose prognostic role is debated. The aim of this study is to evaluate the prognostic value of heart rate variability (HRV) and the role of stroke localization on autonomic control.

Methods

Patients with AIS and sinus rhythm were enrolled in the Emergency Department (Ospedale Maggiore Policlinico, Milan). Autonomic parameters were recorded at the onset (T0) and after thrombolysis. Neurological deficit was assessed at the onset using NIH Stroke Scale (NIHSS); residual disability was rated at 3 months with modified Rankin Scale (mRS). Spectral and symbolic analyses were used to assess HRV. Low frequency and high frequency are respectively markers of sympathetic and vagal modulation in spectral analysis. Symbolic analysis provides 0V% as index of sympathetic modulation and 2LV% and 2UV% as markers of vagal modulation.

Results

We enrolled 41 patients (mean age 68.0 ± 12.8 ; mean NIHSS 9.8 ± 6.4). A prevalent parasympathetic modulation was found in patients with NIHSS ≥ 14 compared to those with NIHSS < 14 . The group with worse mid-term outcome (mRS 3-6) showed higher 2UV% and lower 0V% than patients with lower disability (mRS 0-2). Right-sided stroke showed an association with higher respiratory vagal control.

Conclusion

Patients with a major neurologic impairment in the acute phase of ischemic stroke have an autonomic profile characterized by a prevalent vagal modulation. Considering mid-term outcome, patients with minor functional independence showed a prevalent vagal modulation along with a loss of sympathetic rhythmic oscillation. This autonomic profile may reflect a greater cardiovascular risk in this group of patients.

#1321 - Abstract

COMBINED DIURETIC THERAPY IN A COHORT OF OUTPATIENTS WITH HEART FAILURE: EXPERIENCE OF A CONTINUITY OF CARE UNIT

Cristina Sánchez Sánchez, Miguel Pedromingo Kus, Maria Escamilla Espinola, Juan Igor Molina Puente, Rebeca Sanchez Gonzalez, Ana Cristina Antolí Royo, Victoria Hernández Jiménez, Dolores Lopez Fernandez, Demetrio Sánchez Fuentes
Complejo Asistencial de Ávila, Ávila, Spain

Background

Congestion is the most frequent clinical feature in heart failure (HF), and a main cause of hospital admission. For this reason, diuretics are widely recommended in this population. Once diuretic resistance develops, different therapeutic strategies may be adopted, including combined diuretic therapy (CDT).

Methods

Retrospective observational study of outpatients with HF followed by the Continuity of Care Unit (CCU) in Avila, Spain, from October 2016 through March 2019. Percentage of patients with CDT, diuretics employed, hospital admissions and death rate were analysed.

Results

223 patients with HF were included. 51.6% of them were female. Mean age was 83.69 (SD 7.9). Most patients (78.5%) had a preserved left ventricular function. 81.2% were under combined diuretic therapy (CDT): from them, a 42.6% were treated with a two diuretic combination strategy, 31.8% with three and 6.7% with four. 43.6% had renal failure and the majority (60.1%) presented with a NYHA class II HF. Diuretics most commonly used were as follows: furosemide (98.3%), potassium-sparing diuretics (spironolactone or eplerenone) (85%) and thiazide diuretics (hydrochlorothiazide or chlorthalidone) (54.1%). On the contrary, acetazolamide and SGLT2 inhibitors were only used in 11.6% and 6.6% of the cases, respectively. The admission rate was similar in both groups of patients (CDT vs one-no diuretic use): 41.7% vs 42.9%, respectively. The death rate was slightly higher in the CDT group (23.8% Vs 16.7%).

Conclusion

In our observational study, the majority of patients with HF were treated with CDT. In accordance with previous studies, the predominant diuretic used was furosemide, followed by a combination with aldosterone antagonists and/or thiazides. Although not significant, a higher death rate trend was observed amongst patients with CDT, and a similar admission rate in both groups of patients (combined/non-combined) was noted. However, larger sample size studies, with detailed multivariate analysis, should be performed to confirm these data.

² Department of Internal Medicine, Fondazione IRCSS Ca' Granda, Ospedale Maggiore Policlinico, Milan, Italy

³ ASST Grande Ospedale Metropolitano Niguarda, Milan, Italy

⁴ Department of Preventive Medicine, Fondazione IRCSS Ca' Granda, Ospedale Maggiore Policlinico, Milan, Italy

⁵ Emergency Care Unit, Fondazione IRCSS Ca' Granda, Ospedale Maggiore Policlinico, Milan, Italy

Background

Air pollution and climate change are intrinsically linked emerging hazards for global health. High air particulate matter (PM) levels may trigger out-of-hospital cardiac arrest (OHCA). High temperature could act synergistically with PM in determining OHCA.

The aim of the present study was to investigate the combined effect of PM exposure and temperature on the number of ambulance call-outs for cardiac arrest in a large European metropolitan area with population >4 million.

Methods

We evaluated the association between ambient pollution exposure, temperature, and the rate of OHCA on a 2-years study period, allowing us to investigate 5761 event by using a Poisson model for count data with lag distributed term. Results were further confirmed by bidirectional case-crossover analysis. OHCA diagnosis, defined as sudden cessation of cardiac mechanical activity in the absence of any traumatic cause of cardiac arrest, was based on the call to the dispatch center and confirmed by the ambulance crew based on the results of clinical assessment.

Results

We observed a joint effect of PM and temperature in triggering cardiac arrest. The maximum effect was observed for high levels of PM experienced 3 days before the cardiac event, in the presence of high temperature.

Conclusion

The present study helps to clarify the controversial role of PM as OHCA determinant. It also highlights the role of increased temperature as a key factor in triggering cardiac events. This evidence suggests that tackling both air pollution and climate change might have relevant impact in terms of public health.

#1330 - Abstract

CARDIAC AUTONOMIC CONTROL IN PATIENTS WITH END-STAGE LUNG DISEASE

³ Respiratory Unit and Cystic Fibrosis Adult Center, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy

⁴ Thoracic Surgery and Lung Transplantation Unit, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy

Background

Cardiac autonomic control (CAC) is impaired in chronic obstructive, restrictive and mixed pulmonary diseases. However, the interplay between CAC and severity of end-stage lung has not been studied yet. Analysis of heart rate variability (HRV) is a noninvasive tool to study CAC. Our aim is to investigate the effects of lung disease severity on CAC.

Methods

49 patients on the waiting list of lung transplantation (Tx; 19 men and 30 women, age 38±15 years old) and 49 healthy non-smoking controls (HC; 22 men and 27 women, age 40±16 years old) were enrolled in this case-control study. Tx were divided into two groups, according to disease severity evaluated by the Lung Allocation Score (LAS). Ten minutes ECG and respiration were recorded. Spectral analysis identified low frequency (LF, sympathetic) and high frequency (HF, vagal) patterns. Symbolic analysis identified three patterns, 0V% (sympathetic), 2UV% and 2LV% (vagal). For comparisons Mean-Whitney U test was used. Data are presented as median and interquartile range.

Results

Compared to HCs, Tx patients had higher markers of sympathetic modulation and lower markers of vagal modulation. Patients with higher LAS had lower levels of sympathetic and higher levels of vagal modulation compared to less severe patients.

Conclusion

According to these preliminary data, compared to HCs Tx patients have higher markers of sympathetic modulation and lower markers of vagal modulation.

Nevertheless, more critical patients seem to have an autonomic profile characterized by lower sympathetic and predominant vagal modulation. This pattern can be due to a loss of sympathetic rhythmic oscillation and a subsequent prevalent respiratory modulation of heart rate in patients with a more severe disease.

BILATERAL DEEP VEIN THROMBOSIS WITH FACTOR V LEIDEN DEFICIENCY: A CASE REPORT

Noemi Iakab¹, Noemi Katalin Sidlovszky, Adriana Habor^{1,2}

¹ Emergency Country Hospital, Targu Mures, Romania

² University of Medicine and Pharmacy, Targu Mures, Romania

Introduction

The genetic mutations involved in hereditary thrombophilias represent life-long prothrombotic risk factors, which require long term anticoagulant or antiplatelet therapy.

Case description

We present the case of a 29-year-old male patient, who underwent eye surgery due to traumatic injury on his right eye.

Anterior vitrectomy was performed followed by a period of 2 week immobilization, without thromboprophylaxis. The patient presented to the emergency department shortly after discharge, feverish and with progressive pain and swelling on his right calf. Routine laboratory examinations show positive d-dimer, CRP, mild leucocytosis and slightly elevated liver enzymes. Venous ultrasound described subacute total occlusion of the distal portion of the right femoral vein, and bilaterally on the popliteal veins. Pulmonary angio-CT was performed to exclude any thromboembolic event. Abdominal ultrasound and CT revealed liver steatosis; antiphospholipid antibody testing was negative, thrombophilia panel showed Factor V G1691A Leiden deficiency. Initially Enoxaparin therapy was instated, followed by oral acenocumarol, with close INR monitoring.

Discussion

Prolonged immobilization and Factor V Leiden deficit represent the risk factors for developing deep vein thrombosis in this particular patient's case, who was diagnosed with hereditary thrombophilia.

#1386 - Abstract

ABDOMINAL AORTIC ANEURYSMS AND SECONDARY PREVENTION: ARE WE DOING A GOOD JOB?

Cristina Limia Vita¹, Lucía Paz Fajardo¹, Marta Carmen Esles Bolado¹, Andrea González Pascual¹, Ofelia Casanueva Soler²

¹ Internal Medicine Service. Hospital Sierrallana., Torrelavega, Spain

² Family and community medicine service. Hospital Sierrallana., Torrelavega, Spain

Background

Patients with abdominal aortic aneurysm should be considered candidates to secondary prevention and, therefore, be of benefit of statin therapy. Numerous studies support the use of statins as treatment for aortic aneurysm, establishing a relationship between statin treatment and reduction of complications.

Our aim was to evaluate the proportion of patients with a diagnosis of abdominal aortic aneurysm in which treatment with statins was established as secondary prevention tool.

Methods

We collected data of every patient who has been diagnosed by an image tool of abdominal aortic aneurysm in Hospital Sierrallana, where a population of 165,000 are covered and have place for 260 patients, in 2018 and we have compared information among patients who were already taken statins, those that started statin treatment after the diagnose and those who never received statins before nor after.

Results

22 patients have been included. 22.73% were women, 77.27% men, with an average age of 75.73 years.

We considered several cardiovascular risk factors: smoking habit (59.59% were smokers), hypertension (72.72%), Mellitus diabetes type 2 (22.72%) and dyslipemia (72.72%)

We gathered data about the aneurysm size resulting an average size of 5.1 cm. The smallest one measured 2.8 cm and the biggest one 8.2 cm.

Patients who were receiving statin treatment before being diagnosed of aneurysm, 54.54%, carried on with it afterwards.

Between those who previously weren't taken statins (45.45%), only 50% started treatment after been diagnosed, meanwhile statins weren't administrated to the rest of the group.

Related to patients who were already on statins and kept going on it afterwards (54.54%), 66.6% didn't present aneurysm growth, rupture or demise (almost during 2018). 25% experienced growth of the aneurysm and 16.6% rupture of it.

Conclusion

Hence, despite the fact that our sample of patients is small because of our hospital characteristics, we can conclude that; even though statin therapy reduces aneurysm complications, sometimes professionals don't care about that and they don't begin this treatment after the aneurism diagnosis like secondary prevention. So, it seems reasonable to advise starting statin therapy in the presence of aortic aneurism in patients who weren't already under it.

FROM THE ACUTE CORONARY SYNDROME TO A PAST OF SYPHILIS

Ana Corte Real¹, Pedro Brás², Vera Ferreira², Sílvia Aguiar², Lurdes Ferreira², António Fiarresga², Rui Ferreira²

¹ Centro Hospitalar do Oeste - Hosp. de Caldas da Rainha, Caldas Da Rainha, Portugal

² Centro Hospitalar Lisboa Central - Hosp. de Santa Marta, Lisboa, Portugal

Clinical summary

70 year-old male, with well controlled dyslipidemia and type 2 diabetes, allergic to aspirin and on pre-exposure prophylaxis (HIV), presented with a sudden and persistent chest pain, after an autolimited episode in the previous day. EKG showed inferior ST-segment elevation myocardial infarction. He took triflusal and ticagrelor loading dose. Invasive coronary angiography documented 2 right coronary culprit lesions, both were treated with drug eluting stents. Aneurysmatic segments were also noted in the left anterior descending and proximal circumflex artery. Transthoracic echocardiogram revealed inferior hypokinesia, aortic root (41 mm) and proximal ascending aorta (37 mm) dilation. Syphilis serology demonstrated previous infection, that the patient confirmed properly treated 15 years before.

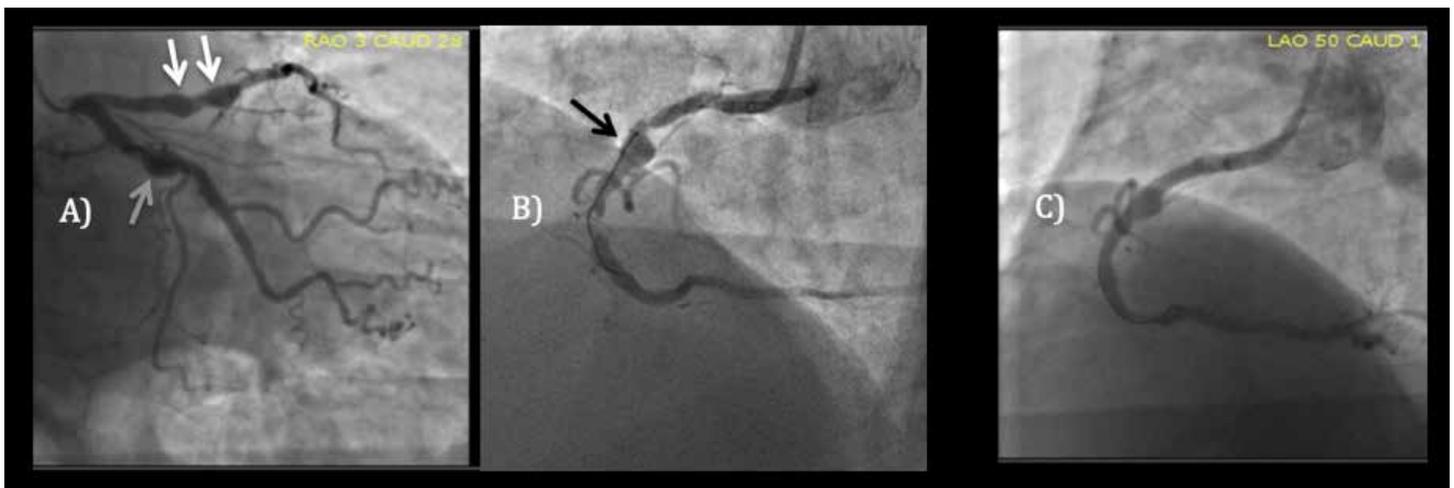

Figure #1397. Invasive coronary angiography showing: A) 50-60% lesion between two aneurysmatic segments in the left anterior descending artery (white arrows), as well as proximal circumflex artery aneurysm (grey arrow); B) culprit lesions in the proximal (80%) and mid segment (99%) of the right coronary artery, note the aneurysmatic segment between the two lesion (black arrow). C) Angiographic final result.

#1399 - Abstract

ATRIAL FIBRILLATION AND SEPSIS - A CALL TO ADDRESS ANTICOAGULATION

Mário Bibi, Alda Tavares, Sara Moreira Pinto, Rute Ferreira, Cristina Rosário

ULSM, Porto, Portugal

Background

Atrial fibrillation (AF) episodes are frequent among septic patients (24%) and its prevalence increases with the severity of the infection (40% in septic shock patients). In spite of that, the AF European guidelines do not mention the septic patient. In a predispose heart, sepsis can elicit AF by inducing a considerable stress response.

A recent study detected a great variability in the decision to initiate anticoagulation during the septic episode among different hospitals and even in the same wards. Nowadays, there are no recommendations for anticoagulation after the septic episode.

Methods

A retrospective study was conducted among patients admitted in an Internal Medicine Ward, between April of 2014 and June of 2015 with diagnosis of AF. Epidemiological, clinical and analytical data was collected and analysed. The objective was to compare AF management in patients with and without sepsis. Statistical analysis was performed with SPSS software v25; values of $p < 0,05$ were considered statistically significant.

Results

A total of 236 admissions and 214 patients were examined. The median age was 77 years and 66% of patients were women. Twenty-seven individuals also had a diagnosis of sepsis. There were more inaugural AF diagnoses in patients with sepsis than without (51.9% vs. 39.2%, respectively; $p=0.209$). The patients with sepsis were less frequently anticoagulated (36.4%), than subgroup

without sepsis (66.8%), with significance difference ($p=0.005$). No statistical significance was found when compared the mortality and readmission rates among septic and non-septic patients.

Conclusion

Our data suggests a different AF care in septic patients, as septic patients were less anticoagulated at discharge. In spite of the apparent lack of impact in the mortality and readmissions rates, we did not study the stroke occurrence nor the anticoagulation initiation after discharge.

There is a growing need to address the AF management in the septic patient. Until then, it can persist some confusion among practitioners and false believes of self-limited AF.

#1406 - Case Report

FROM THE MOUTH TO THE HEART AND BRAIN

Maria João Palavras, Flávia Santos, Ana Albuquerque, Rita Carvalho, Filipa Alçada

Hospital de Santo André, Leiria, Portugal

Introduction

In Portugal, stroke is the leading cause of death. Across the world, it is estimated that 1 in every 6 people will have a stroke, one person suffers a stroke each second and a person dies of stroke every 6 seconds. An ischaemic phenomenon is the most common. Ischaemic strokes are frequently distinguished as thrombotic, embolic or lacunar.

Endocarditis is an important, although less common, cause of cerebral embolism. Patients who develop native or prosthetic valve infective endocarditis have an elevated risk of stroke and consequently have a significant mortality and morbidity rates, especially due to the frequent concomitant multiple sites of brain embolization.

Case description

The authors present a case of a 77 year-old male who was admitted by right hemiparesis and fever (38°C). He had a history of hypertension and dyslipidemia. A CT-scan revealed recent right temporoparietal and left frontal ischemic lesions. Atrial fibrillation was diagnosed by electrocardiogram. The transthoracic echocardiogram revealed a moving mass close to the mitral valve, which induced severe mitral regurgitation. Sequential blood cultures isolated multiple colonies of *Peptococcus* spp.. Penicillin and gentamicin were started and the patient was admitted to a cardiac intensive care unit.

Discussion

The *Peptococcus* spp. is very rarely described as the cause of infective endocarditis, and endocarditis itself is a rare cause for stroke. The treatment for this particular patient involved a multidisciplinary approach, including cardiac surgery to the severely damaged valve and extraction of multiple damaged teeth. It is also unclear whether a preexisting rheumatic heart disease may have contributed to valve damage, which brings some discussion on anticoagulant options.

#1408 - Abstract

RATES OF AND RISK FACTORS FOR CORONARY REVASCUARIZATION IN PATIENTS WITH SUSPECTED UNSTABLE ANGINA AND NORMAL HIGH-SENSITIVITY TROPONIN

Shahar Geva Robinson¹, Tali Shafat^{1,2}, Avi Shimony³, Doron Zahger³, Khen Moscovici⁴, Roni Gilis⁴, Carlos Kafri³, Victor Novack^{1,2}, Lior Fuchs¹

¹ Internal Medicine Division, Soroka University Medical Center, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer Sheva, Israel

² Clinical Research Center, Soroka University Medical Center, Beer Sheva, Israel

³ Department of Cardiology, Soroka University Medical Center, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer Sheva, Israel

⁴ Goldman Medical School, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer Sheva, Israel

Background

In this study, we sought to assess the rates of and define predictors for coronary intervention among patients with acute coronary syndrome (ACS) and normal high-sensitivity cardiac troponin (hs-cTn).

Methods

Data were collected from patients hospitalized with suspected UA and exhibiting normal hs-cTn (troponin T, Normal < 14 ng/L) who underwent diagnostic angiography between the years 2010-2017 in Soroka University Medical Center, a 1100 bed tertiary hospital. Follow-up data were collected up to 1 year after the index hospitalization.

Results

Out of 356 patients who met the inclusion criteria, 181 underwent revascularization (50.8%). Using multivariable analysis, dyslipidemia was found to have the highest association with the performance of coronary intervention (OR 4.54 95% CI 2.46-8.40 p<0.001). The other risk factors included smoking (OR 2.53 95% CI 1.47-4.34 p=0.001), family history of CAD (OR 2.36 95% CI 1.15-4.87 p = 0.02), DM (OR 2.11 95% CI 1.28-3.48 p=0.004), age>65 (OR 1.84 95% CI 1.06-3.19 p =0.029) and previously known ischemic heart disease (OR 1.67 1.03-2.70 p=0.037). After 1-year follow-up, the group of patients who underwent revascularization had a greater rate of clinically-indicated repeated angiographies (13.8% vs 4.0% p=0.001), however, there was no significant difference in revascularization events (4.4% vs 2.3% p=0.27) and there was no cardiovascular-related mortality in either group. The composite outcome of all-cause mortality, repeated revascularization or non-fatal MI (MACE) was higher in the intervention group (10.5% vs 2.9% p=0.004)

Conclusion

In the present study, half of the patients hospitalized due to suspected ACS with normal hs-cTn, who were assessed by angiography, underwent revascularization. After 1-year, cardiac mortality remained the same, repeated coronary angiography rates were significantly higher among the revascularization group, but repeated revascularization rates were not higher. To corroborate the utility of revascularization for these patients, more studies are needed.

ASYMPTOMATIC TYPE A CHRONIC AORTIC DISSECTION

Emanuel Ferreira Costa, Daniela Dantas Rodrigues, Margarida Robalo, Joana Sotto Mayor, Filipa Costeira, Pedro Cerdeira Ribeiro, Sofia Esperança, António Oliveira Silva
Hospital de Braga, Braga, Portugal

Clinical summary

Computed tomography images were obtained to study neoplastic cause as etiology of left pleural effusion after cytological analysis of pleural fluid revealed the presence of basophilic cells, with nucleus cytoplasm ratio increased in an 88-year-old female patient otherwise asymptomatic except for complaints of fever, productive cough, and dyspnea who was admitted for treatment of a respiratory infection. The images show an extensive thoracic and abdominal aorta dissection from the ascending aorta root to the origin of the renal arteries, with a continuous double lumen image and aneurysmal dilatation of the aortic root, with a caliper of 5.3 cm. After 5 months of follow-up for a chronic type A aortic dissection, the patient remains asymptomatic with medical therapy.

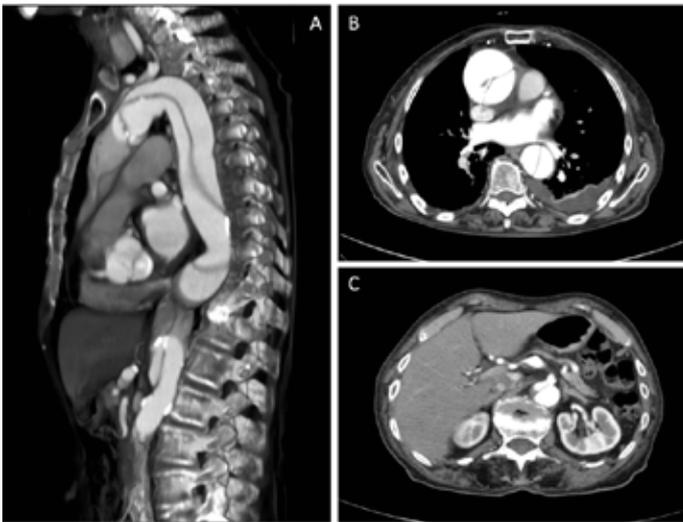

Figure #1420. A- 3D reconstruction image of CT-scan in the sagittal plane showing the extent of aortic dissection with continuous double lumen imaging. B- CT-scan image in the transverse plane showing aneurysmatic dilatation in the ascending aortic root. C- CT-scan image in the transverse plane showing the terminal portion of the false lumen.

#1424 - Abstract

PROGNOSTIC VALUE OF MEAN BILATERAL PROXIMAL EXTENSION OF THE CLOT IN PULMONARY EMBOLISM IN SINGLE CENTRE

Valdis Gibietis, Dana Kigitovica, Sintija Strautmane, Kitija Meilande, Verners Roberts Kalejs, Anastasija Zaichenko, Kristine Make, Andris Skride
Riga Stradins University, Riga, Latvia

Background

Ghanima et al. have proposed mean bilateral proximal extension of the clot (MBPEC) as a radiological score for risk stratification of acute pulmonary embolism (APE) patients. Higher MBPEC score has been associated with increased severity of APE. The aim of this study was to assess the validity of this score in a larger patient cohort.

Methods

The prospective cohort study included consecutive patients in a single centre from June 2014 till April 2019 presenting with APE confirmed by CT pulmonary angiography. Patients were followed up for one year. MBPEC score (1-4) was expressed by calculating the mean value of the largest affected pulmonary artery (subsegmental=1, segmental=2, lobar=3, main=4) in each lung and rounding up to a whole number. Clinical characteristics, treatment modalities and outcomes were assessed in association with MBPEC score.

Results

The study included 392 patients, MBPEC score was 1 in 18.1% (n=71), 2 in 28.8% (n=113), 3 in 20.4% (n=80), and 4 in 32.7% (n=128). Mean heart rate, systolic blood pressure, and pulmonary

embolism severity index (PESI) value did not show any significant association with MBPEC score ($p>0.05$). Higher MBPEC score was significantly associated with elevated Troponin I value (abnormal in 40% of patients with MBPEC=1; 48.8% with 2; 61.7% with 3; 75.8% with 4, $p<0.001$) and higher mean D-dimer value (12.0, 11.8, 14.0 and 17.0 mg/L, respectively, $p<0.001$). Mean B-type natriuretic peptide and serum creatinine were not associated with MBPEC. Thrombolysis was performed in 6 (4.7%) patients with MBPEC=4, no patients with MBPEC=1, one patient with MBPEC=2 and one with MBPEC=3 ($p=0.009$). 30-day mortality was not significantly different between MBPEC score grades ($p=0.798$). 1-year mortality, after exclusion of patients who died in 30 days, was significantly associated with MBPEC score (mortality 8.8%, 37.3%, 25.0%, 11.1%, respectively) with the highest mortality in MBPEC=2 group. Duration of anticoagulation therapy (above or below 6 months) was not associated with MBPEC ($p=0.127$).

Conclusion

Higher MBPEC score was associated with thrombolysis, elevated Troponin I, and higher D-dimer level. The highest long-term mortality was demonstrated in patients with MBPEC=2. PESI score and short-term (30-day) mortality was not associated with MBPEC. In our patient cohort, MBPEC score did not demonstrate convincing accuracy for risk stratification in APE. Further studies are required to assess its potential.

#1428 - Case Report

"FULMINANT" ENDOCARDITIS

Luis Gonçalves Vicente, Carlos Candeias, Ana Baptista, Mario Lazaro

Centro Hospitalar Universitário do Algarve - Faro, Faro, Portugal

Introduction

Endocarditis (IE) is a rare endocardial infection, that may present with high rates of mortality and severe complications such as septic embolism. Diagnosis is based on modified Duke criteria and should be suspected in patients with fever and cardiac risk factors such as valvular prosthesis, cardiac devices and congenital heart or valve disease. Long-term antibiotic therapy is the basis of the treatment while valvular surgery is indicated just in specific cases.

Case description

We report the case of a 69 years old female with known medical history of valvular heart disease (aortic and mitral mechanical prosthesis and pacemaker) and pancreatitis lithiasis. Was admitted to Gastroenterology ward due to acute pancreatitis having a positive clinical response until day eight. The patient then starts with night fever, chills and left upper limb phlebitis with purulent exudate. Laboratory findings showed an elevated inflammatory marker and acute renal failure. After blood was taken for culture a course of flucloxacillin was commenced. 24h

later starts with headache, blurry vision and a decrease in visual acuity. Non contrast head CT scan showed and multiple cerebral and retinal embolism of likely infectious etiology. Was evaluated by Ophthalmology and diagnosed with infectious endophthalmitis with retinal hemorrhage suggestive of Roth spots. Further tests showed a Methicillin-resistant *Staphylococcus aureus* (SA) in hemocultures and upper limb phlebitis exudate. Therefore, by Duke's criteria, started antibiotic therapy due to IE in a prosthetic valve. At day fourteen the patient starts with new motor deficits with the Non contrast head CT scan showing three new hemorrhagic lesions. Transesophageal echocardiogram (TEE) revealed no vegetative lesions. Was then transferred to coronary intensive unit where end up being intubated and mechanically ventilated due to respiratory failure. There was progressive clinical worsening with multiorgan dysfunctions. She was transferred to a non-cardiac intensive care unit where she died 12 days after the onset of the first symptoms.

Discussion

IE is a potentially lethal infection if antibiotic treatment is delayed. Even with prompt initiation of treatment, the mortality rate and incidence of significant complications remains high, particularly in susceptible patients such as the elderly and those with vascular prostheses, cardiac pacemaker or SA infection. This case illustrates the challenge of IE management.

#1437 - Abstract

NUTRITIONAL STATUS (NS) IS A MAJOR RISK FACTOR FOR MORTALITY IN THE HEART FAILURE (HF) POPULATION: RESULTS FROM A CONTINUITY OF CARE UNIT (CCU).

María Escamilla Espínola, Juan Igor Molina Puente, Cristina Sánchez Sánchez, Miguel Pedromingo Kus, Rebeca Sánchez González, Ana Cristina Antolí Royo, Victoria Hernández Jiménez, Dolores López Fernández, María Rocío García Alonso, Manuel Martín Casado, Demetrio Sánchez Fuentes
Complejo Asistencial de Ávila, Ávila, Spain

Background

Malnutrition is still a major and underestimated concern in patients with HF. Nowadays, an easy and efficient validated tool for controlling the NS, in any patient, relies on the CONUT Score (CONUT-S). The aim of our research was to evaluate the association between two variables, mortality and NS, in an HF cohort, based on the CONUT-S.

Methods

Retrospective observational cohort study of 228 outpatients with HF followed by the CCU in Avila, Spain, from October 2016 through March 2019. Data were anonymously examined. The CONUT-S was used to calculate the NS (employing one immune indicator and two biochemical parameters). We classified patients into four groups, according to their NS: severe-moderate-light

undernutrition, or normal state of nutrition. Remaining data referred to the CONUT-S are summarized elsewhere (Ulbarri et al. Nutr. Hosp. 2005). We studied the association between NS and mortality. Differences in baseline characteristics were analyzed by the chi-squared test. Significance was set at a p-value <0.05.

Results

228 outpatients with an HF diagnosis comprised the CCU database. Complete information was only available in 172 of them, selecting them for final analysis. The mean age was 83.7 years (SD 7.9), with a similar proportion of men (47.7%) and women (52.3%). The mean follow-up time amongst all patients was 12 months. 45 patients were classified as NYHA class I (NYHA-I), 103 patients as NYHA-II and 24 as NYHA-III. 128 patients (74.4%) had undernutrition (light, 46%; moderate, 26.7%; severe, 1.7%). 36 (20.9%) patients deceased, and 33 of them (19.2%) had some nutritional disorder. HF was the most frequent cause of death (20 patients dead for this reason). The mean follow-up time amongst deceased patients was 9.9 months. The association found between mortality and NS was assessed using the chi-squared test, and was found to be statistically significant ($X^2 = 25,29$, $p < 0.001$).

Conclusion

In our observational study, almost 75% of patients had evidence of malnutrition. Results obtained from the association between mortality and NS was statistically significant. Malnutrition in HF patients has a poor prognosis.

#1441 - Case Report

HEART-BREAKING INHALERS

David Prescott, Ana Isabel Brochado, Margarida Pimentel Nunes, Inês Branco Carvalho, Isabel Montenegro Araújo, Beatriz Donato, Rita Sérvio, José Luís Ferraro, Vasco Evangelista, António Martins Baptista, José Lomelino Araújo
Hospital Beatriz Ângelo, Loures, Portugal

Introduction

Takotsubo cardiomyopathy (TCM), also named as stress-induced cardiomyopathy, is a rare reversible cardiac syndrome. Like acute cardiac syndromes, it is characterized by chest pain of abrupt onset with ST-segment elevation and elevated cardiac ischemic biomarkers. However, unlike myocardial infarction, there are no critical coronary lesions in invasive coronariography. Echocardiography and invasive ventriculography will show left ventricular apical ballooning, a hallmark of the pathology. Its' pathophysiology is not completely understood, but often correlates with episodes of physical or emotional trauma, likely mediated by endogenous catecholamine production, with subsequent myocardial dysfunction by myocyte injury or ischemia from arterial spasm.

Case description

In this case report we present the case of a forty-seven year old

premenopausal woman who is admitted with a two-day history of precordial pain. She mentioned worsening of her asthma the week before, with need to resort to her inhaled 100ug salbutamol, using up to 2 full inhalers (400 doses) during the week. She had no other possible triggers. On initial observation she had bilateral wheezing on lung auscultation. Biochemical analysis showed heart ischemia and overload with elevated troponin of 2 ug/L and NT-proBNP of 2200 pg/mL. ECG showed T-wave inversion in Lead II. Chest X-ray had no visible changes. Echocardiography revealed systolic dysfunction, left ventricle apical ballooning, an akinetic apex and hypokinetic ventricle walls. During hospital stay she maintained a good clinical evolution with resolution of symptoms and biochemistry changes. Repeat echocardiography at the 6th day of admission showed normal systolic function without ventricular dyskinesia or other changes. After discussion with Cardiology, she was discharged on the 8th day on antiplatelet therapy and referenced to CT-angiography for non-invasive cardiovascular risk staging.

Discussion

Beta-adrenergic agonists are derivatives of epinephrine and stimulate the autonomic sympathetic nervous system, promoting bronchodilation. Towards higher doses, their abuse may serve as a form of exogenous catecholamine administration. There are increasing reports of TCM induced by beta-2-agonist use, especially in post-menopausal women. Since the association is being increasingly recognised, it is extremely important to exclude beta-agonist use as a precipitant, particularly in asthmatic or COPD patients.

#1443 - Abstract

END-ORGAN DAMAGE IN A SERIES OF HYPERTENSIVE PATIENTS

Rui Files Flores, Joana Rita Lopes, Maurício Peixoto, Guilherme Alpedrinha, Sofia Caridade
Hospital of Braga, Braga, Portugal

Background

Our primary goal is to access the prevalence of end-organ damage in hypertensive patients from an outpatient consult.

Methods

We selected patients from an outpatient consultation of a tertiary hospital care center. All patients from July 2018 to March 2019 were inserted. Information regarding date of the outpatient consultation, gender, age, degree and cause of hypertension, antihypertensive classes in use, records of blood pressure values and the presence of target organ damage were collected.

Results

During 9 months, 73 patients were evaluated for a total of 103 consultations. Thirty-four patients were male (46.6%) and 39 were female (53.4%). The mean age was 49.8 years and the median age

45 years. After dividing patients according to the probable cause of hypertension, we found 31 cases (42.5%) of essential hypertension and 14 cases (19.2%) of secondary hypertension. The remainder had no established etiology at the time of the conclusion of this report. In the group of secondary hypertension, we found 6 patients with obstructive sleep apnea, 4 with renal artery stenosis, 2 with aldosterone-producing adrenal adenomas, 1 with chronic kidney disease and 1 with Cushing's syndrome. Twenty-three percent of patients (n=17) had vascular complications related to arterial hypertension with the following distribution: 13.7% of kidney disease (n=10), 12.3% of cerebrovascular disease (n=9), 6.8% of cardiovascular events (n=5) and 2.7% cases of peripheral arterial obstructive disease (n=2). Sixty-three percent (n=46) were medicated with dihydropyridine calcium channel blockers in mono or polytherapy. Mineralocorticoid receptor antagonists (n=2, 2.7%) and central adrenergic agonists (n=2, 2.7%) were less frequently used. The majority of patients (n=44, 60.2%) presented blood pressure within target values.

Conclusion

The mean age of patients found in the outpatient consult was relatively low. Nevertheless, the prevalence of end-organ damage remains high. In the group with vascular events, there was a greater proportion of renal disease secondary to arterial hypertension, followed by cerebrovascular events, both causing serious morbimortality. This case series reflects the importance of blood pressure control beginning in a young age to prevent micro and macrovascular complications of arterial hypertension.

END-STAGE HEART FAILURE AND DYSAUTONOMIA

Diana Ferrão¹, Tiago Alpoim², Guilherme Assis¹, Luís Nogueira-Silva¹, Clara Machado-Silva¹, Pedro Ribeirinho-Soares¹, Catarina Pereira¹, Fernando Nogueira¹, José Marques¹, Jorge Almeida¹

¹ Centro Hospitalar e Universitário de São João, Porto, Portugal

² Instituto Português de Oncologia do Porto Francisco Gentil, Porto, Portugal

Introduction

Amyloidosis is a group of disorders characterized by a defect in protein folding that leads to extracellular anomalous protein deposition in the form of insoluble aggregates - the fibrils. The deposits can virtually occur in any organ, namely the kidney, autonomic nervous system and heart.

Case description

A 75-year-old patient with long term rheumatoid arthritis medicated with immunosuppressants was admitted with decompensated heart failure (HF). She was diagnosed with de novo auricular fibrillation with slow ventricular response, which was interpreted as the HF decompensating factor. She maintained bradycardia of ~40 beats per minute with periods of hypotension

and it was decided to proceed to pacemaker implantation. Despite subsequent heart rate control, she had persistent respiratory failure, peripheral edema refractory to high dose diuretics and symptomatic orthostatic hypotension. She was submitted to a TILT test that confirmed the dysautonomia. The echocardiogram showed marked biventricular and septal hypertrophy, mainly of the right ventricle. The patient was submitted to an endomyocardial and subsequently salivary gland biopsy (to improve the yielding of the findings), which was positive to amyloid substance. The etiologic diagnosis of amyloidosis showed no signs of monoclonal gammopathy. The serum amyloid A protein was positive and when combined with the history of rheumatoid arthritis led to a presumptive diagnosis of type A amyloidosis causing ventricular hypertrophy, with persistently decompensated HF, and dysautonomia. The attempt for definitive identification of the amyloid protein was inconclusive. The patient was discharged and in the next few months she kept relative clinical stability. Ten months after her discharge she was admitted to the emergency room with aggravated respiratory failure and was diagnosed with bilateral community acquired pneumonia. Her clinical status deteriorated rapidly, with multiorgan dysfunction, and she died one week after admission and one year after being diagnosed with systemic amyloidosis.

Discussion

AA amyloidosis is a rare disease that can occur in patients with underlying chronic inflammatory diseases, such as rheumatoid arthritis. Cardiac involvement is uncommon and when present confers bad prognosis. Therapeutic options are still limited and rely mainly on the control of the underlying inflammatory process.

AN ATYPICAL VIRAL PRESENTATION

Isabel Montenegro Araújo, Margarida Pimentel Nunes, Inês Branco Carvalho, David Ferreira Prescott, Ana Brochado, Vasco Evangelista, Sofia Mateus, António Martins Baptista, José Lomelino Araújo

Hospital Beatriz Ângelo, Loures, Portugal

Introduction

Deep vein thrombosis (DVT) is a manifestation of venous thromboembolism, a common pathology in the Internal Medicine wards. Anticoagulation (AC) is the only therapy known. There are recognised triggers whose correction allows, in most cases, the suspension of AC after a stipulated time. However, the challenge is when the cause is not easily identifiable, and the time of therapy becomes unknown.

Case description

The authors report the case of a 29-year-old man with a history of recurrent tonsillitis and active smoking (17 pack-years). No relevant family history. Emergency Department (ED) due to right low back pain, irradiating to the inner thigh area, associated with

premature surfeit, for 1 week. Without trauma, inactivity or recent travels, fatigue, asthenia, weight loss or infectious disease suspect. No signs of bleeding disorder. First ED admission at the beginning of the symptoms discharged with medication for mechanical low back pain without improvement. Current admission, abdominal ultrasound presenting endoluminal filling of the inferior vena cava, with involvement of primitive iliac and hypogastric veins, suggestive of acute/subacute partial thrombosis. Laboratory with abnormal liver biochemical tests with cytocholestatasis. Admitted to medical ward and a full body tomography was performed confirming extensive thrombosis. Started treatment with enoxaparin 80 mg every 12 hours (2 mg/kg/day) and complementary exhaustive investigation to rule out the triggering cause.

Of all the research on autoimmune, infectious diseases and malignancies, the positivity of Epstein-Barr (EBV) VCA and EBNA IgM antibodies, with very high titles, and anti-Cytomegalovirus IgM, but in a very low title, was highlighted. A multidisciplinary discussion was held with Vascular Surgery and Microbiology and it was considered the acute EBV infection the most probable diagnosis, although with an unusual presentation, with vascular thrombotic and hepatic involvement.

After documentation of thrombus chronicity without relevant post-thrombotic syndrome and viral seroconversion, anticoagulation was suspended at 6 months of therapy without recurrence of thrombotic phenomena after 1 year follow-up.

Discussion

DVT is a frequent diagnosis in MI wards, although occurrence in young age, with no clear triggering factors, created a diagnostic challenge only possible to solve with extensive research and multidisciplinary cooperation, allowing the correct therapy and clinical guidance.

#1505 - Case Report

A HEART IN A HEART-SHAPED SHELL

Ana Isabel Andrade Oliveira, Joana Morais, Olga Pires, Inês Burmester, Filipa Rodrigues, Mariana Devesa, Maria João Regadas, Paulo Gouveia

Hospital de Braga, Braga, Portugal

Introduction

Constrictive pericarditis is a rare cause of diastolic heart failure (HF), frequently presenting without a clear etiology. In the developing world tuberculous pericarditis is the most common etiology, while in the developed world previous cardiac surgery, idiopathic pericarditis and chest radiotherapy are the most common causes. When these patients present with multiple comorbidities the correct diagnosis and treatment may be delayed.

Case description

A 68-year-old man with history of HFpEF, atrial fibrillation, right nephrectomy and alcoholism presented with dyspnea, orthopnea, paroxysmal nocturnal dyspnea, nocturia, asthenia, decreased

tolerance for small efforts and 5 Kg of weight loss in the last month. Ascites, bimalleolar edema, jugular venous distension and decreased murmur in the left hemithorax were evident on examination. Laboratory tests showed normocytic normochromic anemia, and the thoracic x-ray revealed a pericardial calcification and pleural effusion, confirmed by CT scan. The CT also revealed ascites, cirrhotic liver and a mass in the left lobe, characterized by MRI as hepatocellular carcinoma. The subsequent study was positive to hepatitis C (genotype 3a). The echocardiogram showed inspiratory deviation of the interventricular septum to the left ventricle and a dilated vena cava without inspiration collapse; cardiac catheterization identified ventricular pressure curves with square root morphology “dip and plateau” and pulmonary hypertension. With these findings, the diagnoses of idiopathic calcified constrictive pericarditis and hepatocarcinoma were assumed. The patient was discharged after stabilization with diuretics, oriented to radiofrequency ablation and cardiology consult. However, one month later he was readmitted with deteriorating cardiovascular and kidney function, resulting from the progressive diastolic dysfunction, rapidly escalating to cardiogenic shock and anuric renal failure that resulted in his death a few days before the scheduled pericardiectomy.

Discussion

Constrictive pericarditis should be suspected in patients with clinical features of right-sided heart failure. In most cases, like ours, the underlying cause is unknown. Pericardiectomy can confer a long-term survival benefit and help in etiology determination. This case was challenging because he presented cirrhosis, hepatocarcinoma and constrictive pericarditis all diagnosed at the same time, making difficult the etiology assessment and therapeutic adjustments.

ESSENTIAL THROMBOCYTHEMIA-RELATED ACUTE MYOCARDIAL INFARCTION: A SMALL SERIES OF TWO CASES

Carlos Pinhão Ramalheira¹, Regina Costa², Silvia Monteiro², Francisco Gonçalves², Rui Baptista², Lino Gonçalves²

¹ Hospital Prof. Fernando Fonseca, EPE, Lisbon, Portugal

² Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Essential thrombocythemia (ET) is a myeloproliferative disorder characterized by expansion of the megakaryocytic elements in the bone marrow, with a persistent increase in the platelet count. The clinical course of untreated ET is dominated by thrombosis, constituting the major causes of morbidity and mortality. Nevertheless, coronary artery thrombosis in ET patient is rare, especially without traditional risk factors.

Case description

We present two cases of myocardial infarction in context of TE

with no other known cardiovascular risk factors. Both patients are a 32 year-old male (Patient 1) and a 47 year-old male (Patient 2) presented in the ER with chest pain as the main complaint. Both were already diagnosed with TE, however only the eldest was correctly medicated for this condition. Both had a normal physical examination and ECG with ST elevation in the anterior leads as well as increased cardiac enzymes at admission. During angiography, both patients had lesions in the left anterior descending (LAD) artery. Patient 1 was referred to surgery since the occlusion involved proximal segments of the left coronary artery, while Patient 2 was submitted to balloon dilatation and stenting. Platelet counts were persistently elevated. At discharge, both patients were treated with dual anti-platelet therapy and citoreductive therapy, and follow-up in Hematology and Cardiology consults.

Discussion

Patients with high platelet counts should be evaluated thoroughly. A platelet-mediated mechanism should be considered in a patient with myocardial infarction without traditional risk factors.

#1523 - Case Report

THROMBOPHILIA AND PULMONARY EMBOLISM

Sara Almeida Ramalho, Tomás Nunes, Elena Pirtac, Ana Gomes, João Namora Santos

Hospital Garcia de Orta, Almada, Portugal

Introduction

Venous thromboembolism (VTE) is related with environmental factors but can also be potentiated by existent hereditary thrombophilia. Factor V Leiden is the most frequent, followed by prothrombin gene mutation 20210A.

We present a clinical case of pulmonary thromboembolism (PTE) associated with an hereditary thrombophilia.

Case description

Male, 60 years old, without known personal clinical history, admitted in the emergency department with tiredness and dyspnea. He had been bedridden for some days, about 1 month before, for flu-like symptoms. The patient had family history of profound venous thrombosis (mother and maternal relatives).

At admission he was afebrile, blood pressure 132/93 mmHg, rhythmic pulse, 114ppm, with right basal crackles on auscultation. The remaining observation was normal and he did not presented clinical signs of profound venous thrombosis. The laboratory results revealed leukocytosis, elevated T troponin and elevated d-dimers. The electrocardiogram showed sinus tachycardia and the thoracic x ray was normal. The transthoracic echocardiogram revealed dilation of right chambers and signs of pulmonary hypertension (pulmonary artery systolic pressure 67 mmHg). Given the possibility of PTE, the patient performed a thoracic computed tomographic angiography which revealed signs of

bilateral pulmonary artery thrombosis. The diagnosis of PTE of intermediate-high-risk (PESI score 110 points) was confirmed. The patient was medicated with non fractionated heparin (NFH) and transferred to an Internal Medicine ward. NFH was changed for low molecular weight heparin and then to apixaban. Given the patient's family history, a search for thrombophilias was performed and heterozygous prothrombin gene mutation 20210a was detected. The patient was discharged under apixaban and referred to the outpatient consultation of venous thromboembolism.

Discussion

The risk of VTE associated with prothrombin gene 20210A mutation is 3-4 times higher in heterozygosity, being even higher in homozygosity. However, testing the presence of hereditary thrombophilias is controversial. This search might be important in patients with VTE younger than 50 years old and with at least 1 first degree family member with history of VTE, as illustrated in this case. It should be considered to investigate the presence of the same mutation in asymptomatic relatives, since they can benefit from the eviction of oral contraceptives and preventive and counselling measures in situations of higher risk of VTE.

#1526 - Abstract

A LOOK OVER 7 YEARS OF PERICARDITIS

Regina Costa, Cátia Ferreira, Nelson Pedro, Lélita Santos, Armando Carvalho

Coimbra Hospital and University Centre, Coimbra, Portugal

Background

Acute pericarditis is the most common disorder involving the pericardium. Despite being recorded in approximately 0.1-0.2% of hospitalized patients and 5% of patients admitted to the Emergency Department for nonischemic chest pain, the exact incidence and prevalence of acute pericarditis are still unknown and therefore epidemiological studies are largely lacking.

Methods

Retrospective study in which were included all patients admitted to an Internal Medicine department meeting acute pericarditis criteria between January 2012 and December 2018. Clinical and demographic data were analyzed through Microsoft Excel 2018 and SPSS v23.

Results

Our sample had 34 patients, 70.6% (n=24) were men, corresponding to 0.02% of all admissions to the Internal Medicine department. Mean age was 59.6 years. Concerning the classification, the majority (88.2%,n=30) had acute pericarditis, 5.9% (n=2) chronic and the remaining were constrictive. Recurrence of symptoms was detected in three patients (8.8%). Slightly more than half was idiopathic (55.9%,n=19), 29.4% (n=10) were infectious of which 40% were due to tuberculosis. Chest pain was the most common finding on physical examination (61.8%,

n=21), followed by dyspnea (53.0%, n=18) and fever (32.4%, n=11). Were performed 227 serological tests searching for infectious diseases and eight suggested viral etiology. On admission 79.4% (n=27) of the patients performed an echocardiogram, of which 85% had pericardial effusion. Only 17,6% (n=6) had typical ECG changes. The mean treatment time was 8.6 weeks. 58.8% of the patients were treated with colchicine and/or NSAIDs; 64.7% were prescribed antibiotics and 29.4% required steroids. Some factors of poor prognosis were identified: 14.8% had severe pericardial effusion; 20.6% developed miopericarditis and 26.5% were under anticoagulant medication.

Conclusion

The authors found both similar and quite distinct results compared to other centres. This may be explained by the relatively benign course of the disease and low yield of diagnostic testing, since the priority is to exclude complications and identify high risk patients in whom a more comprehensive evaluation should be performed, discouraging the establishment of a definite etiology and a better characterization of this entity.

#1533 - Abstract

MORTALITY PREDICTORS OF INFECTIOUS ENDOCARDITIS – A TERTIARY CENTER EXPERIENCE

Alexandra Briosa, Andre Esteves, Ana Broa, Ana Rita Pereira, Ana Marques, Sofia Alegria, Daniel Sebaiti, Ines Cruz

Hospital Garcia de Orta, Lisbon, Portugal

Background

Despite advances in medicine, infectious endocarditis (IE) is still one of the leading causes of morbidity and mortality in patients with valvular heart disease

Aim: To determine the independent predictors of hospital mortality in IE patients.

Methods

Single center retrospective study including suspected / confirmed patients (dts) during the last 12 years (2006-2017). A univariate and multivariate analysis was performed to determine the independent predictors of mortality

Results

174 pts, 75% (n=131) males, mean age of 61±16 years. 41.3% had previous history valvular disease, mainly degenerative disease (24.4%). 54% had hypertension, 25.3% previous heart failure (HF), 12.8% HIV infection and 9.3% previous history of neoplasia. At admission, 58.3% (n=98) had constitutional symptoms and 53.5% had murmur at auscultation (n=91). Native valve IE occurred in 74.1% of the cases (n=129), affecting especially the aortic valve (54%, n=94). The most frequent isolated agent was *Staphylococcus aureus* (*S. aureus*) (24.7%, n=43), followed by

Enterococcus (12.1%) and Streptococcus viridans (11.5%). 20.1% had no identified agent on cultures.

The main complication was HF (42.1%), followed by local valvular complications (35.7%), such as valvular destruction (21.2%) and abscess (14.3%). There were embolic complications in 33.9% of the cases. One third of the pts (33.9%) underwent surgical intervention. The mortality rate was 29.9% and septic shock was the main cause of death (35.6%).

In-hospital mortality was associated with previous HF ($p=0.003$), *S. aureus* ($p=0.048$) or Streptococcus group agents ($p = 0.014$), especially Streptococcus viridans ($p=0.039$), days of hospitalization ($p=0.001$), left ventricular (LV) dysfunction ($p=0.012$), perivalvular abscess ($p=0.007$), development of HF ($p < 0.001$) or septic shock ($p < 0.001$) and with medical treatment only ($p < 0.001$). The logistic regression showed that the days of hospitalization (OR: 0.96, 95% CI 0.93-0.98, $p=0.001$), presence of LV dysfunction (OR: 5.95, 95% CI 1.3-25, $p=0.0017$), development of HF (OR: 4.2, 95% CI 1.4-12.7, $p=0.009$) or septic shock (OR: 12.7, 95% CI 3, 5 - 45.1, $p < 0.001$) and the use medical treatment only (OR, 0.052, 95% CI 0.011 - 0.243, $p < 0.001$) were considered independent predictors of mortality.

Conclusion

IE is associated with high hospital morbidity and mortality. For the observed population, the predictors of mortality were mostly clinical. Surgical treatment plays an important protective role.

#1545 - Case Report

MINOCA, A "WORKING DIAGNOSIS"

Ana Cochicho Ramalho, Claudia Jesus, Inês Rossio, Filipa Moleiro, Helena Vitorino, Eduarda Comenda, Mário Barbosa, Nadine Monteiro, Sofia Marques Santos, Helena Cantante
Hospital Lusíadas Lisboa, Lisboa, Portugal

Introduction

One to 13% of myocardial infarction (MI) occur in the absence of obstructive coronary artery disease. The diagnosis is made fulfilling the universal criteria of MI, without coronary artery stenosis $> 50\%$, and no clinically specific cause for the acute presentation. Some presentations of acute MI with ST segment elevation (STEMI) that in the angiography failed to show the presence of obstruction, were labelled as false-positive STEMI's and no further evaluation or therapy ensued.

Case description

77-year-old female, with cardiovascular risk factors of hypertension, hyperlipidaemia and obesity, also with the diagnosis of hypothyroidism. In use of nebivolol, levothyroxine and lansoprazole. She presented at the emergency department with acute chest discomfort, at rest, irradiating to the left arm, accompanied by nausea and vomiting. She was hypertensive – 203/102 mmHg and had no other noticeable features on examination. The Electrocardiogram showed a sinus rhythm (78

bpm) and a ST segment elevation in D1 and aVL leads, and a ST depression in V3 and V4 leads. The highly sensitive troponin levels were 33 ug/L at admission, reaching a maximum of 46.01 ug/L. She also had a total Creatine Kinase of 1076 UI/L, and a fraction MB of 69.8 ng/mL, and the analysis were otherwise unremarkable. The echocardiography showed akinesia of the apical septal and apical lateral segments, and a normal systolic function.

Acetylsalicylic acid, Ticagrelor and UFH were administered, followed by an emergency catheterization with no sign of obstruction of the coronary arteries. The ventriculography suggested Tako-Tsubo syndrome.

While recovering it was noticed an auricular fibrillation with rapid ventricular response.

A Cardiac Magnetic Resonance disclosed a reduced ejection fraction (38%), hypokinesia of the middle and apical segments of the lateral wall and of the middle segment of the inferior wall. The late gadolinium enhancement showed transmural of 50-75% in the same segments, compatible with MI.

The patient had a Killip Kimbal I progression, and was discharged under acetylsalicylic acid, apixaban, a statin, a b-blocker and an ACE inhibitor.

Discussion

MINOCA is a "working diagnosis", a term that should be used when no specific clinical diagnosis is apparent, sheltering the importance of investigating the underlying aetiology, so the answers to "what's the pathophysiology behind the event?" and "how should we manage such patients?" becomes more and more clear throughout the evolving years.

MARANTIC ENDOCARDITIS

José Brito-Da-Silva¹, Ana P. Ferro², Ana Lisa Lima², Luísa Guerreiro²

¹ Department of Medical Oncology, IPO-Porto, Porto, Portugal

² Department of Internal Medicine, Hospital Pedro Hispano, Matosinhos Local Health Unit, Matosinhos, Portugal

Introduction

Nonbacterial thrombotic endocarditis (NBTE) is a rare condition, with no sex predilection; in almost 80% of cases, an underlying malignant condition is present. Patients are typically asymptomatic until embolization, and up to one half of the patients present with an embolic phenomenon.

Case description

A 58-year-old woman, diagnosed in 2013 with uterine adenocarcinoma, on follow-up to date, and under hypocoagulation due to deep vein thrombosis of the right leg in the past 2 months, presented to the emergency room with slurred speech and a minor central facial paresis, being diagnosed an ischemic stroke. Cerebral CT-scan did not show acute ischemic lesions. Given the elevated thrombotic risk due to her personal history, hypocoagulation was started with a low-weight molecular heparin.

A transthoracic echocardiogram was performed, showing a filiform structure on the anterior leaflet of the mitral valve, confirmed by transesophageal exam, suggestive of vegetation. All the clinical data pointed to a prothrombotic state, namely the history of a malignancy and the occurrence of two different episodes of thrombosis in recent months (both venous and arterial); having in consideration that signs of infection were never present during her stay, the diagnostic hypothesis of a marantic endocarditis was risen. Blood cultures were drawn, as well as a comprehensive study in order to exclude possible negative-culture endocarditis, with agents such as *Coxiella burnetii* and *Bartonella* spp. A thoraco-abdomino-pelvic CT scan was performed, showing newly detected pulmonary nodules and a peritoneal lesion on the right hepatorenal space, raising the hypothesis of disease progression. Given the patient's clinical stability and a high clinical suspicion of the endocarditis being the expression of a paraneoplastic syndrome, she was discharged and oriented to her assistant oncologist, in order to complete the study of a possible progression of the malignant disorder.

Discussion

Treatment of NBTE usually consists of systemic anticoagulation and therapy directed at treating the underlying malignancy or associated condition. It must be continued anticoagulation indefinitely due to the high risk of recurrent systemic embolization. Despite therapy, the prognosis from NBTE is generally poor, therefore its recognition is very important to initiate treatment and try to modify this course of events.

PROGRESSIVE EXERCISE SYNCOPES: A CLINICAL CASE

Vera P Sarmiento, João Pais, Diogo Brás, Mafalda Carrington, Margarida Massas, Ana Bernardo, Vasco Neves, Tereza Veloso, Pedro Semedo, Bruno Piçarra, José Aguiar
Hospital do Espírito Santo de Évora, Évora, Portugal

Introduction

Syncope is a transient sudden loss of consciousness due to an acute compromise of the brain vascular flow. Its differential diagnosis is broad, and the identification of those caused by cardiac diseases is paramount in avoiding preventable deaths.

Case description

66 yo men, previously treated for hyperlipaemia, with history of Hodgkin lymphoma 30 years ago. Two months before, the patient suffered a non-ST myocardial infarction (NSTEMI), for which he was submitted to a coronary catheterization with coated stenting of the right coronary (RC). He was under double antiaggregation, beta-blocker, angiotension II receptor blocker (ARB) and statin since then. Two months after discharge, the patient came in to A&E due to repeated short-lived episodes of light-headedness, blurred vision and sweating, at times followed

by loss of consciousness, from which he spontaneously recovered in seconds. These episodes happened in the context of physical effort since his discharge, and were progressively triggered by less intense exercise. On the day the patient presented to the A&E, he suffered two syncopes at rest. At examination: HR=54 bpm, BP=96/54 mmHg, SpO₂ 98% at room air, afebrile. Heart, lung sounds and neurologic exam were unchanged. Laboratory findings showed an increase of troponin I to 1.16 ng/dL (reference <0.036) with normal inflammatory markers and Hb 11.8 mg/dL. The EKG showed sinus rhythm at 60bpm, with T-wave inversion at DIII and aVF, and repolarization changes in DI and aVL, similar to previous tests. The heart ultrasound showed dilated right chambers with decreased systolic function of the right ventricle (TAPSE 13mm). Pulmonary embolism was excluded on CT. A new NSTEMI was assumed as the most probable diagnosis and the patient was admitted to the Coronary ICU. On the first day of admission, he suffered a symptomatic sinus bradycardia at 23bpm, with sinus pauses lasting for more than 3s. A temporary pacemaker was inserted and a coronary angiography was performed, showing a stent thrombosis of the RC. Clots were aspirated with flow recovery and no residual lesion. The patient was kept anticoagulated and was restarted on low-dose beta-blockers. The pacemaker was removed without complications.

Discussion

The clinical history is crucial when assessing patients with episodes of syncope. In this case, the repeated syncopes were akin to a RC angina due to stent thrombosis, likely with involvement of the sinus artery, resulting in symptomatic bradycardia with decreasing levels of exercise,

#1557 - Abstract

MONTEVIDEO'S OBESITY AND BARIATRIC SURGERY PROGRAM (PCOB): PRE-OPERATIVE ECHOCARDIOGRAMS ANALYSIS

Eugenia Thomas, Gustavo Bruno, Lucia Spangenberg, Andrea Vaucher, Álvaro Huarte
Hospital Maciel, Montevideo, Uruguay

Background

Obesity is a chronic epidemic disease that affects life quality and causes greater morbidity and mortality. It's an independent cardiovascular risk factor, developing symptomatic coronary disease, atrial fibrillation and heart failure (HF). Patients with advanced obesity stages who suffer from HF, excluding other aetiologies, are diagnosed of obesity cardiomyopathy characterized by a preserved left ventricular ejection fraction (LVEF).

Describe anatomical and functional left cardiac echocardiographic alterations in a population of morbid obese patients.

Methods

An analytical study was performed in Maciel's Hospital Obesity and Bariatric Surgery Program (Montevideo-Uruguay) between

June 2014 and September 2016. The inclusion criteria were 18 to 64 years old, a body mass index (BMI) greater or equal to 40 kg/m² or greater to 35 kg/m² with comorbidities. Patients with cardiomyopathy of known aetiology, atrial fibrillation, hyperthyroidism and poor echocardiographic window were excluded. A preoperative transthoracic echocardiogram was performed. These variables were defined according the Interamerican Society of Echocardiography and Cardiovascular Imaging: left ventricle mass, left atrium diameter, left ventricle diastolic diameter, interventricular septum, posterior wall, LVEF and diastolic dysfunction (DD). The diagnosis of left ventricular hypertrophy (LVH) was made based on the index of left ventricle mass indexed to high 2.7. These variables were analysed.

Results

We included 79 patients, 66 (83.5%) women, age average was 45.8 ± 10.22 years. The median BMI was 53.1 ± 9.05. Of these patients 50 (63.29%) had HT and 33 (41.77%) DM. LVH was diagnosed in 56 (70.88%), being the excentric hypertrophy pattern the most frequent (53.2%). 20.25% of the patients evidenced DD and 41.77% increased left atrial size. LVEF was greater than 50% in 97.5% of the cases. It was found a positive correlation (0.22) between BMI and LVH (p: 0.047). In order to understand which covariables are influencing LVH linear additive models were used. None of them were significative. Considering the Akaike's information criteria and the number of significant coefficients, the best model included IMC, LDL and HT variables (LVH~BMI + LDL + HT + BMI * LDL). Contribution to the development LVH was 8.8 for HT and 1,55 for IMC.

Conclusion

Eccentric LVH is the most frequent echocardiographic alteration in obese patients. The most important variable related to LVH development is HT, but BMI is a significant factor implied.

#1561 - Case Report

EMOTIONAL STRESS INDUCED SPONTANEOUS CORONARY ARTERY DISSECTION

Mulham Shikh Hamdon, Victoria Gonzalez
Wayne State University, Detroit, United States

Introduction

Spontaneous coronary artery dissection is an important yet often forgotten cause of ACS, especially in women presenting with acute myocardial infarction. Although frequently associated with varying precipitating risk factors, we are presenting a case, intense emotional stress alone leading to dissection and no other identifiable underlying predisposing risk factors

Case description

A 47-year-old woman with no cardiovascular risk factors was admitted for acute ST-segment elevation myocardial infarction.

She reported no home medications including hormonal therapy and has no smoking or recreational drug use history. The night prior to her arrival, she recalled having a very stressful event. The following morning, she was awoken by severe substernal chest pain which was constant and radiated to the left chest. Also she had 2 episodes of non-bloody emesis. The initial EKG showed ST elevation in leads V1, V2, and V3 with no reciprocal changes. A bedside echocardiogram showed ejection fraction of 50% with apical hypokinesis, so she had immediately coronary angiography which revealed spontaneous coronary artery dissection (SCAD) of the proximal left anterior descending artery with TIMI 3 flow throughout the coronary tree. No intervention was performed and there was complete resolution of ST-segment elevation post-cardiac catheterization. The patient was treated with dual antiplatelet therapy and was discharged home with plan for follow-up computed tomography angiography in 3 months.

Discussion

This case is a unique example of non-atherosclerotic SCAD presenting in a patient with no predisposing risk factors and solely precipitated by emotional stress. Once believed to be a very rare condition, spontaneous coronary artery dissection, has become an increasingly important differential for the cause of myocardial infarction in women 43 to 52 years of age. The underlying etiology of SCAD appears to be multifactorial, however, up to 20% of cases are labeled as idiopathic. Typically, patients have a clearly identifiable predisposing arteriopathy; fibromuscular dysplasia being the most common. Others include postpartum status, multi parity, connective tissue disorders, systemic inflammatory conditions, and hormonal therapy. Most patients do not have conventional risk factors for coronary artery disease. Interestingly, the patient presented in this case had no such arteriopathies. This patient also lacked any history or evidence of another causes.

#1564 - Case Report

SINCE EMBRYO IS THE HEART FORMED – A CASE REPORT OF LEFT VENTRICLE NONCOMPACTION

Rebeca Martins Natal, Vasco Neves, Pedro Ventura
Local Health Unit of Guarda, Guarda, Portugal

Introduction

Left Ventricle Noncompaction (LVNC) is a rare cardiomyopathy, with unknown prevalence, characterized by exuberant left ventricle (LV) trabeculation. It has been suggested that may be due to a dysfunction of the cardiac embryogenesis. Clinical manifestations can occur at any age and include heart failure (HF), arrhythmias, thromboembolic events and sudden cardiac arrest.

Case description

The presented clinical case refers to a 49-years-old male, former smoker (19 pack-year units) with personal history of obesity grade I, obstructive sleep apnea, depression and LV slight dilatation

documented echocardiographically 15 years ago, after an episode of angor; without further follow-up. Chronically medicated with amitriptyline. No relevant family history. This patient attended our outpatient clinic with complaints of easy fatigue with progressive worsening in the last 3 months. First complementary exams revealed no relevant findings in laboratory results, EKG with complete left bundle branch block previously unknown; transthoracic echocardiography showed dilated cardiomyopathy with severe systolic function depression (ejection fraction (EF) of 33%), hypokinesis of the septum, apex and inferior wall; Holter 24h without alterations. Posteriorly, myocardial scintigraphy excluded underlying ischemia or necrosis and, finally, cardiac magnetic resonance revealed trabeculated LV myocardium, especially in the medial and distal segments of the lateral, anterior and inferior walls, with noncompaction criteria. Patient was then referred to the cardiology clinic, started classic treatment for HF with reduced EF and was subsequently placed an implantable cardioverter defibrillator (ICD).

Discussion

With the advent of new cardiac imaging techniques, LVNC has been increasingly diagnosed, and may be a more common cause of HF than previously assumed. There are no standardized diagnostic criteria. Treatment consists of the treatment of HF, if present, and consider anticoagulation, as well as placement of ICD.

#1575 - Case Report

OSBORN WAVE IN HYPOTHERMIA

Viktor Malyarchuk¹, João Gomes², Daniela Meireles¹, Joel Pinto¹, Jorge Henriques¹

¹ Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

² Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Hypothermia can cause very characteristic changes in electrocardiogram (EKG) though the slow conduction of impulses through the potassium channels. This results in an increase in all intervals. J wave or Osborne wave although isn't pathognomonic (as it also appears in hypercalcemia, intracranial hypertension, subarachnoid hemorrhage, Brugada syndrome and others), it is the most specific EKG finding in hypothermia. It is characterized by a positive deflection of J point (end of QRS complex and beginning of ST segment) and represents the distortion of the earliest membrane repolarization phase. Its more prominent in V2-V5 and its height is proportional to the severity of the hypothermia.

Case description

An 87 years old female, with a history of hypertension, type 2 diabetes and early stages of dementia. Presented to the emergency department (ED) with an altered state of consciousness (apathy and language alterations) that began 4 days earlier, at that time she was medicated with etizolam and rivastigmine due to insomnia and dementia.

At admission at the ED, she had general weakness and was normotensive (blood pressure of 125/65 mmHg), dehydrated, hypothermic (tympanic temperature 34.8°C) and bradycardic at 40 beats per minute (bpm). Neurological examination showed left hemiparesis, facial left paralysis and global aphasia. EKG showed sinus bradycardia at 40bpm, prolonged QT and Osborne J wave. Analytical study without relevant changes, with normal TSH, free T4 and normal troponins. Urinalysis showed leukocyturia and nitrituria. Chest X-ray was normal and head CT scan showed no acute hemorrhagic or ischemic lesions.

The patient started empiric ceftriaxone, peripheral warming with thermic blanket, fluid therapy and flumazenil. After reaching a temperature of 36°, she showed clinical improvement as well as hemodynamic stability, recovery of state of consciousness and neurological deficits. A repeated EKG was normal, without any J wave.

Discussion

Although Osborne's J-wave is not the most frequent or pathognomonic electrocardiographic abnormality of hypothermia, it is important to recognize it because it may be confused with ST elevation and may lead to unnecessary treatments. The authors present this case for the documentation of this classic electrocardiographic alteration, not always recognized, but important for the establishment of differential diagnoses.

ANTIPHOSPHOLIPID SYNDROME PRESENTING AS CONGESTIVE HEART FAILURE

Anilda Barros, Rita Homem, Maria Garcia, Vanda Spencer
Hospital Garcia de Orta, Almada, Portugal

Introduction

Antiphospholipid syndrome (APS) is an autoimmune multisystemic disease characterized by persistently elevated levels of procoagulant antiphospholipid antibodies (aPL), predisposing to recurrent venous or arterial thrombosis. It may occur in isolation (primary APS), this being the most frequent form, or associated with other autoimmune disorders, infections, malignancies or drug use (secondary APS). The clinical manifestations are heterogeneous and vary according to the affected vascular territory, with venous thromboembolism being the most common consequence.

Case description

The authors present the case of a 70-year-old man, with a history of hypertension and type 2 diabetes, hospitalized for enlightenment of massive ascites and peripheral edema of 1-month evolution. From the initial exams performed, echocardiogram showed signs of right ventricular overload and dysfunction, with pulmonary embolism (PE) being later diagnosed by lung scintigraphy. In the aetiological study it was established the final diagnosis

of primary APS, based on the presence of one clinical criteria (confirmed venous thrombosis) plus one laboratorial criteria (circulating anticardiolipin antibodies IgG type), and the patient started oral anticoagulant therapy with Warfarin for target INR values between 2 and 3.

Discussion

This case intends to emphasize the initial presentation of PE as an congestive heart failure and the importance of the diagnosis of APS for an adequate therapeutic approach of these patients requiring special care. Although the new direct oral anticoagulants have several benefits in the treatment and prevention of venous thrombosis in the general population, their efficacy in APS still awaits confirmation in specific studies and only the use of Warfarin or other vitamin K antagonists is recommended.

AORTIC ANEURISM OCCLUSION

Nuno Bernardino Vieira, [Alexandra Avila](#), Vanda Conceição, Maria José Grade, Luísa Arez

Serviço de Medicina 3 - Unidade Hospitalar de Portimão do Centro Hospitalar Universitário do Algarve, Portimão, Portugal

Clinical summary

A 75-year-old male came to the Emergency Room due to a 2-day course of intense pain in the lower limbs and oliguria, with a previous history of severe peripheral arterial disease. Physical examination revealed an abolishment of the pulses in the lower limbs. A CT angiography showed acute occlusion of aortic aneurysm (3.4 cm maximum caliber) below the emergence of the superior mesenteric artery. It involves the right renal artery, which was occluded. The left kidney presents stenosis in its path, with an emergency located immediately above the occlusion. Below celiac trunk he had complete occlusion of the aorta. The case was discussed with the vascular surgery of the reference hospital.

#1600 - Abstract

AORTIC ELASTIC PROPERTIES ABNORMALITIES AS AN EARLY MARKER OF THE DEVELOPMENT OF AORTOPATHY IN PATIENTS WITH BICUSPID AORTIC VALVE

[Andrey Rudoy](#), Yaraslau Valiuzhenich, Aleksandr Bova, Aleksey Uryvaev

Belarusian State Medical University, Minsk, Belarus

Background

Bicuspid aortic valve (BAV) is a common congenital heart defect. Pathological changes affect both the valve complex and the aortic wall, which leads to the development of aneurysm / vessel dissection. The low predictive value of the currently used markers of adverse events leads to the search for new indicators that can characterize abnormalities in the microarchitecture and biomechanics of the vascular wall.

The aim of the study was to evaluate the elastic properties of the aorta in patients with a bicuspid valve by the method of two-dimensional speckle-tracking echocardiography in patients with BAV with aneurysm and without.

Methods

We examined 47 patients (22 patients with BAV, 25 healthy volunteers). For the first time in the Republic of Belarus, a two-dimensional speckle-tracking echocardiography of the ascending aorta to evaluate aortic wall function was performed. Student's test was employed to compare, respectively, continuous and categorical variables between different groups. Spearman and Pearson coefficients were employed to evaluate linear relationships between categorical and continuous parameters, respectively.

Results

Aortic dimensions on the Valsalva's sinuses, the sinotubular and ascending section in patients with BAV significantly exceeded the values in the control group ($t=3.18, p=0.002$; $t=2.68, p=0.01$; $t=3.39, p=0.001$). Aortic stiffness in patients with BAV was higher compared with the control group ($t=3.5, p=0.001$), while the extensibility and global circular deformation were reduced ($t=2.39, p=0.02$; $t=2.48, p=0.01$).

An increase stiffness in group with BAV and aneurysm of the thoracic aorta was 16.3 (13) versus 6.12 (4.2), $p=0.05$ in patients with BAV without aneurysm. Besides a reduction in global circular deformation in patients with thoracic aortic aneurysm compared with patients with BAV without aortic enlargement: 7.14 (2.9%) versus 8.6 (3.3%), $p=0.02$ was found.

Conclusion

- Pathological process in patients with BAV spreads to the aortic ring, aortic root and the ascending aorta with the formation of BAV-associated aortopathy.
- BAV-associated aortopathy is characterized by an increase in aortic size at all anatomical levels.

- BAV-associated aortopathy correlates with the violation of the aortic elastic properties at all anatomical levels which manifested by a decrease in global circular deformation, as well as an increase in the stiffness of the vascular wall.

#1610 - Abstract

NON-INVASIVE PERIPHERAL TRANSCUTANEOUS ELECTRONEUROSTIMULATION: NEW POSSIBILITY FOR NON-PHARMACOLOGICAL TREATMENT OF ARTERIAL HYPERTENSION?

Konstantin Yu. Malakhov¹, Valentin A. Kokorin², Alexander A. Gurov¹, Irina V. Kirichok³, Vladimir V. Malakhov¹, Andrey A. Fedorov⁴, Evgeny Yu. Bersenev⁵

¹ Inferum Group - Medical Department, Ekaterinburg, Russia

² Pirogov Russian National research medical university, Moscow, Russia

³ Municipal Polyclinic #175 of the Moscow Healthcare Department, Moscow, Russia

⁴ Physical therapy, Exercise Therapy and Sports Medicine department - Urals State Medical University, Moscow, Russia

⁵ National Research Center of Russia - Institute of Biomedical Problems of the Russian Academy of Sciences, Moscow, Russia

Background

The aim: to assess the efficacy and safety of the non-invasive device for peripheral transcutaneous electroneurostimulation (TENS) in patients with arterial hypertension (AH)

Methods

We performed 2 randomized sham-controlled studies involving 105 patients. In the first one, 77 patients (24 men, 53 women, mean age 62.5±11.6 years) were allocated to active treatment and sham control groups in ratio 1:1. In the second one, 28 patients (8 men and 20 women, mean age 70.1±6.9 years) suffering from AH and comorbid disorders were allocated to active treatment and sham control groups in ratio 3:1. All patients with the verified AH diagnosis had taken the recommended pharmacotherapy but did not achieve target blood pressure (BP) levels. The patients underwent the procedure of TENS 3 times per day for 14 days using device ABP-051 (Ekaterinburg, Russia). In control group, the procedure was performed using sham devices. In the second study, BP rates were monitored for 14 days after the treatment course.

Results

Both studies showed similar antihypertensive effect of the method. At the end of the treatment period, the significant decrease of systolic BP on 15.1±3.6 mm Hg ($p<0.05$) and diastolic BP on 6.0±0.8 mm Hg ($p=0.06$) was found. BP decrease was observed regardless of the AH grade. The combined results of the both studies showed that target BP was achieved in >80% of the patients (84.6% and 81.0%, respectively). There was no significant change of the BP values in the control

groups ($p<0.05$). The follow-up after the treatment showed that antihypertensive effect was maintained for 14 days. During the treatment period, there were no specific adverse effects related to the procedure.

Conclusion

The study showed antihypertensive effect of the non-invasive transcutaneous electrostimulation in patients with AH, who did not reach the target BP levels on pharmacotherapy. Further studies are necessary to confirm our preliminary results.

NOT EVERYTHING THAT RESEMBLES PNEUMONIA, IS PNEUMONIA. DIAGNOSTIC TECHNIQUES VS CLINICAL SEMIOLOGY

Juliana Chen Xu, Dolores Vazquez, Sónia Da Costa Fernandes, Angela Coelho, Teresa Pinto
CHPVVC, Póvoa De Varzim, Portugal

Introduction

Pulmonary embolism (PE) results from an alteration in the elements comprising Virchow's triad which leads to the obstruction of either the pulmonary artery or one of its branches. Certain conditions increase the risk for this alteration, such as prolonged bed rest, genetic mutations, neoplastic lesions, and others.

Clinic of PE is not pathognomonic, so it is essential to make a differential diagnosis to distinguish it from other pathologies such as pneumonia.

Notwithstanding that the Computed Tomography Angiography (CTA) is the gold standard test for the diagnosis of PE, its availability is not widespread, especially in smaller hospitals.

Case description

70-year-old male. History of obesity, hypertension, active smoking, non-functioning pituitary macroadenoma, chronic lung disease.

The patient resorted to the emergency department (ED) due to cold sweats and sudden pleuritic pain at the base of the right hemithorax without cough, sputum or dyspnea. Physical examination showed hemodynamical stability, afebrile, saturation of 94% on room air. On auscultation: no murmurs; with crepitations in the right hemithorax base.

Diagnostic techniques and procedures (DTP) showed right base condensation and C-reactive protein 7.38mg/dL with mild leucocytosis ($11.87 \times 10^9/L$).

The patient was hospitalized for community-associated pneumonia with significant pleuritic pain and empirical antibiotic therapy was initiated.

During hospitalization, and considering that the patient still presented severe pleuritic pain with need for therapeutic escalation to control pain, without fever, cough or expectoration, and with inflammatory parameters remaining stable, it was considered the possibility of PE, which was later confirmed by

CTA, the corresponding condensation image being a pulmonary infarct area. In the echocardiographic study, the patient exhibited dilated right chambers and signs of pulmonary hypertension.

On follow-up consultations, head CT showed an expansive homogeneous lesion with osseous molding of 16x26mm at the sellar pavement, of probable tumoral residue/relapse. MRI was requested.

Discussion

During the stay in the ED, the chest X-ray image was prioritized, considering it to be pneumonia, delaying the PE diagnosis and the probable paraneoplastic etiology.

The purpose with this case is to demonstrate the importance the clinical semiology holds, the signs and symptoms being the indicators for the diagnosis and to avoid neglecting these when giving preference to the DTP.

#1627 - Abstract

THE SIGNIFICANCE OF PRE-EXISTING LEFT VENTRICULAR REMODELING IN RELATION TO RISK STRATIFICATION IN NON-ST ELEVATION MYOCARDIAL INFARCTION

Madalina Andreea Munteanu¹, Camelia Nicolae²

¹ Clinical Hospital Th. Burghel, Bucharest, Romania

² University of Medicine Carol Davila, Bucharest, Bucharest, Romania

Background

Background: Left ventricular remodeling is the process by which ventricular size, function and shape are regulated by mechanical, genetic and neurohormonal factors. The occurrence of pre-existent left ventricular (LV) remodeling in a non-ST elevation myocardial infarction (NSTEMI) carries significant risk.

Methods

Methods: We retrospectively analyzed 36 patients (23 men and 13 women) with NSTEMI according to the adapted guide. The average age is 69.1±13.4 years. The analysis was carried out based on the results of echocardiography (ECHO) according to classical criteria for defining LV geometry in the moment of presence as the development of myocardial infarction. We have also used the Grace Score in relation with LV remodeling for stratification of NSTEMI.

Results

Results: All patients were analyzed. LV remodeling was observed in 34 patients (96%). 20 (55%) presented concentric hypertrophy, 8 (23%) concentric remodeling and 6 (18%) eccentric hypertrophy. We grouped patients in 3 groups depending on their Grace Score: low grade risk with Grace <108, intermediate risk with Grace Score between 109-140 and high risk with Grace Score > 140. Thus, in the study group, the type of remodeling associated with the Grace Score shows for high risk-75% concentric hypertrophy and 25% concentric remodeling, for intermediate risk-50% eccentric

hypertrophy, 25% concentric remodeling and 25% concentric hypertrophy and for low risk-50% concentric remodeling, 34% eccentric hypertrophy and 16% concentric hypertrophy.

Conclusion

Conclusions: Concentric hypertrophy is mainly associated with the study group, consisting of NSTEMI patients with a high risk Grace greater than 140. The presence of concentric ventricular hypertrophy, echocardiography diagnosed on hospitalization of patients with NSTEMI could advocate for the formulation of the immediate indication of PCI.

#1634 - Abstract

HOW ARE PATIENTS WITH SACUBITRIL-VALSARTAN? BASIC HEART FAILURE UNIT OF SECOND LEVEL HOSPITAL

Carlota Tuñón De Almeida, Maria José Ruiz Olgado, Victor Madrid Romero, Carlos Aldasoro Frias, Sara Muñoz Alonso, Victoria Palomar Calvo, Juan José Torres Ramos, Montserrat Chimeno Viñas, Luis Miguel Palomar Rodríguez

Complejo Asistencial de Zamora, Zamora, Spain

Background

Description of clinical and analytical profile of patients who started treatment with sacubitril-valsartan in its first years of commercialization in a basic heart failure unit.

Methods

Descriptive and retrospective review of patients through the evaluation of each patient's medical record who started treatment with sacubitril-valsartan from 31st January 2017 to 7th February 2019.

Results

In our sample, a total of 115 patients were analysed, 92 of which (80%) were male and 23 (20%) female. Age average was 72.6 years, with a typical deviation of 9.5 years, and a range of 45 to 87 years. Heart failure etiology was: ischemic (38.3%), dilated without ischemia (40.9%), and valvular (2.6%). More than half of the patients (53%) had Atrial Fibrillation.

The average LVEF was 32% (typical deviation of 10). Average glomerular filtration rate (before treatment was initiated) was around 61 ml/min.

As for the previous treatment in relation to heart failure, 100% of the patients were treated with angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, 74% of them received antialdosteronic treatment, 92.2% had a beta blocker, and 86.1% diuretic treatment (mostly furosemide). 12.2% took ivabradine and 6% amiodarone.

Of these patients, 31 (27%) were implantable automatic defibrillator (IAD) carriers, of which 12 of them (40%) had ischemic heart failure. On the other hand, 4 of the patients (3.5%) were carriers of Cardiac-resynchronization therapy (CRT), and

16 (13.9%) carriers of both IAD-CRT. The rest of them, a total of 59 patients (51.3% approximately half the sample), had no device implanted on them.

Analytical data, previous to establishment of the new treatment, were: average pro-BNP of 3486 pg/mL, potassium of 4.6 mEq/L, sodium of 140 mEq/L and haemoglobin of 13.9 mg/dL.

Based upon NYHA functional class, 6 patients (5.1%) had a functional class I, 59 (50.4%) had a functional class II, 32 (27.4%) a functional class III, and finally, 5 patients (4.3%) were in functional class IV.

Conclusion

Patients of our Heart Failure unit who received Sacubitril/Valsartan, did it within the indications of the latest guides of clinical practice, published in 2016, having a high rate of previous beta blocker and antialdosteronic use. In future studies, we will evaluate if the evolution of the patients in our sample was similar to those included in the PARADIGM-HF study, regarding clinical and analytical improvement, and reduction of events in their follow-up.

#1661 - Case Report

SEQUENTIAL NEPHRON BLOCKADE – A CLINICAL CASE OF SEVERE DIURETIC RESISTANCE

Mariana Fidalgo, Beatriz Samões, Sofia Pereira, Manuela Sequeira
Centro Hospitalar Vila Nova Gaia / Espinho, Vila Nova De Gaia, Portugal

Introduction

Diuretic resistance is a frequent problem in heart failure [HF] patients, with an estimated prevalence of 20-30%. It refers to the inability to alleviate congestive symptoms despite appropriate or escalating diuretic dosages.

Case description

A 75-year-old man presented to the ER with progressive worsening of peripheral edema, dyspnea to increasingly smaller efforts and orthopnea.

He had multiple cardiovascular risk factors, hypertensive cardiopathy (NYHA II/IV) with preserved left ventricular ejection fraction [LVEF] (under furosemide and bisoprolol), pulmonary hypertension and permanent atrial fibrillation (under apixaban). He had chronic kidney disease and COPD GOLD A, with no recent exacerbations.

At presentation he had a BP of 118/84 mmHg, HR of 90 bpm (arrhythmic and irregular), polypnea and no fever. Cardiac and pulmonary auscultation was globally hypophonic. Abdomen was distended, with significant wall edema. He had bilateral leg and thigh edema.

Blood work: discrete creatinine elevation with no other significant alterations. Arterial blood gas: hypercapnic respiratory insufficiency with $pO_2 < 60$ mmHg. Chest x-ray revealed small bilateral pleural effusion. Transthoracic echocardiogram showed

right ventricle dysfunction and minor LVEF reduction. Abdominal echography found severe abdominal wall edema with no significant ascites.

Patient was admitted for therapeutic optimization. He was started on intravenous furosemide, under regular control of renal function and ionic balance. Despite increasing dosages (max.160mg/day), patient's weight remained stable with no improvement of congestive signs and symptoms.

On day 6 he was started on sequential nephron blockade with double diuretic therapy (furosemide plus metolazone). This resulted in a significant elevation of urinary output with gradual improvement in effort capability and no worsening of renal function. At discharge he no longer had respiratory insufficiency and had lost 17.5 kg. Follow-up appointment: patient was stable in NYHA II/IV under furosemide alone.

Discussion

Diuretic efficacy is evaluated based on weight loss and/or urinary output. Sequential blockade of sodium reabsorption in different nephron segments with two or more diuretics of different classes generates a synergic effect that counteracts several resistance mechanisms and significantly increases diuresis. Under close monitoring, it is a very safe and effective strategy to achieve congestion relief in the resistant patient and should not be feared.

#1663 - Case Report

THE DIAGNOSTIC CHALLENGES OF A CASE OF AORTIC DISSECTION

João Corrêa, Ana Branco, Eduardo Cernadas, Dália Estêvão, Ana Rita Elvas, Leopoldina Vicente

Serviço de Medicina Interna - Centro Hospitalar Universitário Cova da Beira, Covilhã, Portugal

Introduction

Aortic dissection is a disruption of the medial layer provoked by intramural bleeding, resulting in separation of the aortic wall layers. Aortic dissection is relatively rare (incidence estimated at 6 cases per 100,000 persons per year) but has an elevated mortality rate, of up to 20%. Early and accurate diagnosis and treatment are crucial for survival.

Case description

Female patient, 77 years-old, comes to the emergency room (ER) with intense pain in the superior thoracic and cervical regions, with acute onset whilst resting in a sitting position 30 minutes after dinner, associated with nausea and vomiting. In the ER, patient presented as hypotensive, with a normal and regular heart rate, without asymmetries in peripheral pulses or alterations on cardiac and pulmonary auscultation, benign electrocardiogram (ECG), slight elevation of myocardial necrosis markers with progressive descent, acute renal failure, slightly elevated inflammatory markers and interstitial infiltrate on chest radiography without mediastinal widening. With fluid resuscitation chest pain ceased

and hemodynamic stability was achieved.

During ward admission, never again did the patient have intense chest pain or hypotension. Upper endoscopy was performed which revealed peptic esophagitis and hiatal hernia. Patient also developed atrial fibrillation with rapid ventricular response, left-side pneumonia, acute decompensated heart failure and left pleural effusion that evolved to bilateral. Consecutive chest radiography revealed a progressive increase in cardiac silhouette and mediastinal widening so a computed tomography (CT) scan and transthoracic (TT) echocardiogram were requested. TT echocardiogram showed an ascending aortic dilation of 60mm and images suggestive of the presence of thrombus on the aortic wall. Urgent thoracic CT angiography was performed and revealed a type I aortic dissection.

Discussion

A patient presenting with chest pain can be a diagnostic challenge given the wide array of possible causes that range from benign to life-threatening situations. This becomes especially true in the elderly population in whom signs and symptoms may be more difficult to appreciate and who may have co-existing diseases that can explain the symptoms, as in this case.

While, an aortic dissection often presents acutely as a catastrophic illness with severe chest pain and acute hemodynamic compromise, other forms of presentation and evolution should be considered.

#1667 - Abstract

IRON DEFICIENCY IN HEART FAILURE- A RETROSPECTIVE STUDY

Sofia Gomes Brazão¹, Ana Luisa Correia², João Filipe Gomes³, Ana Filipa Correia⁴, José Pedro Fernandes⁵, Fábio Salgueiro Rego¹, José Bernardes Correia², José Pereira Moura³, Armando Carvalho⁴

¹ Internal Medicine, Coimbra, Portugal

² Centro Hospitalar e Universitário de Coimbra e Faculty of Medicine, Coimbra, Portugal

³ University of Coimbra, Coimbra, Portugal

⁴ Coimbra, Coimbra, Portugal

⁵ Portugal, Coimbra, Portugal

Background

Recently iron deficiency (ID) has played an important role in heart failure (HF). These conditions are associated with poor clinical status and worse outcomes. The 2016 European Society of Cardiology Guidelines recommended that intravenous ferric carboxymaltose (FCM) should be considered in symptomatic patients with heart failure with reduced ejection fraction (HFrEF) and ID (serum ferritin <100 µg/L, or ferritin between 100–299 µg/L and transferrin saturation <20%) in order to alleviate HF symptoms. The aim of this study was to characterize the diagnosis and management of ID anaemia in patients with HF.

Methods

A retrospective cohort study was conducted on patients admitted

in an internal medicine ward between May and October of 2018 with the diagnosis of HF and anaemia.

Results

Four hundred and ninety seven patients were analyzed, of whom 195 had HF and anaemia. The median age was 85 year old and 58.5% were female. An echocardiogram evaluation was performed in 49.2% of the patients and 35.1% had HFrEF. BNP was tested in 90.25% of the patients with a mean value of 833 pg/mL. Most of the patients had chronic kidney disease on stage 3 (35.4%) and only 4.6% had no kidney damage. The average haemoglobin was 9.5 mg/dL. Ferritin levels were evaluated in 81% of the cases, with an average ferritin of 318mg/L. Only 26.2% had absolute iron deficiency (Ferritin <100µg/dL), and 32.8% had ferritin in the range of 100-300 µg/L. From the patients with ferritin levels less than 300µg/L, 96.3% were tested for transferrin saturation which was inferior to 20% in 39.5% of the cases. Mortality in the 6 month follow-up period was 38.5%, with 8.7% not surviving past the initial admission. Of the 178 patients surviving the initial admission, there was a total of 92 hospital readmissions directly related to HF within the follow-up period. Oral iron therapy was prescribed in 27.2% patients on discharge. Only 9.74% had intravenous iron therapy and 21% had blood transfusion.

Conclusion

This study shows the impact of HF on readmission and mortality rates. Although some studies have reported the benefits of FCM treatment in patients with HF, ID is still an underdiagnosed entity. In our opinion, it is important to screen for ID even in the absence of anaemia as FCM treatment has shown improvement in functional capacity and quality of life.

#1671 - Abstract

EVALUATION OF PATIENTS WITH ACUTE PULMONARY EMBOLISM, ACCORDING TO TROPONIN & CREATININE AT ADMISSION AND IT'S PROGNOSTIC IMPACT

Fabiana Gouveia, Diogo Raposo André, Rafael Nascimento, Teresa Raposo André, Rita Vieira, João Miguel Freitas, Luz Brazão
Hospital Central do Funchal, Funchal, Portugal

Background

Pulmonary embolism (PE) is a fatal entity in which risk stratification plays a key role. The determination of Troponin T (TpT) - cardiac necrosis marker - and Creatinine (Cr) - a marker of renal dysfunction - may be useful in the short-term prognostic evaluation of PE patients.

Methods

Retrospective analysis of patients diagnosed with PE at a Central Hospital in 2017. Of the 117 patients with the diagnosis of acute PE, only 116 performed an analytical evaluation at the entrance. These were stratified according to the values of TpT, Cr and the

Early Mortality Risk (EMR) developed by the European Society of Cardiology (ESC): right heart dysfunction, cardiac biomarkers, Pulmonary Embolism Severity Index (PESI) score and hypotension/shock. The data obtained were treated by IBM SPSS Statistics® Version 25 and the Pearson Chi-Square, Linear Association and ROC Curve tests were used.

Results

Of the 116 patients, TpT was only evaluated in 90 (58 women and 32 men). As shown by EMR, TpT is one of the factors included in the cardiac biomarkers group. In this study, TpT evidenced the presence of a relationship with statistical significance for EMR, as found in previous studies (95% CI, $p=0.005$). In this sense, we proposed to determine the association between EMR and altered values of Cr on admission.

Of the 116 patients with a determination of Cr value at diagnosis, 76 were women. According to the EMR stratification, 19 patients had a low risk of early mortality and 18 patients at high risk. Of the study sample, 50% had a high Cr - defined as a value above the estimated median of 1.01 (min 0.5, max 5.3).

It was found that there was a statistically significant association between the EMR of ESC and the altered values of Cr at the time of diagnosis with Pearson Chi-Square Test (95% CI, $p=0.012$). However, the ROC curve shows that the altered values of Cr do not have great discriminative power in relation to mortality (AUC=0.632).

Conclusion

Each factor alone does not have sufficient discriminative power to measure mortality, due to its low specificity and sensitivity, but it is possible to estimate the risk of early mortality in the diagnosis of acute PE.

HEPATIC CYST, A DIFFERENT MANIFESTATION

Bruno David Freitas, Ana Garrido Gomes, Maryna Telychko, Sandra António

Hospital de Santarém, Santarém, Portugal

Clinical summary

88 year old woman, with known history of hypertension, chronic heart failure and myelodysplastic syndrome, presented in Emergency Department with dyspnoea of progressive onset without other symptoms. As part of workup, the patient underwent CT scan (thorax and abdomen) which revealed a hepatic cyst (145mm in diameter) that compressed right heart cavities. After exclusion of other causes as pulmonary embolism, pulmonary hypertension, respiratory infection as well as hydatid cyst, it was drained with resolution of dyspnoea.

The analysis of content was compatible with pure biliary cyst.

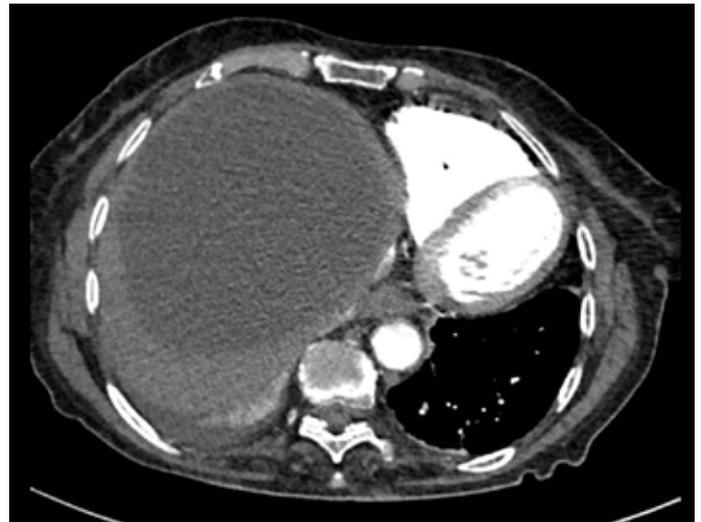

Figure #1673.

#1709 - Abstract

THE IMPACT OF HYPERTENSIVE PREGNANCY DISEASES IN AN INTENSIVE CARE UNIT

Isabel Montenegro Araújo¹, Inês Vieira Santos², Ursula Segura¹, Carlos Pereira¹, Patrícia Patrício¹, António Messias¹

¹ Hospital Beatriz Ângelo, Loures, Portugal

² Hospital Espírito Santo de Évora, Évora, Portugal

Background

Hypertensive disease occurs in up to 10% of pregnancies, establishing one of the major causes of maternal morbidity and mortality. It is the main cause of prematurity as well as admission to the ICU. In Portugal, it is the second cause of maternal death. These disorders may complicate 5%–10% of all pregnancies and are the leading cause of maternal and perinatal mortality and morbidity worldwide. Several risk factors are known to determine its occurrence, and it is important to monitor the women who present them to avoid such outcome.

Methods

The authors present the analysis of the obstetric population admitted to an Intensive Care Unit (ICU) whose cause of admission was hypertensive pregnancy disease (preeclampsia, eclampsia, HELLP syndrome) or in which it manifested during hospitalization. The demographic characteristics, personal antecedents and control of the risk factors prior to hospitalization were evaluated, as well as the evolution during the same. The clinical processes (of the hospitalization of obstetrics, birth unit and the intensive care unit) of all the patients admitted by the pathology previously described in the SMI during the period from February 2012 to March 2019.

Results

During the referred period, there were 126 hospitalizations of pregnant or puerperal patients. Admissions of hypertensive complications were present in 51 patients (corresponding to 41%

of admissions) and as a cause of admission in 39%, that is, the majority of these women.

Women ages were between 21 and 45 years. Most of the hospitalizations took place in the puerperium (42 hospitalizations - 82%). Among the relevant medical antecedents, pre-gestational hypertension or gestational hypertension, with insufficient control, was especially important, and it should be noticed that in some cases the pregnancy was not monitored and it was not possible to determine or classify the hypertensive disease as present before 20 weeks of gestation. Among the patients with hypertensive disease, there were no maternal deaths, however, 5 fetal deaths occurred (one after admission to the ICU).

Conclusion

The control of risk factors is of high importance in order to avoid an unfavourable outcome in this population. Good follow-up of these women during gestation, as well as tight surveillance during the peri-parturition period, is important, since hypertensive disease can have devastating consequences.

#1728 - Case Report

PULMONARY VALVE ENDOCARDITIS

Inês Mendes, Maria João Baptista, Francisco Araújo, José Lomelino Araújo

Hospital Beatriz Ângelo, Loures, Portugal

Introduction

Right heart infective endocarditis represents 5-10% of all endocarditis. Pulmonary valve endocarditis corresponds to 1-2%, usually in people using IV drugs or having some congenital cardiopathy.

Case description

We present a 72 year caucasian male, with a medical history of an aortic mechanic valve (4 years before), type 2 diabetes mellitus and hip replacement 3 months before. No toxicofilic habits.

He presented in the ER with fever and productive cough. Blood tests revealed inflammatory parameters and the X-ray showed a hypotransparency in the right superior lobe. He was diagnosed with a pneumonia and started amoxicillin and clavulanic acid plus azithromycin.

For a better characterization, he did a thoracic CT that revealed an extensive pneumonia and a trans-thoracic echocardiogram that showed a normal aortic valve.

During the investigation, there was a blood culture positive result for *Streptococcus Gallolyticus* and a switch to ceftriaxone. He went through an upper endoscopy (chronic gastritis) and colonoscopy (normal). He finished 14 days of ceftriaxone and withdrawal asymptomatic, with negative control blood cultures.

One month later, he went back to the ER, presenting with fever and cough.. This time he had a transesophageal echocardiogram that showed a pulmonary valve vegetation (18x11mm), with a normal aortic valve. There was again a positive blood culture for

S. Gallolyticus. Cardiothoracic surgery suggested conservative approach, so the patient completed 4 weeks of benzathine penicillin and 2 weeks of gentamicin. He repeated the trans-thoracic echocardiogram at the 22nd day, showing a vegetation 18x7 mm (with moderate pulmonary valve insufficiency associated). Withdrawal asymptomatic, with negative blood cultures.

Again, one month later he went back to the ER, presenting with fever, repeated the echocardiogram showing a bigger vegetation (22x12 mm). This time he went under surgery with a pulmonary valve substitution after completing 2 weeks of benzathine penicillin and 2 weeks of gentamicin.

Discussion

We must suspect of pulmonary valve infective endocarditis when the patient presents with the tricuspid syndrome: repeated respiratory events, anemia and microscopic hematuria. Usually the isolated microorganism is a *S. aureus* or a B group *Streptococcus*. It has a better prognosis than the left heart endocarditis. There are no guidelines for pulmonary valve endocarditis specifically but the few case reports in literature usually describe a surgery after 4-6 weeks of antibiotic.

#1729 - Abstract

THE COST OF HEART FAILURE IN A SECONDARY HOSPITAL

Maria João Morgado Nabais Baldo

ULS Guarda, Guarda, Portugal

Background

The HF is a serious public health problem worldwide with high morbidity and mortality. In 2012, HF cost 102 billion euros worldwide. Despite of the high prevalence of this pathology, there are few studies that approach this pathology from an economic point of view. The objectives are: 1. To evaluate the cost of patients with HF treatment in a secondary hospital. 2 To evaluated which variables has most influenc

Methods

The methodology was retrospective observational study with static analyses (SPSS 24) The population was all patients hospitalized in the internal medicine ward for 8 months with the primary diagnosis of HF in ICD-10. Exclusion criteria were: less than 18 years of age, transfer to other hospital, abandonment and discharge against medical orders, poorly coded process and hospitalization period <24 h. They were organized in groups: Demography, Diagnosis Complementary Diagnostic Tests, Pharmacological Therapy, Clinical Data, Procedures, Professionals and Hospitalization.

Results

The HF patient (n°156) is predominantly: female (54%), aged 83.85±7.641, with a rankin 1-3, with chronic HF (88.6%) in NYHA IV (97.5%), with a HFmEF (34.8%), ischemic etiology (24.7%), an

infection being the main cause of decompensation (50.6%). They have 5, 96 ± 2.43 comorbidities (most frequent HTA (88.6%)). They stayed 12.7 ± 7.942 days in the hospital, 51.9 % went to their own home (with a mortality rate of 5,1%). In the Clinical data: BP: 89.79 ± 22.43 , HR: 79.73 ± 18.61 , Hb: 11.07 ± 2.141 , O_2 : 2.083 ± 0.299 , pH: 7.423 ± 0.087 , CI C: 31.0%. The total cost was 64841.6 €, (4103.90 ± 2563.36) and a total daily cost of 355.99 ± 113.91 . complementary diagnostic tests accounted for 15.55% of costs (100858.04 €), procedures represent 14.27% (112004.45 €), pharmacological therapy 4.41% (28649.94 €), health professionals 18.02% (116848.58 €) and hospitalization 44.67% (289767.05 €). No strong correlation was demonstrated between the various variables in the bivariate analysis. In the parametric tests it was identified: difference between days of hospitalization and patient autonomy (t: 0.017), and in the cause of decompensation and the days of hospitalization (δ : 0.034) but that were not reflected in the total cost

Conclusion

There are different factors that aggravate the HF and consequently should aggravate the costs but this fact has not been proven in this study. Although the characteristics of the HF are well defined, the study of her cost still an unknown area and need more investigation

#1736 - Abstract

HOMOCYSTEINE AND ALL-CAUSE MORTALITY IN RETINAL VEIN OCCLUSION

Paula Reyes-Suárez, Candelaria Martín-González, Esther Martín-Ponce, Antonio Martínez-Riera, Alina Pérez-Ramírez, Julio Alvisa-Negrín, M.J Sánchez-Pérez, J Viña-Rodríguez, Melchor Rodríguez-Gaspar

Servicio de Medicina Interna, Hospital Universitario de Canarias. Universidad de La Laguna, San Cristóbal De La Laguna, Spain

Background

Increased homocysteine has been considered as a potential risk factor for retinal vein occlusion, a condition that includes central retinal vein occlusion or branch retinal vein occlusion. Retinal vein occlusion has been associated with an increased risk of cardiovascular morbidity and mortality. The aims of this study were to evaluate the relationship between homocysteine and the different types of retinal vein occlusion, and to analyse the prognostic value of homocysteine levels on long-term mortality in these patients.

Methods

We measured serum homocysteine levels in 477 consecutive patients with retinal vein occlusion who were followed up as outpatients.

Results

We included 254 men and 223 women, aged 62.9 ± 12.8 years. 70% had branch retinal vein occlusion and 30% central retinal vein

occlusion. Only 58 patients (12.9%) lacked a history of vascular risk factors and 143 patients (31.8%) had more than three cardiovascular risk factors. 48 patients (10%) showed previous cardiovascular diseases. 73 patients (15.8%) died and the follow-up period was 89.9 ± 52.5 months. Subjects with higher homocysteine levels showed a higher mortality ($p < 0.001$), especially among those with branch retinal vein occlusion. Homocysteine > 15 $\mu\text{mol/L}$ significantly predicted all-cause mortality with an HR of 2.07 ($p = 0.025$) after adjusting for other variables.

Conclusion

In patients with retinal vein occlusion, higher levels of homocysteine were independently related to all-cause mortality. This relationship was more significant for patients with branch retinal vein occlusion but not with central retinal vein occlusion.

#1770 - Abstract

EPICARDIAL ADIPOSE TISSUE (EAT) IN CHRONIC HEPATITIS C AND IN NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD) IS ASSOCIATED WITH CARDIOVASCULAR DAMAGE

Giovanna Oberti¹, Giordano Sigon², Roberta D'Ambrosio³, Giuseppina Pisano¹, Paolo Francione², Rosa Lombardi³, Pietro Lampertico⁴, Anna Ludovica Fracanzani⁵

¹ Ca' Granda IRCCS Foundation, Milan, Italy

² Policlinico Hospital, Milan, Italy

³ University of Milan, Department of Pathophysiology and Transplantation, Milan, Italy

⁴ CRC AM e A Migliavacca Center for Liver Diseases, Milan, Italy

⁵ Gastroenterology and Hepatology. Fondazione Ca' Granda IRCCS Ospedale Maggiore Policlinico, Milan, Italy

Background

Alcoholic Fatty Liver Disease (NAFLD), the most common liver disease in developed countries with a prevalence of about 30%, is considered the hepatic manifestation of metabolic syndrome, thus patients with NAFLD are at risk for cardiovascular damage. Chronic hepatitis C (CHC) has been associated to different clinical conditions including insulin-resistance and development of atherosclerosis. Epicardial adipose tissue (EAT), considered the true visceral fat, has been proposed as a cardiometabolic risk factor in patients with NAFLD.

Aim. To evaluate the role of EAT in NAFLD and CHC patients.

Methods

From 2015 to 2018, 130 patients with CHC (mean age 57.8 ± 11.8 yrs), 148 patients with NAFLD (mean age 56.9 ± 7.5) and 290 controls of general population from the same geographic area (mean age 57.5 ± 10.8) were enrolled. Clinical and biochemical parameters, cardiovascular assessment, (carotid intima media thickness (IMT) and carotid plaques and EAT thickness by ultrasound) were evaluated at enrollment. We arbitrarily

considered as increased the EAT value higher than the mean of controls (3.8±2.6 mm).

Results

Despite higher prevalence of hypertension (56% vs 24%, $p < 0.0001$), diabetes (26% vs 3%, $p < 0.0001$), hypercholesterolemia (55% vs 24%, $p < 0.0001$), and higher BMI (28.3±4.1 vs 24.8±5.3, $p < 0.0001$) of NAFLD than CHC, patients with NAFLD and CHC had similar atherosclerotic damage (carotid IMT 0.81±0.2 vs 0.82±0.2 mm, $p = 0.4$), carotid plaques (34% vs 35%, $p = 0.98$), while cardiac parameters E/A > 1 (34% vs 46% $p < 0.0001$) and EAT (5.5±2.8 vs 7.1±2.6 mm, $p < 0.0001$) were significantly higher in patients with CHC. Considering as increased EAT thickness value > 3.8 mm (mean of controls) we evaluated variables associated with increased EAT at multivariate analysis. Increased EAT was significantly associated with carotid IMT (OR 8.5, 95%CI 2.2-33, $p = 0.001$), and E/A (OR 0.2, 95%CI 0.1-0.4, $p < 0.0001$). Taking in to account all metabolic parameters at multivariate analysis the presence of HCV infection was significantly associated with increased EAT (OR 6.8, 95%CI 1.4-33, $p < 0.001$).

Conclusion

In conclusion, patients with CHC have cardiovascular damage comparable to patients with NAFLD. EAT thickness may represent a good tool for the identification of patients at risk of cardiovascular damage and should be performed in patients with CHC.

#1778 - Abstract

CHARLSON COMORBIDITY AND AVD-DEZIS SCORES IN PATIENTS ADMITTED DUE TO HEART FAILURE DECOMPENSATION: PREDICTIVE CAPACITY OF MORTALITY AND READMISSIONS

Diana Isabel Dias, Filipe Machado, Andreia Tavares, Heloisa Ribeiro, Yolanda Martins

Entro Douro and Vouga Hospitalar Center, Santa Maria Da Feira, Portugal

Background

In 1987, Charlson proposed a prognosis predictor score combining the patient age with his comorbidities (aCC-age adjusted Charlson comorbidity index) later updated as an in-hospital mortality predictor (mCC-modified Charlson comorbidity index). The AVD-DezIs score is a functional score validated in our hospital since 2013 that provides a patient global capacity pontuation based on the ability to perform the daily life and instrumental activities. We aim to evaluate the hability of these scores predicting 1 and 3-years mortality, emergency department and ward 30-days readmissions due to heart failure (HF) decompensation.

Methods

The 1 January-31 December 2016 discharged patients with discharge diagnosis of "congestive/left/non specified systolic/

non specified dyastolic HF" accordingly to portuguese validated Heterogeneous Diagnosis Group were analysed. The 1 and 3-years mortality, emergency department and ward 30-days readmissions comparative analysis accordingly to the aCC, mCC and AVD-DezIs scores was done using SPSS v.25 and $p < 0.05$ was considered as statistically significant.

Results

We have analysed 327 patients (33.3% male, 77±10 years) which presented a median mCC score of 10, aCC of 11 and AVD-DezIs of 6.1. The 30-days emergency department readmission rate was 30.6% (n=100), 17.4% (n=57) were hospitalized again and mortality rate was 20.8% (n=68) at 1 year and 13.5% (n=44) on 3 years after discharge. There was not significant difference on mCC between groups regarding and aCC scores groups 1-year mortality (2.69±1.89 vs 2.30±1.76, $p = 0.11$) and 3-years mortality (2.36±1.79 vs 2.39±1.80, $p = 0.94$) but higher aCC and mCC scores were associated with more frequent emergency department readmissions at 30-days (2.22±1.66 vs 2.82±1.78, $p = 0.01$). No relation was found between mCC and 30-days inward readmissions (2.30±1.69 vs 2.69±2.16, $p = 0.15$). The aCC analysis demonstrates similar results. In the AVD-DezIs score analysis, statistical significant association was noted between a lower functional score and the 1-year mortality (mdn=4.00; AIQ 9 to 0 vs mdn=10-; AIQ 18 to 0; $p = 0.00$). There was no statistical association between AVD-DezIs score and the 3-year mortality and readmissions.

Conclusion

In HF the patient functional status seem to relate with 1-year mortality but comorbidity scores relate more with the early emergency readmissions. However, new prognosis predictor scores are needed and patients should have individualized health care in order to prevent readmissions and delay death.

#1780 - Case Report

AN UNUSUAL CASE OF CARDIAC CACHEXIA

Francisco D'Orey, Bruno Sousa, Rosa Alves, Tiago Judas

Hospital Garcia de Horta, Almada, Portugal

Introduction

Cachexia and unexplained weight loss are common presentations in the Internal Medicine wards, frequently representing a diagnostic challenge for the internist

Case description

We present a case of a 78 year-old man with admitted to the ward for investigation of significant weight loss, weakness and severe hyponatremia (Sodium 118 mmol/L). He had a past medical history of a low grade colon adenoma and ischemic heart disease. He was not a smoker or a drinker. On examination he had mild peripheral oedema, was hypotensive and had signs of cachexia.

On the analytic investigation he was pancytopenic, had a marked elevation of the ESR, and markers of hepatic cholestasis. His chest

radiograph showed a left-sided pleural effusion. Pleural liquid had characteristics of a transudate with cytology negative for malignancy. The thoracic-abdominal-pelvic computerized tomography did not show and suspicious lesions. We collected a bone marrow biopsy which showed signs of medulla hypoplasia but did not show any evidence of hematopoietic malignancy. Due to high suspicion of occult malignancy he underwent a positron emission tomography (PET) which did not highlight any suspicious lesions for malignancy or systemic infection but did show signs of pericardial calcifications. In view of this he had an echocardiogram which confirmed a constrictive pericarditis. We increased diuretic therapy with good symptomatic results. He was discharged with from our ward with outpatient follow-up in Cardiology with the aim of pericardial decortication.

Discussion

This case represents a serious and longstanding manifestation of chronic pericarditis. Due to the significant picture of weight loss and cachexia, an occult malignancy seemed to be the most likely diagnostic hypothesis. With this case the authors demonstrate the significance of pursuing an exhaustive clinical investigation and keeping a high level of suspicion for less common causes of cachexia. In this challenging case the diagnosis turned out to be a syndrome of Cardiac Cachexia secondary to a constrictive pericarditis. Cardiac cachexia is a neuroendocrine and metabolic syndrome characterized by an anabolic-catabolic unbalance which leads to a state of weakness and cachexia.

A VERY DIFFERENT SEIZURE

Alexandra Coimbra, Jorge Prazeres, Raquel Rodrigues, Tânia Vassalo, Fernanda Mendes
Santa Maria Hospital, Lisbon, Portugal

Introduction

The syndrome of reversible posterior encephalopathy, is an entity that begins to be more present in the clinical spirit, which contributes to a rapid diagnosis, with direct implication in the reversibility of the signs and symptoms.

Case description

Woman, 40 years, leucodermic, autonomous, no relevant personal history. Paroxysmal episodes of palpitations and anxiety, one week later an episode of sudden alteration of the state of consciousness and mandibular contraction. In the emergency department: hypertension (205 / 110mmHg), tachycardia (130 beats per minute), apyrexia, without meningeal signs. During observation with four episodes of generalized seizures. In the post-critical period, on neurological examination: paresis of the left upper limb grade 4 (scale of Medical Research Council). Treated with anticonvulsant therapy (sodium valproate and levetiracetam) and antihypertensive (labetalol infusion). Laboratory evaluation without alterations (namely elevation of the acute phase parameters, thyroid function and toxic

research). Unchanged cranioencephalic computer tomography scan, electrocardiogram with sinus tachycardia, transthoracic echocardiogram with left ventricular hypertrophy, fundoscopy without alterations. Admitted in the Intensive Care Unit and after in the Medicine ward. Electroencephalogram showing non-specific encephalic dysfunction. Cranioencephalic magnetic resonance with changes suggestive of reversible posterior encephalopathy syndrome. Doppler ultrasound of the neck and transcranial vessels and posterior cervical computed tomography with angiography compatible with long and stenotic dissection of the left internal carotid artery and presence of mural thrombus without surgical indication. Study of secondary hypertension: elevation of catecholamines and metanephrines; scintigraphy with metaiodobenzylguanidine and renal ultrasound was normal. After tension control cranioencephalic magnetic was normal; catecholamines and metanephrines with a significant reduction of the dosed values; doppler ultrasound of the vessels of the neck with almost total recanalization. Patient is asymptomatic under anticonvulsive, antihypertensive and antiaggregating therapy.

Discussion

This entity presents nonspecific signs and symptoms, but when conjugated at any given moment, they should raise the suspicion. The imaging method of choice for documentation is magnetic resonance, sometimes unavailable. The spontaneous carotid dissection have some cases related with this syndrome.

#1790 - Abstract

PADUA SCORE: PREDICTOR OF THROMBOTIC RISK AND PROPHYLACTIC ANTICOAGULATION THERAPY IN HOSPITALIZED PATIENTS

Joao Figueira, Paulo Ramos, Rodrigo Vicente, Vasco Tiago, Fernando Aldomiro
Hospital Professor Doutor Fernando da Fonseca, Lisbon, Portugal

Background

Venous thromboembolism (VTE) is considered the leading cause of preventable death in hospitalized patients. Better prognosis depends on early stratification of thrombotic risk and prophylaxis. Guidelines recommend the use of prophylactic anticoagulation with low molecular weight heparin (LMWH) in hospitalized patients who have high risk of VTE. Padua score and IMPROVE bleeding risk score (IBRS) are important stratification tools to assess thrombotic and haemorrhagic risk in hospitalized patients. The use of these scores in reducing thrombotic events is not yet consensual. The objective of this study was to determine the applicability of the Padua and IBRS scores in the decision for prophylactic anticoagulation in patients hospitalized in an Internal Medicine department.

Methods

A retrospective analysis of the electronic case files of patients admitted to an Internal Medicine department between June

and December of 2017 was carried out, and the Padua and IBRS scores were applied. The anticoagulant therapy decision and VTE episodes were assessed.

Results

Initially 640 patients were included, but 4 patients were excluded for insufficient data and 145 for having undergone therapeutic anticoagulation, leaving a sample of 491 patients. In these, the haemorrhagic risk according to IBRS was evaluated; 118 were classified with high haemorrhagic risk and were excluded.

In the remaining 373 patients, the Padua score was applied; 130 were classified with low thrombotic risk and 243 with high thrombotic risk.

In the low thrombotic risk group, in 44.6% (58) prophylactic LMWH was used and 55.4% (72) did not undergo anticoagulation. In this group there was 1 thrombotic event in the anticoagulated group and no thrombotic event in the non-anticoagulated group. Amongst the 243 patients with high thrombotic risk, in 56.8% (138) prophylactic LMWH was used and 43.2% (105) did not undergo anticoagulation. In this group, there was 1 thrombotic event in the anticoagulated group and 2 thrombotic events in the non-anticoagulated group.

Conclusion

We found that the decision to initiate prophylactic anticoagulation was not concordant with that recommended by the Padua score in about 50% of the patients. The clinical decisions did not result in significant differences in the number of thrombotic events. More studies are needed to evaluate the applicability of risk scores in the decision for prophylactic anticoagulation for VTE prevention in hospitalized patients.

#1811 - Abstract

HYPERTENSION: COMPARING REAL-LIFE PATIENTS IN AN INTERNAL MEDICINE WARD TO THE EUROPEAN SOCIETY OF CARDIOLOGY ARTERIAL HYPERTENSION GUIDELINES

Ivo Barreiro, Rosário Silva, Patrícia Almeida, Amélia Pereira
Hospital Distrital da Figueira da Foz, EPE, Figueira Da Foz, Portugal

Background

Hypertension is a leading cause of the global burden of disease, doubling the risk of cardiovascular diseases.

New guidelines for the management of hypertension have been recently published by the European Society of Cardiology. It recommends that a stricter approach on lowering blood pressure (BP) levels is beneficial.

Report's objective was to evaluate if hospitalized patients with hypertension in our institution have adequate BP control at discharge, and if there were patient characteristics more prevalent in the non-controlled group.

Methods

A cross-sectional, observational study report regarding patients hospitalized in the Internal Medicine wards in our institution, with the diagnosis of hypertension.

Results

154 patients included in the study. 53.2% were male; 29.9% elderly and 63% very elderly. 16.2% of patients had ischemic coronary disease (ICD); 36.4% had diabetes; 42.2% had heart failure (HF); 31.8% had atrial fibrillation (AF); 76.6% had chronic kidney disease (CKD). 27.3% of patients were being treated with angiotensin-Converting Enzyme inhibitors (ACEi); 15.6% with Angiotensin Receptor Blockers (ARB); 23.4% with Calcium Channel Blockers (CCB); 68.2% with loop diuretics; 3.9% with thiazide-like diuretics; 11.7% with potassium-sparing diuretics; 36.4% with beta-blockers; 14.3% with single-pill combinations (3.9% with ACEi+CCB; 3.9% with ARB + CCB; 1.9% with ACEi+thiazide-like diuretics; 3.9% with ARB+thiazide-like diuretics; 0.6% with ACEi+CCB+thiazide-like diuretics); 3.9% with other drugs. 5.8% of patients were not taking any antihypertensive medication. Median systolic BP (SBP) values were 126.2 ± 15 mmHg; and 41.6% of patients had controlled SBP levels. Median diastolic BP (DBP) values were 67.2 ± 12 mmHg; 81.8% of patients had controlled DBP levels. 33.8% of patients had both SBP and DBP values controlled. 58.6% of patients with uncontrolled SBP were males. 31.1% were elderly, 58.9% were very elderly, 13.3% had ICD, 41.1% had diabetes, 36.7% had HF, 27.8% had AF; 74.4% had CKD. Out of patients with uncontrolled SBP, 62.2% had mean levels lower than target SBP levels. There were no statistically significant differences between patient characteristics or pharmacological therapy of patients with controlled or uncontrolled BP.

Conclusion

The amount of patients with controlled hypertension is subpar, mostly due to patients with BP profiles lower than target levels. There were no statistically significant differences between each subgroup regarding characteristics and pharmacological therapy

#1821 - Abstract

PREVALENCE OF VALVULAR HEART DISEASE IN A GUATEMALAN HOSPITAL

Luis Benjamin Godínez, Gabriel Antonio Rios, Juan Francisco Barrios, Gonzalo Díaz, Mervyn Steven Galindo
Instituto Guatemalteco de Seguridad Social, Guatemala, Guatemala

Background

The burden of valvular heart disease (VHD) in the Guatemalan population is scarcely known. The prevalence of valvular disease increases sharply with age, owing to the predominance of degenerative etiologies. Valvular heart disease remains common in developing countries, because of the prevalence of rheumatic heart diseases and by the increase in that of degenerative valve diseases. Aortic stenosis and mitral regurgitation are the two most common

types of valvular disease in industrialized countries. The study aim was to assess the prevalence of VHD in the Guatemalan population.

Methods

We perform an observational retrospective study of the in-hospital population of a teaching hospital from 2016 to march of 2019. We review the echocardiography reports from 1,209 patients in look for VHD and demographic data. The continuous variables were expressed with dispersion measures and the categorical variables in frequencies and percentages. Student's t test was used to compare quantitative data; The chi-square test was used to compare qualitative data.

Results

Of the 1,209 patients, 798 (66%) were men, the mean age was 62 years and the most common diagnosis were heart failure (33%) and ischemic heart disease (13%). VHD was present in 48% of the population and mitral insufficiency was the most common valvulopathy and was present in 29% of the patients and it was most prevalent in men (66%). Patients with mitral regurgitation had an average Left ventricular ejection fraction (LVEF) of 37% SD = 17 and patients without mitral regurgitation had an average LVEF of 50% SD=18% (P <0.001). In aortic insufficiency, the average LVEF was 40% SD=18 and without aortic insufficiency, the mean LVEF was 47% SD=18% (P <0.001). In the case of mitral stenosis, the average LVEF was 27% SD=10 and without mitral stenosis 51% SD=17% (P <0.001). In aortic stenosis, the average LVEF was 29% SD=13 and without aortic stenosis the LVEF was 51% SD = 17% (P <0.001).

Conclusion

VHD was common in our study population and was present in nearly 1 of every 2 patients. Mitral insufficiency was the most prevalent valvulopathy. VHD also has a profound effect in LVEF and patients with either insufficiency or stenosis had a much lower LEVF.

#1849 - Abstract

THE NEUTROPHIL/LYMPHOCYTE INDEX AND ITS CORRELATION WITH TROPONIN AND PATIENTS WITH ACUTE CORONARY SYNDROME WITH STEACS/SCEST

Astrid Paola Hernández, Gabriel Antonio Ríos

Instituto Guatemalteco de Seguridad Social IGSS, Guatemala, Guatemala

Background

The neutrophil/lymphocyte index is an inflammatory marker of prognostic value in cardiovascular diseases¹. It has been proposed as a new indicator of the systemic inflammatory state of the patient and has been correlated with the prognosis in different cardiovascular pathologies. The aim of this study was to correlate the neutrophil / lymphocyte index with troponin I levels in patients with acute myocardial infarction with and without ST segment elevation.

Methods

Transverse retrospective analytical study that included 55 patients, more than 18 years old, with a history of arterial hypertension, diabetes mellitus and ischemic heart disease and with STEACS/ SCEST who underwent levels of triponine I, Neutrophil Index/ Lymphocyte. These laboratories were performed in the first blood count performed after the onset of symptoms, after their arrival at the hospital. The Pearson correlation coefficient was used; Chi square was used for categorical variables and student t for numerical variables for the other variables.

Results

Of the 55 patients included, 47 (85%) were male and 36 (65%) patient with SCEST. Risk factors were 56% with hypertension, 29% with type II diabetes mellitus, 7% with ischemic heart disease and 7% with chronic smoking. Our analysis showed a null correlation between the neutrophil/Lymphocyte index and troponin I levels. Low correlation index with R2 of 0.0001.

Conclusion

Therefore, to affirm that this index can be included in prognostic scales of acute myocardial infarction can be debatable. In the subanalyses, no significant difference was found between neutrophil/ lymphocyte in patients with or without ST elevation.

ACUTE LIMB ISCHAEMIA – AN IMAGE OF EXTENSIVE AORTIC-ILIAC THROMBOSIS

Filipa Taborda, Maria João Lobão

Hospital de Cascais, Cascais, Portugal

Clinical summary

A 65-year-old woman, with a history of ischaemic cardiopathy, dyslipidaemia and prior stroke, presents to the Emergency Room referring pain in both legs for 4 days. A doppler ultrasound excluded venous thrombosis and she was discharged. On the following day, she returns with mention of aggravated limb pain, now extended to inferior quadrants of the abdomen. It was then evident a low temperature of the limbs, though symmetric, with signs of hypoperfusion. During her stay, she refers paresthesias and skin become marbled, rapidly progressing to cyanosis, feet paralysis and absence of any sensation. A computed tomography angiography showed an extensive aortic-iliac thrombosis with irreversible acute limb ischaemia. The patient recused revascularization surgery, given the risks, dying in hours.

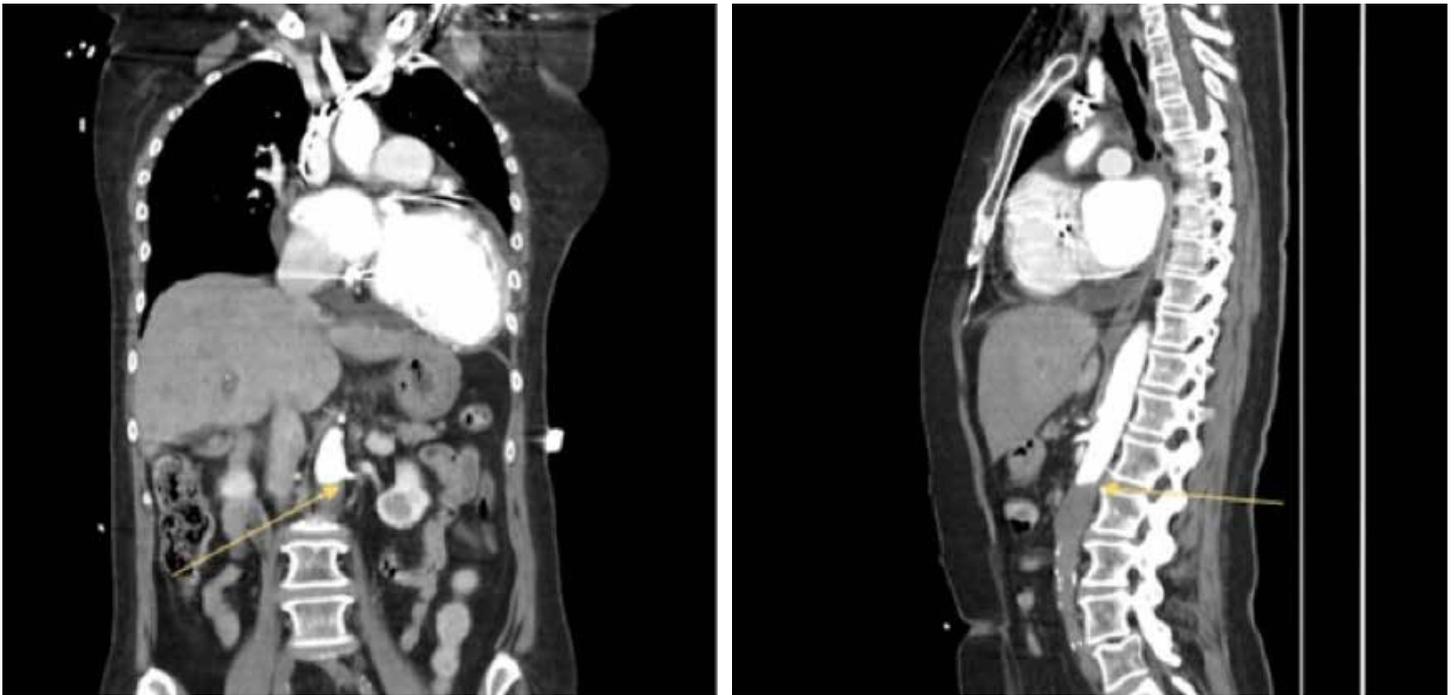

Figure #1853.

#1859 - Case Report

DELAYED PULMONARY EMBOLISM DIAGNOSIS DUE TO A “HISTORY” OF CONTRAST ALLERGY

José João Martins, Ana Margarida Mosca, David Garcia, Rosário Araújo, António Oliveira E Silva
Hospital de Braga, Braga, Portugal

Introduction

Approximately 112 out of 100,000 people will have an acute pulmonary embolism (PE) in their life, making it a common disease. However, the clinical presentation is very unspecific and often leads to delayed recognition. The ideal diagnosis tool is a contrast-enhanced computed tomography (CT) of the lungs. The contrast used has an incidence rate of 0.15 to 0.7 percent of adverse reactions with only a small proportion of those being fatal.

Case description

The patient is a 70-year-old male, independent, with multiple risk factors for thrombotic events and a history of previous venous thrombosis. He presented to the emergency department with a dyspnea of acute onset accompanied by pain in the right hemithorax, he denied any other symptoms. His physical examination was unremarkable. Analytically a type 1 respiratory failure and an elevated C-reactive protein were present. Given the high pre-test likelihood of PE the next step would be an imaging study, however venous ultrasonography was unavailable and the patient told a story about feeling very unwell when around 30 years he received a contrast injection and had to take intravenous medications. Therefore, it was opted to perform a CT scan of the lungs without contrast. The scan revealed only chronic abnormalities such as emphysema and fibrosis. The patient was

then admitted to the medical ward on with a temporary diagnosis of tracheobronchitis and started on a course of doxycycline. Given the lack of recovery a few days later, a contrast-enhanced CT scan of the lungs with pre-medication to reduce the chances of allergy was performed. The exam showed multiple perfusion deficits on the territory of the median lobar artery of the right lung confirming the existence of PE. The patient was started on therapeutic anticoagulation with improvement in his clinical status, he was discharged a few days later with oxygen supplementation which he eventually stopped because it was no longer needed.

Discussion

A clinical case that demonstrates a common issue: non-documented allergies. In the case of our patient it is impossible to measure the impact that the delayed diagnosis of PE had on his prognosis. Had the diagnosis happened sooner the patient would have had a shorter hospital stay and perhaps more of his lung functional capacity could have been rescued. The reverse is also true, the patient could have had an anaphylactic shock with the contrast administration. We hope that this clinical case serves as a reminder of the importance of documenting allergies,

#1898 - Case Report

HEMOPTYSIS AS A RARE AND LIFE-THREATENING PRESENTATION

Daniel Duarte, João Araújo, Ricardo Cordeiro, Carina Rôlo Silvestre, Aurora Bragança, António Domingos
Centro Hospitalar do Oeste - Torres Vedras, Torres Vedras, Portugal

Introduction

Hemoptysis is a manifestation of numerous diseases, including airway diseases, infection, trauma, coagulation disorder, rheumatologic and pulmonary vascular diseases.

Rupture of thoracic aortic aneurysm (TAA) usual present with severe chest or back pain. However, massive hemoptysis can be a rare and life-threatening presenting symptom due to aorto-bronchopulmonary fistula.

We present a case of a patient with rupture of TAA and aorto-bronchopulmonary fistula who presented with back pain and hemoptysis.

Case description

A 85-year-old man, salesman, with personal history of pulmonary tuberculosis in childhood and benign prostatic hyperplasia.

Presented to the ER with moderate to large hemoptysis and back pain for a few hours. Physical examination revealed hypotension, hypoxemia and lung auscultation with decrease of breath sounds in the left side.

Blood tests showed anemia with no other alterations. Chest radiography revealed a widened mediastinum and pleural effusion. CT scan was performed and showed TAA with filiform rupture and large hematoma (8 cm), moderate hemothorax and small pneumothorax.

Aminocaproic acid was prescribed and the patient was promptly transferred to Vascular Surgery. Endovascular aortic repair with stent-graft was performed in the operating room. Postoperative period was complicated by hemothorax, small pneumothorax and respiratory infection.

Flexible bronchoscopy was performed and revealed blood clots without active bleeding or presence of bronchial fistula.

Patient was discharged after 57 days without symptomatology and integrated into a pulmonary rehabilitation program.

Discussion

In the literature there are few cases of TAA presenting with hemoptysis. The most frequent symptom of TAA rupture is chest or back pain, although acute and massive hemoptysis can be present. Aorto-bronchopulmonary fistulas are the main cause of hemoptysis and constitutes a surgical emergency. Other symptoms such cough, dyspnea and wheezing can be present.

Chest radiography show a widened mediastinum, enlargement of TAA or pleural effusion (hemothorax). CT scan is the optimal imaging test to detect and measure TAA and identify rupture.

Endovascular aortic repair of the TAA is characterized by the placing of a stent-graft and is now the preferred technique for treatment. Comparing to the open thoracic aorta surgery, endovascular aortic repair is a less invasive approach.

In our case an early diagnosis and treatment was essential given the severity and risk of death of the patient.

CYCLING WITH LERICHE SYNDROME

Rui Osório, Ana Sofia Moreira, Ramiro Sá Lopes, Teresa Salero, Yessica Costa

Centro Hospitalar do Algarve - Hospital de Faro, Faro, Portugal

Clinical summary

Leriche's syndrome is a thrombotic occlusion of the abdominal aorta and/or iliac arteries, a subtype of peripheral disease and associated with increased cardiovascular risk. An active 55-year-old male with history of alcoholism, smoking, arterial hypertension and poorly controlled heart failure, with no prior complains, was brought to the ER in cardiac arrest. After reversal, the patient was admitted to the intensive care unit. Due to jaundice and elevated hepatic enzymes, a contrast-enhanced CT was preformed showing complete occlusion of the abdominal aorta distal to the origin of the right renal artery without opacification of the left renal artery. The important network of collateral vessel allowed him to remain asymptomatic, riding his bicycle every day to work, prior to this event.

Figure #1918. Occluded aorta with collateral circulation.

#1925 - Abstract

VENOUS THROMBOEMBOLISM RISK ASSESSMENT IN MEDICAL HOSPITALIZED PATIENTS AND EVALUATION OF OUTCOMES: A PROSPECTIVE, SINGLE CENTER ANALYSIS

Sara Garez Gomes, João Gramaça, Teresinha Ponte, Filomena Carneiro, Fátima Campante

Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Background

More than half of in-hospital medical patients have increased venous thromboembolic risk, which may be significantly reduced

with primary thromboprophylaxis. There are studied risk scores, among them the Padua Prediction Score for Risk of Venous Thromboembolism. We also had in consideration an increased bleeding risk in patients with thrombocytopenia ($<50,000/\mu\text{L}$), active gastroduodenal ulcer or a bleeding event in the previous 3 months.

Methods

This is a non-interventional prospective analysis of 32 hospitalized medical patients evaluated in one given day, applying the Padua score and recording 45-day all-cause mortality, thromboembolic and bleeding events, emergency room (ER) admission and second hospitalization. We excluded patients under therapeutic hypocoagulation.

Results

Of the 32 patients in the overall population, 7 were doing therapeutic hypocoagulation. In the remaining intention-to-prevent (ITP) population 64% (14 patients) had a Padua score ≥ 4 ; in this group there were 5 (35%) not doing primary thromboprophylaxis, 2 with no discriminated reasons and 3 (12%) due to increased bleeding risk. In this small analyzed sample, there was a 45-day all-cause mortality rate of 12.5% in the overall population, but of just 4% (1 fatality) in the ITP population. There were no thrombotic or bleeding events in the 45-day span; the 45-day all-cause ER admission in the ITP population was 28%, even though there was only 1 instance of new hospitalization in this group (4%), of a unrelated cause (pneumonia). The recorded fatality was of a patient with a risk score of 5 in which the enoxaparin dosage was reduced to 20 mg id due to renal function; alas there was no recorded cause of death.

Conclusion

The authors think in order to infer statistically significant data we need to increase the analyzed sample, possibly involving other medical centers, as well as increasing the follow-up time. Interestingly we observed that all the 45-day ER admissions were patients with a score ≥ 4 , with a median of 5 and average of 5.29; a 2012 Harvard analysis using this score found no relationship between administration of anticoagulation and reduced rate of VTE or mortality, however a Padua ≥ 4 was associated with increased all-cause mortality.

#1928 - Case Report

OVERLAPPING HEPATORENAL AND CARDIORENAL SYNDROMES: TWO CLINICAL ENTITIES OR ONE COMPLEX SYNDROME

Dina Rodriguez Pita, Salvador Morais Sarmiento, Andreia Amaral, Hugo Inácio, Sofia Mateus, Daniela Marto, Ana Brito, Miguel Leite, Catarina Espírito Santo, Catarina Salvado
Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

Introduction

Hepatorenal (HRS) and cardiorenal syndrome (CRS) are both severe conditions with common pathogenic features.

HRS is a complication of chronic liver disease or fulminant hepatitis, where splanchnic vasodilation leads to decreased glomerular function rate (GFR).

CRS is a condition in which damage to one organ (heart or kidney) can lead to acute or chronic dysfunction of the other, resulting in reduced cardiac output, elevation of central venous pressure, and renal dysfunction.

Both syndromes result in arterial under filling and accumulation of fluid in the extracellular and extravascular spaces. The reduced effective arterial blood volume promotes sodium and water retention by activating the sympathetic nervous system as well as the renin-angiotensin-aldosterone and vasopressin systems.

Given their intertwined pathogenic mechanisms, the treatment of one may lead to the benefit of the other. For instance the administration of human albumin with vasoconstrictors, used to treat HRS, has a positive impact also on the cardiorenal regulation systems. The authors describe a case of overlapping HRS and CRS where this approach was crucial to treatment success.

Case description

A 53-year-old man with alcoholic liver disease presented with exertional dyspnoea, orthopnoea and abdominal distention. Physical examination showed jugular vein distension, decreased air movement over the lower third of both lung fields, abdominal distension, flank dullness, and peripheral edema.

Laboratory results revealed factor V 32.5%, aspartate transaminase 1566 U/L, alanine transaminase 1727 U/L, total bilirubin 3.68 mg/dl, and prothrombin time 2.5, GFR: 29 mL/min/1.73, brain natriuretic peptide level 1706 pg/mL; and sero-ascitic albumin gradient >1.1 g/dl. Imaging revealed ascites and portal hypertension.

Clinical status kept worsening despite HRS standard treatment; but improvement was achieved after inotropic intervention.

Discussion

New insights into the pathophysiological mechanisms behind hepatorenal syndrome have challenged the conventional model of liver-kidney disease, supporting the heart as an important mediator of the untoward renal effects. In this case, poor clinical response after conventional therapy of HRS and improvement after introduction of inotropic therapy (traditionally reserved for CRS) suggests cardiac dysfunction as a relevant trigger or perpetrator of HRS.

Overlapping HRS and CRS is probably best considered as one complex clinical syndrome rather than two separate entities.

#1930 - Abstract

PULMONARY EMBOLISM: AN APPROACH IN INTERMEDIATE CARE UNIT

Rui Osório, Margarida Viana Coelho, Domingos Sousa, Ramiro Sá Lopes, Sílvia Castro, Cristina Granja

Centro Hospitalar do Algarve - Hospital de Faro, Faro, Portugal

Background

Although all the cardiovascular diagnosis and treatment advances the morbidity and mortality of pulmonary embolism (PE) remains high. Annual incidence of venous thromboembolism (VTE) is around 23-69 cases per 10 000 population, the PE represent approximately one-third of the VTE cases. It is estimated that around 10% of patients with acute PE die during the first 1-3 months, 1% of patients admitted to hospital die of acute PE and 10% of all hospital deaths are PE-related.

Methods

A retrospective observational study was made with patients admitted in the intermediate care unit (IntCU) during the year 2018. The patients were characterized by gender, age, time of admission in the ICU and hospital, symptoms, severity index (PESI, hypotension (Systolic blood pressure < 90 mmHg), elevated troponin and natriuretic peptide (BNP), echocardiography changes), thrombolysis, destiny at discharge, outcome and mortality rate.

Results

In one year, 16 patients were admitted in the IntCU, 50% male and 50% females, the mean age was 62,8 years, the mean average time in the IntCU was 5,3 days and in the hospital was 17,9 days. The main described symptoms were shortness of breath (40%), chest pain (24%), fatigue and syncope (12% each). Most patients admitted in the IntCU came from de emergency department (56.25%), and most of them were transferred to the Internal Medicine ward to continue treatment and investigation. The PESI index average was 132 (representing class V, very high risk), 25% presented hypotension on admission, 56.3% presented an increased BNP, 81.3% increased Troponin I and 81.3% presented echocardiographic changes. 55,6% of patients were submitted to thrombolysis with rt-PA (one didn't complete the perfusion due to hemorrhagic dyskinesia). All the very high-risk patient (n=5) did thrombolysis and 66.7% of the intermedian high risk (n=4 of 6) patient also were submitted to thrombolysis. The mortality rate was 6.25%.

Conclusion

Severe forms of acute PE have 10 to 24.5% of mortality (in 30 days) and close monitoring and possible thrombolysis may be advice. Thrombolysis resolves thromboembolic obstruction and reduces pulmonary artery pressure and resistance increasing cardiac output. In fact, up to 92% of patients appear to responded favorably to thrombolysis. The severe forms of acute PE seem to benefit of thrombolysis, and such treatment and close monitoring should be done in an IntICU environment.

ABDOMINAL AORTIC ANEURYSM – AN AWFUL SURPRISE

Filipa Botelho De Viveiros Cardoso, Teresa Souto Moura

Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

Clinical summary

Abdominal aortic aneurysm (AAA), is relatively common and has high mortality (tenth most common cause of death in the Western world). Risk factors are: male, age (>50 years), smoking, hypertension and atherosclerotic vascular disease. Computer angiography is the gold standard for diagnosis and immediate surgical repair indicated for aneurysms with symptoms or expanding >0.5 cm in 6 months.

I hereby present an infrarenal AAA, with 10 cm, which was contained in the retroperitoneum and therefore poorly symptomatic. When it ruptured the patient's abdomen increased suddenly and had livor. Despite fast diagnosis, imaging and surgery, the hemodynamic instability prevailed and survive only 3 days.

Figure #1933.

ARRITMOGENIC POTENTIAL OF MACROLIDS - A CLINICAL CASE

Sónia Coelho¹, Ana Vera Marinho², Marisa Miranda², José Luiz Luzio², Paulo Martins²

¹ Centro Hospitalar Universitário Cova da Beira, Covilhã, Portugal

² Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Acquired long QT syndrome (LQTS) may complicate treatment with some antibiotics, such as macrolides, involving the risk of torsades de pointes.

Case description

Female, 33 years old, smoker. Admitted with community acquired pneumonia (CAP), requiring invasive mechanical ventilation and aminergic support. Intravenously azithromycin and amoxicillin/clavulanic acid (amoxiclav) were initiated. On the 6th day of hospitalization at the Intensive Care Unit, continuous electrical monitoring showed prolongation of the QT interval, confirmed by electrocardiogram (ECG). This condition evolved with torsades de pointes, followed by cardiac arrest in ventricular fibrillation, recovering spontaneous circulation after immediate defibrillation. Serum potassium, magnesium, calcium and troponin values were normal. No changes were observed in transthoracic echocardiogram. She suffered two more cardiac arrest in a shockable rhythm, with successful defibrillation. Cardiac catheterization showed post-capillary pulmonary hypertension, without coronary disease. Pulmonary embolism was excluded by thoracic angiogram. Diagnosis: acquired LQTS, secondary to azithromycin. A temporary pacemaker was implanted, "protecting" the progressive decrease of the QT interval, being withdrawn days later, with a normal ECG. Her respiration improved gradually. Cardiac magnetic resonance revealed no changes. Genetic study was negative for channelopathies. At the secondary prevention level she implanted a transvenous implantable cardioverter-defibrillator.

Discussion

The arrhythmogenic risk of some groups of antibiotics (quinolones and macrolides), including acquired LQTS, is known. According to guidelines, azithromycin is commonly used, associated with amoxiclav for the treatment of CAP. This clinical case illustrates the cardiovascular risk of this option. The majority of arrhythmias related to the use of quinolones and macrolides occurred in patients with risk factors for QT prolongation. In the present case, the only risk factor is the female gender, which in the literature review seems to be more affected. Therefore, the choice of antibiotic should respect a careful analysis of the existence of risk factors for QT prolongation, including the combination of therapies with arrhythmogenic potential. In patients at high risk, we should consider other options or electrocardiographic monitoring.

THINKING OUTSIDE THE BOX: GRADE III ARTERIAL HYPERTENSION IN ELDERLY PATIENT

Cristiana Drăganescu¹, Octavian Zara¹, Cornelia Voiculescu¹, Alice Balaceanu¹, Ion Dina¹, Ruxandra Jurcut²

¹ Hospital Saint John, Bucharest, Romania

² Fundeni Hospital, Expert Center for Rare Cardiovascular Genetic Diseases, Bucharest, Romania

Introduction

High blood pressure in elderly patient involves etiological and treatment particularities. Associated with asymptomatic or

minimally symptomatic genetic diseases, it requires complex investigations. Obstructive hypertrophic cardiomyopathy may occur in the context of both metabolic and neuromuscular genetic diseases as well as chromosomal dysfunctions. Severe form is rarely associated with grade III hypertension, especially in the elderly patient without renal disease.

Case description

A 72-year-old patient is referred to an Internal Medicine Department to investigate an elevated blood pressure above 200 mmHg. The patient was diagnosed with blepharospasm several years ago and treated with botulinum toxin. Family history reveals neurological and renal disorders in first degree relatives.

Patient had ambulatory treatment with beta blocker, conversion enzyme inhibitor and statin. The electrocardiogram showed left ventricular hypertrophy. Cardiac ultrasound revealed severe obstructive hypertrophic cardiomyopathy. Genetic testing and additional investigations have diagnosed multiple impairments in an elderly patient with minimal symptoms.

Discussion

The elderly patient with grade III hypertension and inherited cardiac and neurological disorder is a challenge regarding the diagnostic and treatment.

#1967 - Case Report

DONEPEZIL AS A CAUSE OF CARADIOGENIC SYNCOPE - ELDERLY HEAVEN OR HELL?

Cátia Fava Gaspar, Helena Greenfield, Liliana Carneiro
Hospital Pedro Hispano, Matosinhos, Portugal

Introduction

Due to population ageing, it has become more common in daily practice to find elderly patients medicated with anti-dementia drugs, Donepezil being a highly prescribed drug, but not free of adverse effects.

Case description

The authors present the case of an 80-year-old woman, with a history of hypertension, dyslipidaemia, obesity and incipient dementia medicated with Donepezil 10 mg, once daily. The patient was admitted in the cardiology ward of the Internal Medicine department, for the evaluation of two episodes of syncope of undetermined aetiology. Initially the syncopal episodes were assumed to be in the context of an acute myocardial infarction without ST segment elevation since the patient had cardiovascular risk factors and the high sensitivity troponin raised to a maximum of 2345 ng/L. To confirm that presumptive diagnosis, a transthoracic echocardiogram was performed, and it showed a slightly decreased left ventricular systolic function associated with apical akinesia, suggestive of Takotsubo stress induced cardiomyopathy. A cardiac magnetic resonance confirmed the diagnosis. Upon review of the patient's history, a QTc prolongation

was found on the patient's admission electrocardiogram (ECG), with an initial QTc duration of 522 milliseconds. The patient had no dysrhythmias on cardiac monitoring. A confirmatory ECG confirmed long QT syndrome. An exhaustive review of patient medication was performed, and Donepezil was the only possible causative drug identified. Cessation of Donepezil resulted in normalisation of the QT interval (417 milliseconds). The patient remained asymptomatic, with no recurrence of dizziness or syncope.

Discussion

The importance of preserving cognition and global function and of delaying dementia onset and progression is evident to all, however it is important to recall that drugs are not free of side effects. In the case of Donepezil, and other anti-dementia agents, the risk of QT prolongation and subsequent cardiac arrhythmias is known and an initial ECG should be performed before initiating therapy. This case illustrates a long-term side effect, reminding us of the importance of taking a thorough drug history while considering potential drug toxicity/interactions as part of the comprehensive geriatric assessment

#1971 - Abstract

"THE GREAT MASQUERADER": A RETROSPECTIVE OBSERVATIONAL STUDY ON ACUTE PULMONARY EMBOLISM ON A SECONDARY HOSPITAL

Filipe Cunha Santos, João Rodrigues, António Barbosa, Joana Caires, Maria João Baldo, João Correia
ULS Guarda, Guarda, Portugal

Background

Acute pulmonary embolism (PE) is the third leading cause of cardiovascular disease and it presents on a wide range of severity. This study aims to investigate the clinical, laboratorial and tomographic features of patients with PE admitted to a secondary hospital.

Methods

We conducted a retrospective observational study at a secondary hospital and reviewed all patients hospitalised in 2018 with a primary or secondary diagnosis of PE from ICD10.

We excluded patients younger than 18 years old, deceased in the first 24h, transferred to another hospital, not admitted and those with missing data.

Clinical, laboratorial, and tomographic data was collected and statistical analysis performed using IBM® SPSS® Statistics 25.0.

Results

We studied 59 patients, with a mean age of 75.6±16.1, from which 54.2% were males.

The most frequent symptoms at presentation were dyspnea (64.9%), chest pain (35.1%), fatigue (40.4%) and fever (22.8%).

Hypoxia was present in 60.3% patients, tachycardia in 44.1%, tachypnea in 33.9%, hypertension in 23.7%, hypotension in 13.6% and 5.1% were admitted to the intensive care unit. 49.2% had a respiratory tract infection. Mean Wells score was 3.2±2.5, with the most frequent being 1.5. Mean PESI was 130.3±43.9. Most frequent comorbidities were hypertension in 55.9%, type 2 diabetes in 27.1%, dyslipidemia in 27.1% and heart failure in 25.4%. The most frequent risk factors were immobilization for more than 48h in the last month in 30.5% and previous hospitalization in 27.1%. Mortality rate was 13.6%, from which 37.5% were in-hospital.

We found a linear correlation between LDH and hospitalization days ($p<0.001$), as well as bilateral PE ($p0.052$), but not its extension. There was a correlation between BNP and hospitalisation days ($p0.038$). There was a statistically significant difference between the color of the Manchester triage and the extension of PE ($p0.025$). No difference was found with hospitalisation days.

We found no association between the PESI or Wells score and the tomographic features or days of hospitalisation.

No difference was found between vital signs, hemoglobin, creatinine at presentation and tomographic features.

We found no difference between age or tomographic features and days of hospitalisation.

Conclusion

There seems to exist an association between LDH, BNP and hospitalization days. We found a correlation between LDH and the color of the Manchester triage with tomographic features. No other associations were found.

#1977 - Abstract

MANAGEMENT OF ATRIAL FIBRILLATION IN PATIENTS WITH AN ACTIVE CANCER: A RETROSPECTIVE STUDY

Alda Tavares, Mário Bibi, Sara Moreira Pinto, Rute Morais Ferreira, Cristina Rosário

Hospital Pedro Hispano, Oporto, Portugal

Background

Management of Atrial fibrillation (AF) in patients (pts) with active cancer can be challenging. Limited data are available because cancer pts were frequently excluded. The aim of this study was to describe clinical characteristics and prescription of anticoagulants (ACs) in pts with AF and with/without active cancer.

Methods

A retrospective study was conducted, among pts admitted with AF in an Internal Medicine Ward, between April of 2014 and June of 2015. Epidemiological and clinical data were analysed according to presence/absence of active cancer (diagnosis or any anticancer treatment in last 6 months, metastatic or recurrent disease). Statistical analysis was performed with SPSS® software v25, and values of $p<0,05$ were considered statistically significant.

Results

Among 214 pts admitted, 16 had active cancer: 9 pts had the diagnosis made and 8 were submitted to anticancer therapy in the last 6 months, 5 had metastatic disease and 4 had a recurrence. The most common sites of cancer were breast (25,0%), gastrointestinal (25,0%) and lung (18,8%). The median time between the diagnosis of cancer and admission was 4 months (range: 0-82).

An apparently higher rate of male sex and younger people occurred in cancer pts, without significant difference. The rate of cardiovascular risk factors (CVRF), heart disease, previous stroke or thromboembolic event was higher in non-active cancer pts, without significant difference. Similar CHA₂DS₂-VASc and HAS-BLED scores rates were obtained in the two groups. New-onset AF was diagnosed 95 pts (44,4%), of these 6 had cancer (37,5%). Death during hospitalization occurred in 23 pts, with a higher rate in cancer pts (p=0,018).

To the date of discharge, ACs was prescribed to 5 cancer pts (45,5%) and 112 non-cancer pts (62,2%). Antagonists of vitamin K were prescribed in 82 pts, direct oral anticoagulants in 30 and low-molecular-weight heparin in 5. No significant differences were found concerning class ACs prescription and contra-indications in the 2 groups. Contraindication to ACs was identified in 6 cancer pts (anaemia, recent major surgery/stroke, haemorrhage, pericardial effusion and pericarditis).

Conclusion

Face to non-cancer pts, active cancer pts have similar rate of CVRF and comorbidities, but they have a higher mortality. They appear to be similarly treated with anticoagulant therapy. Larger studies on the optimal anticoagulation strategy of cancer patients with AF are needed.

#1995 - Case Report

LEFT VENTRICULAR THROMBUS CHALLENGE: A CASE REPORT

Dina Rochate^{1,2}, Svitlana Hhihoryan¹, Maria José Grade¹, Luísa Arez¹

¹ Centro Hospitalar Universitário do Algarve – Unidade de Portimão, Portimão, Portugal

² Hospital do Divino Espírito Santo de Ponta Delgada, Ponta Delgada, Portugal

Introduction

Left ventricular thrombus (LVT) is a potential cause of thromboembolic complications such as stroke. The overall prevalence in the general population is low. The prototypical substrate is a recent anterior myocardial infarction (MI) with an akinetic apex. Few cases after an old MI are described. Anticoagulant therapy with Warfarine is the preferred therapy.

Case description

Male, 59 years old, caucasian with history of MI 10 years before, heart failure (CHF) and hypertension, medicated. Previously

asymptomatic when initiates fatigue with progressive aggravation, edema of the lower limbs (LL), scrotum, abdomen and decrease of the urinary output. On physical examination the patient was hypotensive (BP 99/76 mmHg), with a systolic murmur in the mitral area, pulmonary auscultation with bilateral crackling, edema of the abdominal wall, scrotum and LL. Analytically with anemia (Hb 13.7 mg/dl) and pro-BNP 6471 pg/ml. Infra-ST V6 and T wave inversion in the precordial leads already known in electrocardiogram. He was hospitalized for decompensated CHF, went on diuretic reinforcement with a good edema and respiratory response, and performed an transthoracic echocardiogram (TE) showing severely dilated left ventricle (LV) with severely depressed global systolic function, FEj 17% and diffuse hypokinesia. In the apical level a hyperechogenic and heterogenic image, discretely movable, suggestive of thrombus. Contrast-TE confirmed severely diminished global systolic function (FEj 13%) and apical thrombus with dimensions of 30x25mm. The case was discussed with cardiology and anticoagulation in therapeutic dose with enoxaparin was initiated and switch for oral anticoagulation with Warfarin for life. 13 days later the patient developed right hemiplegia, dysarthria with deviation of the labial commissure and worsening of consciousness. An Angio-CT was performed which excluded hemorrhagic lesions and no indication for thrombectomy. One day after, with no neurological deficits, it was assumed Transient Ischemic Attack in a context of low cardiac output.

Discussion

The diagnosis of intracardiac thrombi remains clinically relevant, with associated risks of systemic embolization. There are uncertainties in the management of LVT as data on the use of non-vitamin K antagonist anticoagulants is limited, and their use instead of warfarin cannot be recommended. This case report shows the embolic risk even under classic anticoagulant, highlighting the need for more studies with other drugs.

MASSIVE CARDIOMEGLY IN A PATIENT WITH HEART FAILURE

Adriano Pacheco Mendes, André Gonçalves Mendes, Ruben Raimundo, Isabel Lavadinho, Isabel Soles

Unidade Local de Saúde do Norte Alentejano, Portalegre, Portugal

Clinical summary

We report a case of a 74-year-old woman, previously independent in activities of daily living and with a established diagnosis of heart, that was admitted in the emergency department complaining of severe leg edema, persistent dyspnea at rest, exercise intolerance and paroxysmal nocturnal dyspnea aggravated over the past 4 months. According to her personal and medical history, she had been not attending to her medical appointments and, therefore, the close heart failure monitoring that was demanded. A massive cardiomegaly was seen on chest radiograph and on chest ct scan (cardiothoracic ratio 0.85). There was no evidence of pleural

effusion and echocardiography revealed an extreme extreme dilation of both atria and severe mitral and tricuspid regurgitation.

Figure #1997. Massive cardiac enlargement due to heart failure.

#2008 - Case Report

INVERTED TAKOTSUBO CARDIOMYOPATHY

Diana Pires Fernandes¹, Miguel Tavares², Andrés Carrascal¹

¹ Unidade Local de Saúde do Nordeste, Bragança, Portugal

² Centro Hospitalar Universitário do Porto, Porto, Portugal

Introduction

Takotsubo syndrome is a stress-related cardiomyopathy in which changes in the segmental kinetics are capable of causing ventricular dysfunction. In this clinically reversible pathology that is more common in postmenopausal women, although the physiology is not fully understood, it appears to exist changes in the adrenergic receptors and in the local/serum levels of catecholamines. Inverted Takotsubo is a rare variant in which the pattern of kinetic changes is antagonistic to the more common alterations of basal hyperkinesia and apical ballooning.

Case description

We present a 60-year-old woman with a history of hypothyroidism, smoking, and severe emphysema associated with alpha 1 anti-trypsin deficiency.

Activated prehospital emergency due to sudden onset of dyspnea and syncope, so she was intubated by deterioration of consciousness, agonal respiration with severe metabolic/respiratory acidosis, and atrial flutter that reverted spontaneously to sinus rhythm. In the emergency room, given the clinic of acute cardiac insufficiency and a slight elevation of biomarkers, tachyarrhythmia was assumed as the precipitating event after exclusion of ionic disturbances, acute cranioencephalic event and pulmonary thromboembolism. The patient was admitted for intensive care.

In the control electrocardiogram, T-wave inversion was verified in the anterolateral leads and an echocardiographic evaluation was performed, limited to the subcostal plane due to severe emphysema. The findings of moderate left ventricular dysfunction with akinesia of the medial portions of all walls and preservation of apical contractility suggested an inverted Takotsubo pattern. The patient underwent cardiac catheterization, which confirmed the kinetic changes and absence of significant coronary disease, and was extubated without intercurrents at 48 hours, when the context of labor conflict and anxious personality was reached. Pheochromocytoma was excluded and beta-blocker initiation was performed with good response.

Discussion

A picture of acute cardiac failure in which elevation of biomarkers and electrocardiographic changes may be present, makes stress cardiomyopathy mimic other conditions, particularly acute myocardial infarction. Thus, the observation of alterations in segmental contractility by echocardiography allows this distinction to be made. If, until recently, the diagnostic criteria involved exclusion of coronary disease, recent records show that it can coexist but it isn't responsible for the ventricular changes

#2015 - Medical Image

A RARE ECG PATTERN ASSOCIATED WITH MYOCARDIAL INFARCTION

Luciana Faria¹, João Caiano Gil², Adriana Alves²

¹ Centro Hospitalar Póvoa de Varzim/Vila do Conde, Vila Do Conde, Portugal

² Unidade Local de Saúde de Matosinhos, Matosinhos, Portugal

Clinical summary

A 68-year-old male presented to the emergency department complaining of anterior chest pain for 2 hours. Initial ECG (panel A) showed upsloping ST depression and tall T waves in leads V1-V5, and an initial troponin I test was normal. An ECG 10 minutes later, revealed ST elevation (panel B). Emergent coronary angiography showed an occlusion of the left anterior descending artery, which was successfully treated with a drug-eluting stent. Hyperacute T waves are an early sign of acute ischemia, characteristically, broad-based and symmetrical, with increased amplitude and often associated with reciprocal ST depression in the precordial leads and elevation in aVR – the Winter pattern. This pattern should be recognized early and prompt cardiologist consultation along with serial ECG should be done.

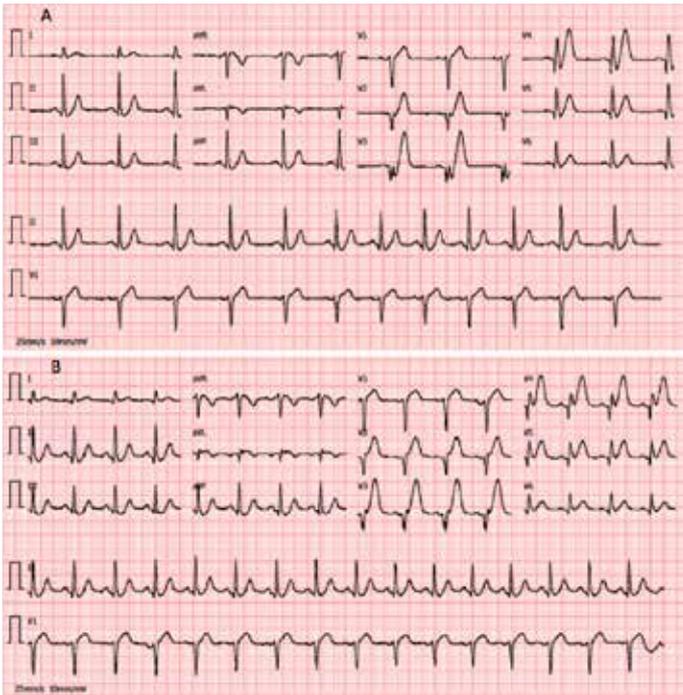

Figure #2015. ECG A and B.

#2016 - Case Report

A CASE OF A HIDDEN HEYDE SYNDROME

Daniela Soares Santos, Ana Luisa Nunes, Arsénio Santos, Armando Carvalho

Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Heyde syndrome is the association between aortic stenosis and bleeding from gastrointestinal (GI) angiodysplasia. GI bleeding via arteriovenous malformation (AVM) results from acquired von Willebrand syndrome. Von Willebrand factor (VWF) is assumed to be critical in the pathway for adequate suppression of angiogenesis. Patients with Heyde syndrome are assumed to be at increased risk for bleeding due to mechanical destruction of von Willebrand multimers, as they pass turbulently through the narrowed aortic valve. Although some patients with this syndrome have normal VWF levels, other mechanisms of angiodysplasia such as decreased gastrointestinal perfusion have been implicated. In this case, we present our experience with this syndrome.

Case description

A 82 years-old Caucasian female was sent to internal medicine for chronic anemia study. She had a previous hospital admission by normocytic normochromic anemia requiring transfusion of packed red blood cells (PRBCs). Esophagogastroduodenoscopy revealed antral erythema and gastric biopsy was compatible with autoimmune gastritis. Had normal full colonoscopy and labeled red blood cell scintigraphy failure to identify active bleeding sources. Anti-parietal cell antibodies were positive. It was initiated intramuscular B12 vitamin replacement with improvement, but hemoglobin continued to drop. Patient had history of diabetes,

arterial hypertension and hypothyroidism.

In our first observation she referred asthenia, without blood losses. Presented pallor and a systolic murmur. Blood test showed iron deficiency anemia with hemoglobin 6.3 g/dL. An echocardiogram revealed severe aortic stenosis with aortic valve mean pressure gradient of 44 mmHg and aortic valve area of 0.7 cm². It was necessary regular transfusion of PRBCs although oral iron replacement. Patient was submitted to an aortic valve replacement by a bioprosthetic Crown 21 valve. At three weeks follow up presented symptoms improvement and normal hemoglobin (12.5 g/dL). Iron replacement was suspended. At six months follow up patient's hemoglobin was stable at 12.1 g/dL with normal ferritin at 140 ng/mL.

Discussion

Physicians need to be thoughtful and consider Heyde syndrome in patients with aortic stenosis. Only aortic valve replacement can solve anemia and surgery must be considered. Our case shows that sometimes we have more than once disease causing a problem remembering the importance of follow up.

#2020 - Case Report

REFRACTORY INFECTIVE ENDOCARDITIS: DON'T FORGET BRUCELLA ENDOCARDITIS!

Anis Hariz¹, Mohamed Salah Hamdi¹, Imen Boukhris¹, Nour El Houda Gueddich², Ines Kechaou¹, Samira Azzabi¹, Lamia Ben Hassine¹, Chakib Kooli¹, Eya Cherif¹, Narjess Khalfallah¹

¹ Charles Nicolle Hospital, Tunis, Tunisia

² Principle Military Hospital of Instructions of Tunis, Tunis, Tunisia

Introduction

Occurrence of Brucella infective endocarditis (BE) is rare. Its frequency is less than 1% of infective endocarditis. Brucella melitensis is usually the responsible bacteria. BE usually involves valve remodeled by rheumatic disease or congenital malformation. The clinical presentation of endocarditis is usually belated in comparison to the acute phase of the disease. Heart failure may be the revealing feature of BE. We herein report the case of a seemingly refractory infective endocarditis revealing BE.

Case description

A 56-year-old farmer with no medical history was admitted for a two-month story of nocturnal fever. Physical examination noted a patient with recent orthopnea and left facial palsy with recent aphasia. He had a fever of 38.7 °C. Signs of right and left-sided heart failure were observed, as well as the presence of diastolic murmur in the aortic area. Examination also showed splenomegaly. Laboratory evidence of inflammation were found. Estimated glomerular filtration rate was altered at 40 ml/min. Cerebral computed tomography highlighted the presence of ischemic lesions. Transthoracic cardiac ultrasound showed highly altered aortic valves, aortic regurgitation. Infective endocarditis was highly suspected; as such, transesophageal echocardiography

was performed confirming the presence of vegetations on the aortic valve. Blood cultures were initially negative. The patient was treated with a combination of amoxicillin and gentamycin. Clinical outcome was unfavorable as the fever persisted. One week later, blood cultures were confirmed positive to *Brucella melitensis*. Wright serology was performed and also positive. Diagnosis of BE with neurological and renal involvement was thus retained.

The patient received appropriate antibiotic therapy with a combination of rifampicin and Doxycycline with rapid regression of fever. Laboratory evidence of inflammation also subsided. Aortic valve replacement was then successfully performed and microbial culture confirmed the diagnosis of BE.

Discussion

BE is a rare but serious condition potentially leading to severe cardiac valves destruction. It remains the leading cause of death in brucellosis. It requires early diagnosis with an urgent and aggressive therapeutic attitude. While blood culture may not necessarily be positive in case of infective endocarditis, it's important to consider bacteria such as *Brucella* especially given an adequate clinical context. Treatment is based on appropriate antibiotic therapy and valve replacement.

TIREOTOXICOSIS: AN INTOXICATED HEART

Telmo Borges Coelho, Mariana Brandão, Henrique Elvas, Diogo Ramalho, Maria Alves, Paula Ferreira, Manuela Sequeira, Vítor Paixão Dias

Centro Hospitalar Vila Nova de Gaia|Espinho, Vila Nova De Gaia, Portugal

Introduction

Amiodarone-induced thyrotoxicosis (AIT) is common in patients with heart failure (HF) and may precipitate arrhythmic events and exacerbation of HF. It is secondary to iodine overload or a direct toxic effect, resulting in destructive thyroiditis.

Case description

We report the case of a 88-year-old man with multiple cardiovascular risk factors and history of HF usually in NYHA functional class I, and paroxysmal atrial fibrillation (AF), medicated with amiodarone and apixaban.

The patient was admitted for clinical worsening of HF (minimal effort dyspnea, orthopnea and nocturnal paroxysmal dyspnea) and palpitations. At admission to the emergency department, he had an AF with rapid ventricular response (RVR), with difficult heart rate control (HR), even after infusion of amiodarone. Chest radiography suggested the presence of pulmonary congestion and bilateral pleural effusion.

During hospitalization, the thyroid hormone assay revealed TSH and free T4 values, of respectively <0.005 $\mu\text{IU/ml}$ and 3.53 ng/dL , suggesting AIT as a precipitating factor in the episode of AF with RVR and exacerbation of HF. The ultrasound evaluation of the thyroid demonstrated cystic nodularities with benign

characteristics. Treatment with Prednisolone and Thiamazol besides bisoprolol and digoxin (for HR control) was started and Amiodarone was suspended.

The patient showed progressive improvement of symptoms after intensification of diuretic therapy. He underwent a transthoracic echocardiogram, which showed worsening of left ventricular ejection fraction. The patient was discharged under thiamazol and prednisolone and will be followed as outpatient.

Discussion

The case illustrates the complex interaction between thyrotoxicosis and AF, both with potential for decompensation of preexisting heart disease. In this patient, a rhythm control strategy with amiodarone in order to eliminate AF as a precipitant of clinical exacerbation of HF culminated in the development of AIT, resulting in a worsening of underlying dysrhythmia and cardiopathy, which could be fatal. Thus, there seems to be a fine line between cause and consequence in the worsening of the clinical condition of a previously stable patient with multiple co-morbidities. The authors emphasize the relevance of thyroid function assessment in AF and HF settings, as well as the importance of a high degree of clinical suspicion for AIT, since persistent therapy with amiodarone may lead to significant morbidity and mortality

#2033 - Abstract

EFFICACY AND SAFETY OF BALLOON PULMONARY ANGIOPLASTY IN PATIENTS WITH CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION-PORTUGUESE CENTER EXPERIENCE

Daniel Sebaiti, Alexandra Briosa, Rita Calé, Filipa Ferreira, Maria José Loureiro, Sofia Alegria, Silvia Vitorino, Pedro Santos, Debora Repolho, Gonçalo Morgado, Helder Pereira

Hospital Garcia de Orta, Almada, Portugal

Background

In patients with chronic thromboembolic pulmonary hypertension (CTEPH) refused for pulmonary endarterectomy (PEA) and in patients with residual or recurrent pulmonary hypertension (PH) after PEA, the only treatment available in Portugal, until recently, was pulmonary vasodilator therapy (PVT).

Aims

evaluate immediate efficacy and safety of balloon pulmonary angioplasty (BPA) beyond PVT in patients with non-operable CTEPH or residual/recurrent PH. A Portuguese initial single center experience.

Methods

From December 2017 to December 2018, we performed a total of 57 BPA sessions in 12 patients. Hemodynamic and clinical aspects were evaluated at diagnosis, before the 1st session (on PVT) and after the last session of BPA in 7 consecutive CTEPH

patients (mean age 61 years, 57% female) who completed the BPA treatment (mean of 5 sessions per patient). A detailed analysis in terms of technical aspects and procedure related complications was performed for the 57 procedures.

Results

Technical aspects: femoral access was used for all procedures; a total of 230 vessels were treated in 139 segments (mean of 4.0 ± 1.9 vessels in 2.4 ± 1.0 segments per session); most frequent type of treated lesions was web lesions (71%); 11 pressure-wire guided sessions for patients with mean pulmonary artery pressure (PAP) >40 mmHg. The median duration between CTEPH diagnosis and first BPA was 55 months and from first to last BPA session was 4 months. WHO FC II, III, IV distribution was 6/1/0 after PVT, respectively. After BPA, there was significant additional improvement of mean PAP ($p=0,026$) and 86% of patients improved to WHO FC I; there was a trend for decrease in pulmonary vascular resistance, improvement of cardiac index and NT-proBNP reduction. Procedure-related adverse events occurred in 24% of the interventions, and they were all minor: 3 distal wire perforations; 4 pulmonary artery dissections (no need for intervention); 5 mild to moderate haemoptysis; 3 reperfusion edemas (grade 2, without need of mechanical ventilation); 2 access site complications and 1 contrast nephropathy KDIGO AI staging 1.

Conclusion

Balloon pulmonary angioplasty on top of pulmonar vasodilator therapy further improves short term hemodynamics and functional class in this group of patients. BPA can be safely performed, there was no need of invasive ventilation or surgery and no procedural-related death.

#2039 - Case Report

CAN THE LIGHTNING STIKE TWICE?

Estefânia Tupin, Tiago Pacheco, Rita Valente, Filipa Cardoso, Isabel Germano

Centro Hospitalar Universitário de Lisboa Central, Lisboa, Portugal

Introduction

Antiphospholipid syndrome is an autoimmune disease in which autoantibodies are formed that facilitate the formation of blood clots in arteries and veins. It is more common in women and is diagnosed usually between the age of 30 and 40 years old.

Case description

The subject of this case report is a man with 42 years old with a diagnosis of HIV-type 1 infection under antiretroviral therapy with undetectable viral load and good immune status, chronic hepatitis C, neoplasm of the rectum treated with surgery, radiotherapy and chemotherapy without relapse, erectile dysfunction, deep venous thrombosis of the left inferior limb in 1999, intravenous drug use in the past, over 20 years ago and heavy smoking habits.

He was admitted in the hospital after several weeks of pain in

the inferior right limb. He has had complaints of intermittent claudication for several months and an arterial Doppler had been asked for. In the emergency room an arterial and venous Doppler was made and he was diagnosed with deep venous thrombosis of the right limb. But the Doppler also identified multiple atheromatous plaques with diffuse distribution, superficial femoral artery occlusion as well as segmentar occlusion of the homolateral posterior tibia and peroneal arteries, raising suspicion for a thromboangiitis obliterans also known as Buerger disease.

During his hospitalization a thoraco-abdominal-pelvic CT scan was made to exclude cancer. An acute pulmonary thromboembolism was diagnosed despite the absence of symptoms. He was observed by Vascular Surgery because of the suspicion of Buerger disease and tobacco eviction and anti-aggregation with aspirin and statin use for a LDL lower than 100 were recommended. Anti-coagulation with anti-cummarinic was initiated. The vascular study came positive for anti-beta2 GP1 antibody in two measures separated by three weeks compatible with a diagnosis of antiphospholipid syndrome.

Discussion

This case presents a diagnostic challenge. Buerger disease is a rare condition and usually does not affect larger vessels so deep venous thrombosis is not a common presentation neither is pulmonary thromboembolism. Plus the arterial Doppler did not identify haemodynamic significant lesions in the left limb. On the other hand antiphospholipid syndrome is rare in men, the anti-beta2 GP1 antibody count was positive but very low and hardly explains the diffuse atherosclerotic lesions at such a young age.

#2041 - Abstract

ADMISSION TO AN INTERNAL MEDICINE WARD: AN OPPORTUNITY FOR ABDOMINAL AORTIC ANEURYSM SCREENING

Sara Raquel Pereira Martins, Ana Maria Oliveira, Tânia Araújo Ferreira, Catarina Castelo Branco, Ricardo Marinho, Gabriela Teixeira, João Neves, Luis Loureiro

Centro Hospitalar do Porto, Porto, Portugal

Background

Abdominal aortic aneurysm (AAA) screening has been shown to effectively reduce AAA-related mortality in asymptomatic older men. Ultrasonography (US) is the preferred method due to its high sensitivity and specificity, safety, reproducibility and low-cost. Portugal lacks any organized AAA screening program and the results of the first population-based screening were recently published, reporting a 2.1% prevalence of AAA. Internal medicine ward admission might provide an opportunity for screening, since many patients not only meet the criteria for it but also have a high prevalence of risk factors for AAA. This study seeks to assess if US could be easily learned and correctly performed by internal medicine doctors and if AAA screening in internal medicine ward would be justified.

Methods

5 internal medicine (IM) residents received 5 hours of abdominal aortic US measure training with an experienced US operator; after which they performed the AAA screening from November 17-April 19. Inclusion criteria: males aged 65 or above, admitted in the IM Ward. Exclusion criteria: previously known AAA. 100 randomly selected patients had US scan performed by 2 of the IM residents, blinded to each other's results. 24 (24%) of those were repeated by a Vascular Surgeon (VS), also blinded to previous results. Aortic diameter >3cm was considered aneurysmatic. Statistical analysis was performed using SPSS v21.0

Results

Prevalence of AAA was 9% (n=9). Intraclass correlation coefficient (ICC) between IM residents measurements (n=100) was 0,96 (IC 95% 0.94-0.97) and Wilcoxon Signed Ranks Test reported no difference between such measurements [measure 1 median: 16.85 (IQR 15.40-19.58), measure 2 median:17,00 (IQR 15.00-19.70); p=0,86] . ICC between both the IM residents and the vascular surgeon measurements (n=24) was 0,97 (IC 95% 0.94-0.98) and Friedman test also described no difference between those 3 measurements (measure 1 median:18,60 (IQR 14.43-33.93), measure 2 median:18,25 (IQR 14.68-35:43); measure by VS median:18,00 (IQR 14.67-34.20); p=0.747]. AAA diagnosis by IM was 100% accurate when reviewed by a VS.

Conclusion

IM residents with minimum US training appear to perform aortic US accurately. AAA prevalence in IM wards seems to be higher than reported in the general population. Hospitalization at IM ward could represent an opportunity for AAA identification, improving such patients care without adverse sequelae.

MASSIVE BIATRIAL DILATATION

Mário Ferreira, Marta Fonseca, Sara Magno, Catarina Melita, Liliana Fernandes, Zélia Neves, João Machado
Hospital Prof Doutor Fernando Fonseca, Lisboa, Portugal

Clinical summary

76-year-old woman, with history of chronic obstructive pulmonary disease, Cor Pulmonale, valvular cardiopathy and atrial fibrillation is admitted to the hospital in anasarca for decompensated chronic heart failure.

Chest radiograph in Antero-Posterior projection presented massive cardiomegaly and subcarinal angle >90°, with important bilateral lung restriction.

The transthoracic echocardiogram revealed normally dimensioned left ventricle with conserved systolic function, although D-SHAPE pattern was observed. To emphasize, a marked biatrial dilatation (LA 68 cm², vol=312 ml and RA 74 cm², vol=375ml) and dilatated right ventricle with decreased longitudinal function and severe tricuspid insufficiency (PSAP=58mmHg).

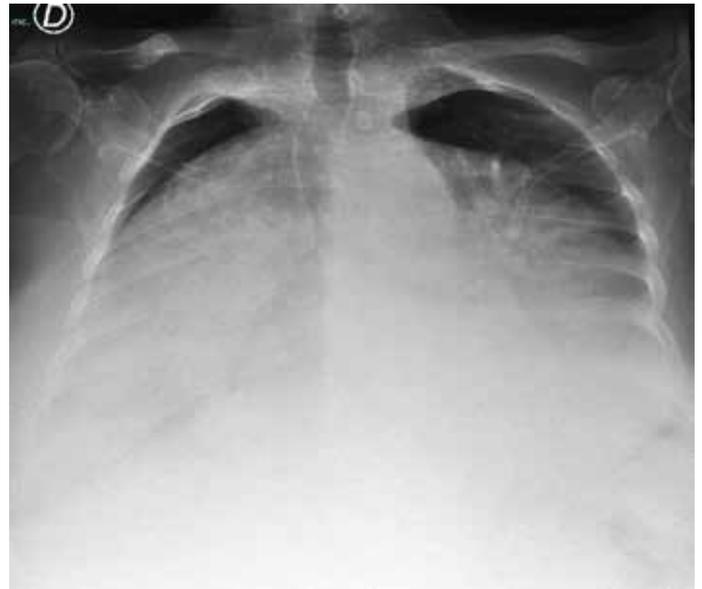

Figure #2051. Antero-posterior chest radiograph.

#2053 - Abstract

HYPERTENSIVE DISORDERS IN PREGNANCY. INTERNIST INSIGHT

Maria Gema Pelayo Garcia

Internal Medicine Department, Hospital Punta de Europa, Algeciras. UGC-AGS Campo de Gibraltar, Algeciras, Spain

Background

Hypertensive disorders of pregnancy (pre-eclampsia, eclampsia, haemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome and gestational hypertension) affect up to 10% of pregnancies. Women with a hypertensive disorder of pregnancy have increased risks of post-pregnancy hypertension, ischaemic heart disease, and stroke. The aim of our analysis is to outline the decisive factors that can contribute in development of this adverse clinical outcome.

Methods

We conducted a descriptive, observational study and collected data from clinical charts between 2016-2018 in our hospital linked to maternal and gestational age, pre-existing medical conditions as pregestational diabetes, hypothyroidism, chronic hypertension, fist pregnancy, multifetal pregnancy, past history of preeclampsia and lowering-blood pressure treatment.

Results

N: 24. Age: <25yr: 7 (29%), 25-35 yr:10 (41.6%), >35-45 yr:8 (33%). Nuliparity: 15 (62.5%). One set of twins in one pregnancy. Gestational age: 20-35 wk: 50%. Hypothyroidism: 5 (21%), previous hypertension: 5 (21%). In 2 cases, HELLP syndrome was suspected and diagnosed. Breastfeeding was desired in most cases, 79%. Intensive intravenous antihypertensive treatment was used in 8 women (33%). Oral labetalol, enalapril and calcium channel blockers were the most widely prescription applied after hospitalization.

Conclusion

Most affected patients are nulliparous. Half of the cases present with new-onset hypertension and proteinuria at ≥ 34 weeks of gestation. All pregnant women with new onset hypertension or worsening hypertension after 20 weeks gestation should be evaluated for preeclampsia. Consequently, a comprehensive approach is mandatory to address this distressing complication. Cardiovascular disease prevention in women with hypertensive disorders of pregnancy should include blood pressure monitoring initiated soon after pregnancy.

MITRAL RHEUMATIC DISEASE

Hugo Miguel Rodrigues Almeida¹, Beatriz Rodríguez², Sonia Canadas³, Rita Fernandes¹, João Correia⁴

¹ Hospital Sousa Martins, Guarda, Portugal

² ULS Guarda, Salamanca, Spain

³ Complejo Asistencial Universitario de Salamanca, Guarda, Portugal

⁴ ULS Guarda, Guarda, Portugal

Clinical summary

A 56-year-old woman, from Africa, presented a sudden clinic of precordialgia, irradiated to the extremities and associated with nausea. No other associated clinic.

Background of rheumatic fever in childhood. No usual medication. Physical exploration emphasizes grade IV / VI systolic murmur, of greater intensity in the mitral focus.

In the diagnostic exams, troponin elevation was observed with no electrocardiographic changes. Echocardiography showed a severely dilated left atrium, with severe mitral valvulopathy (thickening of the valves and severe mitral regurgitation) and moderate tricuspid valvulopathy, with indirect criteria of pulmonary hypertension.

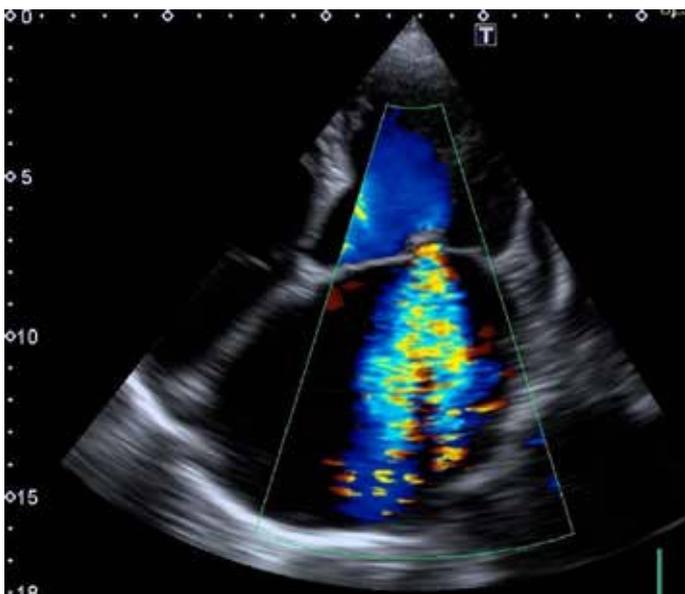

Figure #2055.

#2061 - Abstract

POTASSIUM LEVELS AT ADMISSION IN ACUTE HEART FAILURE- IMPACT ON 90-DAY READMISSION RISK

Sérgio Maltês¹, João Presume¹, Francisco Albuquerque¹, Gonçalo Cunha¹, Bruno Rocha¹, Sofia Furtado², Rita Homem³, Ana Rita Santos¹, Joana Maurício⁴, Inês Felizardo Lopes², Mariana Popovici², Inês Lopes Da Costa², Inês Edígio¹, Inês Nabais⁵, Francisco Adragão⁶, Catarina Rodrigues¹, Inês Araújo¹, Luís Campos¹, Cândida Fonseca¹

¹ Centro Hospitalar Lisboa Ocidental, Lisboa, Portugal

² Centro Hospitalar Lisboa Central, Lisboa, Portugal

³ Hospital Garcia de Orta, Setúbal, Portugal

⁴ Hospital Prof. Doutor Fernando Fonseca, Lisboa, Portugal

⁵ Hospital de Cascais, Lisboa, Portugal

⁶ Centro Hospitalar Universitário do Algarve, Portimão, Portugal

Background

Heart failure (HF) is an increasingly prevalent syndrome and a main cause of hospitalization. Patients admitted due to acute heart failure (AHF) have high risk of early readmission and death. The association between abnormal levels of serum potassium ([K⁺]) at admission in patients with AHF and risk of readmission or death is still a matter of debate. Our goal was to assess the correlation between [K⁺] levels and clinical outcomes in patients admitted for AHF.

Methods

This was a single-center retrospective observational cohort study enrolling consecutive patients admitted for AHF in a HF Unit from 11/2017 to 10/2018. For patients with multiple readmissions, only the first was considered. All-cause admissions, admissions for AHF and all-cause death at 90 days were assessed.

Results

Overall 154 patients were included; 54% were male with a mean age of 77 ± 11 years; 46% had HF with preserved ejection fraction. 40% had ischaemic heart disease and 32% had an hypertensive aetiology; 76% of patients had hypertension, 42% diabetes mellitus and 59% had chronic kidney disease; 72% of patients were treated with a renin-angiotensin-aldosterone system inhibitor (RAASi), 79% with a beta-blocker (BB). When assessing rehospitalization by admission [K⁺] levels <3.5 mmol/L, 3.5-4.5 mmol/L, 4.5-5.5 mmol/L and >5.5 mmol/L, a "J curve" phenomenon was observed, with [K⁺] levels between 4.5-5.5 mmol/L associated with lower readmission rates. This finding was observed regardless of the use of guideline-directed medical therapy (RAASi or BB). In contrast, discharge [K⁺] levels did not correlate with readmission rates. Admission [K⁺] levels outside the 4.5-5.5 mmol/L range were the only predictors of all-cause readmission at 90 days (odds-ratio (OR) 2,778, 95% confidence interval (CI) [1,211; 6,369], $p=0,016$). Admission [K⁺] levels, urea and creatinine were predictors of readmission for HF at 90 days. After adjusting for confounding factors, admission [K⁺] levels was the only predictor

for HF readmissions (adjusted OR 3,236, 95% CI [1,003; 10,101], $p=0.049$). Discharge NT-proBNP log level was the only predictor of all-cause death at 90 days (crude OR 0,038, 95% CI [0.006; 0,375], $p=0.004$)

Conclusion

In our cohort of patients admitted for AHF, [K+] at admission outside the range of 4.5-5.5mmol/L was independently associated with a higher risk of all-cause and HF readmission at 90 days. These results were independent of the use of RASSi or BB. Serum K+ levels may be a useful tool to stratify the risk of readmission.

A CASE OF ACUTE AORTIC DISSECTION TYPE A

Rui Osório, Ana Sofia Moreira, Ramiro Sá Lopes, Teresa Salero, Catarina Mendonça

Centro Hospitalar do Algarve - Hospital de Faro, Faro, Portugal

Clinical summary

Acute aortic dissection is an uncommon disorder which can have fatal results. If the treatment is delayed or misdiagnosed can reach mortality rates of 1-2% per hour. Twenty percent of the patients die before reaching the hospital and 30% on admission.

A 63-year-old male, with history of hypertension and aortic aneurysm, was presented in the emergency room with severe chest pain, syncope and hypotension. Troponin I and BNP levels were normal and no changes in ECG were detected. Due to suspicion of aneurism rupture contract-enhanced CT was preformed, which detected an acute ascending and descending aortic dissection (type A – Stanford classification). The patient was rush to third-level hospital to cardiovascular surgery, a valve conduit was place and the patient survived.

#2082 - Case Report

CARDIOVOCAL SYNDROME – A RARE MANIFESTATION OF PULMONARY HYPERTENSION

Marta Mendes Lopes, Inês Fialho, Catarina Lameiras, Énia Ornelas, Maria Do Céu Dória

Professor Doutor Fernando Fonseca Hospital, Amadora, Portugal

Introduction

Cardiovocal syndrome or Ortner's syndrome refers to hoarseness caused by cardiopulmonary disease and results from left recurrent laryngeal nerve palsy. This nerve arises from the left vagus nerve at the level of the aortic arch ascending between the right pulmonary artery and aorta to innervate the ipsilateral vocal cord muscles. Its close relationship with multiple structures makes it vulnerable to compression, being in rare cases the first manifestation of cardiopulmonary disease including pulmonary hypertension.

Case description

A 59-year-old woman, natural from Guinea-Bissau, without relevant medical history except an iron deficient anaemia, presented with exertional dyspnoea and precordial pain with nine months of duration. Her pain was pressure-like, non-radiating and accompanied by bilateral lower limb oedema. At physical examination, it was noted a systolic murmur in the left sternal border, bilateral basal rales at lung auscultation, bilateral malleolar oedema and also hoarseness with several months of duration that the patient did not value. To investigate for possible heart failure, she underwent transthoracic echocardiogram that revealed a preserved ejection fraction as well as an enlarged right pulmonary artery with an estimated pulmonary artery systolic pressure of 64 mmHg without other relevant findings. Because of the presence of hoarseness and an enlarged pulmonary artery, she underwent laryngoscopy that revealed a left vocal cord palsy. A cervical ultrasound and thoracic CT scan were performed, excluding other causes of recurrent laryngeal nerve compression and confirming an enlarged pulmonary artery. The etiologic investigation of pulmonary hypertension remains in course. The patient's symptoms have improved under optimized medical therapy, however, after one month the hoarseness still persists.

Discussion

In this case we describe an extremely rare cause of vocal cord palsy, which resulted from compression of the left recurrent laryngeal nerve by an enlarged right pulmonary artery. Pulmonary hypertension or some other cause leading to pulmonary artery dilation, whether temporary or 'dynamic' may be responsible for vocal fold palsy, therefore, the presence of hoarseness in a patient with cardiopulmonary disease should alert clinicians for this diagnosis. Moreover, early recognition of the cause of the nerve compression is of extreme importance, since reversibility of the palsy depends on the duration of injury.

CHEST PAIN AS A CLINICAL PRESENTATION OF AN AORTIC ANEURYSM

Maria João Gomes, Filipa Ferreira, Inês Bargiela, Sandra Alves
Hospital Professor Doutor Fernando Fonseca, Amadora, Portugal

Clinical summary

The authors present the case of a 78-year-old woman, with medical history of arterial hypertension and atrial fibrillation who was admitted for fatigue and oppressive chest pain. The

laboratory findings included elevated D-dimer levels (3815 ng/dL) and slightly raised troponin T levels. The transthoracic echocardiogram revealed a structurally normal left ventricle with severely impaired systolic function without dyskinesia, an enlarged left atrium and an aneurysmal dilation of the ascending aorta (7 cm) without evidence of dissection. The computed tomography pulmonary angiography excluded pulmonary embolism, but showed an aneurysmal dilation of the ascending and descending thoracic aorta as well as a thrombosed sacular aneurysm of the aortic arch measuring 4,5 x 2,5 cm.

Figure #2085.

#2105 - Case Report

ACUTE PULMONARY OEDEMA AS THE MAIN SIGN OF A THYROID STORM

Rita Carneiro Silva, Mónica Mesquita, Fernando Salvador, Paula Vaz Marques

CHTMAD, Vila Real, Portugal

Introduction

Thyroid storm is the most extreme form of thyrotoxic crisis, however, it often has a poorly specific clinical presentation. Congestive heart failure may be the presenting feature of thyroid storm, with acute pulmonary edema being its most extreme form. The coexistence of these two medical emergencies induces high mortality, making identification and a rapid approach essential.

Case description

A 61-year-old man with a history of alcoholic liver cirrhosis, paroxysmic atrial fibrillation, peripheral venous insufficiency and degenerative osteoarticular disease with spinal stenosis, was brought to the emergency department due to sudden worsening of dyspnea and somnolence. He presented with symptoms and signs compatible with acute pulmonary hypertensive edema, with evident respiratory effort, paleness, sweating, hypertension, tachycardia, scattered crackles on auscultation and marked peripheral edema. After review of systems, the patient also admitted progressive unexplained weight loss, diarrhea and tremors of the upper limbs associated with sweating and feeling of heat. Laboratory results revealed respiratory acidosis,

undetectable TSH (<0.01 mIU/L) and free T4 >100 pmol/L, and a thyrotoxic crisis was diagnosed, highly probable a thyroid storm, according to the Burch-Wartofsky Point Scale. In addition to the supportive treatment with nitrate perfusion, furosemide and non-invasive mechanical ventilation, treatment with antithyroid drugs, inorganic iodide, beta-blocker and corticosteroid was started and he was monitored in an Intermediate Care Unit. The presence of high titer thyrotropin-receptor antibodies confirmed Graves' Disease as the cause of hyperthyroidism. The patient clinically improved, having completed the stabilization and complementary investigation in Internal Medicine ward, and being discharged to consult.

Discussion

This case emphasizes the importance of always investigating all etiologies of acute heart failure according to recommendations. In the presence of heart failure, beta-blocker titration to inhibit the peripheral effects of thyroid hormone requires careful monitoring. It is important to suspect a thyroid storm in the presence of compatible symptoms, even in the absence of previously diagnosed hyperthyroidism, given its poor prognosis when not addressed in a timely manner.

#2110 - Case Report

ANEURYSM OF THE ABDOMINAL AORTA MANIFESTING AS RECURRENT ABDOMINAL PAIN

Daniela Sousa Viana, Guilherme Cardoso, Joana Rua, Carmem Pais, Natália Lopes, Paula Marques

Centro Hospitalar de Trás os Montes e Alto Douro, Vila Real, Portugal

Introduction

Aneurysm of the abdominal aorta (AAA) is the most common arterial aneurysm and often an incidental finding. Most frequently found in women, their elective surgical treatment mortality is estimated in 0.6-5.3%, rising to 40% in emergency situations. Most commonly asymptomatic, they may express through deep back and abdominal pain. When expanded enough to press another local organ or ruptured, symptoms are more significant. Medical imaging is important for diagnosis, surveillance and treatment.

Case description

64 years-old man, with relevant background including hypertension, dyslipidemia, cerebral vascular disease, extensive aortic atherosclerotic disease and an untreated fusiform AAA with 4 cm diameter. The patient had several admissions to the emergency department over four months. He described episodic low back pain, often with abdominal irradiation, assumed in the context of obstructive nephrolithiasis, supported by abdominal CT, and treated symptomatically with temporary remission after discharge. Considering his medical condition and comorbidities, his recent medical history seemed unjustified. Meanwhile, due to known aortic disease, he was under follow-up in vascular surgery and was appointed for elective surgery. Preoperative CT revealed slight irregularity over the posterior lateral wall of the aneurysm with associated periaortic fat densification, suggesting instability, without contrast leak – suggesting ulcerated AAA in need for emergent intervention. After undergoing surgery, six months have passed without any further episodes of abdominal pain. To date, he is with apparent clinical resolution.

Discussion

Recurrent abdominal pain can contemplate a wide range of etiologies. In this case, the recurrent character of the pain should lead to consider a more extensive differential diagnosis, besides renal calculus, diverticulitis and herniation. Screening and follow up are necessary specially with at risk patients after diagnosis. Although the AAA didn't show any signs of rupture, being more likely asymptomatic, its surgical approach induced remission of the symptoms. Therefore, the ulcerated AAA may probably explain the clinical syndrome.

#2111 - Case Report

DISSECTION OF THE AORTA PRESENTING AS DISSEMINATED INTRAVASCULAR COAGULATION

Anis Hariz¹, Mohamed Salah Hamdi¹, Imen Boukhris¹, Nour El Houda Gueddich², Ines Kechaou¹, Lamia Ben Hassine¹, Samira Azzabi¹, Chakib Koolo¹, Eya Cherif¹, Narjess Khalfallah¹

¹ Charles Nicolle Hospital, Tunis, Tunisia

² Principle Military Hospital of Instructions of Tunis, Tunis, Tunisia

Introduction

Disseminated intravascular coagulation (DIC) is a systemic, diffuse and uncontrolled activation of the coagulation process. It results in the formation of fibrin deposits leading to vascular thrombosis but also, hemorrhage secondary to massive consumption of hemostasis factors. Various pathologies may be responsible for DIC especially infectious and neoplastic diseases; aneurysms and dissection of the aorta are a rare cause. We herein report the case of a secondary DIC, revealing a dissection of the aorta.

Case description

A 75-year-old male with a smoking history of 60 P/Y was admitted for petechial purpura and ecchymosis involving the face and the forearms as well as signs of global heart failure. He had a medical history of hypertension with congestive heart failure. Laboratory routine tests were consistent with DIC as it showed low prothrombin time at 30%, elongated partial thromboplastin time, low fibrinogen serum level at 0.8g/l and elevated concentration of fibrin degradation products. Full blood count also noted the presence of low white blood cells count at 2900/mm³, anemia with hemoglobin of 8g/dl and low platelet count at 7000/mm³. Infectious investigations did not yield positive results: blood cultures, as well as the viral serologies, were negative and echocardiography showed no signs of infective endocarditis.

Computed tomography of the abdomen indicated the presence of an aneurism of the aortic arch with dissection and detachment of a calcified intimal flap of the aorta. Diagnosis of a DIC complicating aortic dissection was retained. Clinical outcome was marked by rapid deterioration of respiratory and renal function followed by multivisceral failure resulting in the patient death.

Discussion

DIC is a very serious hematological complication that usually occurs in the presence of severe sepsis or during neoplastic diseases. Nevertheless, other rarer etiologies must always be considered such as allergic reaction, fat embolism, aneurysm and dissection of the aorta as was the case in our patients. Aortic dissection is found to be a rare cause of DIC. Dissection of the aorta remains a rare yet a grave etiology of DIC. It needs to be considered especially if no obvious cause is found in patients with cardiovascular risk factors.

#2124 - Abstract

QUALITY OF ORAL ANTICOAGULATION THERAPY WITH VITAMIN K ANTAGONISTS: 10 YEARS OF EXPERIENCE

Renato Guerreiro, Susana Quintão, Catarina Bastos, Juliana Campos, Inês Sarmento, Irene Verdasca, Jorge Dantas, Rui Morais, José Guia, Filipa Marques, Inês Araújo, Ana Leitão, Cândida Fonseca

Oral Anticoagulation Clinic, Hospital de São Francisco Xavier, CHLO, Lisbon, Lisbon, Portugal

Background

In the era of direct oral anticoagulants, vitamin K antagonists (VKA) still play a central role in oral anticoagulation (OAC). The difficulties in the INR adjustment, in order to achieve an effective OAC are well known. The Time in Therapeutic Range (TTR) > 60% is the recommended indicator to evaluate the efficacy of VKA treatment.

The aim of our work is to evaluate the quality of VKA treatment in an OAC Practice over the past 10 years.

Methods

In a population on VKA, point-of-care INRs were first monitored using the Hyt-Gold, and the Gota v.8.1.3 computer program. We quantified TTR, % of thrombotic and hemorrhagic events related to OAC during 10 consecutive years, in a nursing consultation with medical staff collaboration.

Results

Between 2008 and 2017, an average of 765 (+/- 139) patients were monitored per year. 51% men and 65% (+/- 5) were 70 years old and over. The most frequent indication for OAC is Atrial Fibrillation/Atrial Flutter (mean 52% (+/- 1) patients/year), followed by acute thrombotic events and cardiac valve disease. We performed an average of 10285 (+/- 2118) appointments/year. From 2008 to 2017 the mean TTR were 74, 73, 74, 75, 79, 82, 82, 84, 81 and 82%, respectively. TTR was higher than 60% in 72, 72, 68, 72, 79, 84, 84, 81, 81, 82% of these patients respectively from 2008-2017; major haemorrhages developed in 0.19, 0.49, 0.56, 0.47, 0.54, 0.46, 0.85, 1.37, 0.97, 0.19%; minor bleeding arised in 5.57, 1.09, 2.81, 4.85, 4.03, 4.91, 4.96, 4.34, 6.12, 5.57%; and thrombotic events occurred 0.96, 0.24, 0.22, 0.12, 0.22, 0.0, 0.36, 0.96, 0.81, 0.96% /year.

Conclusion

The permanently high TTR's achieved over the last 10 years, in addition to the minimal rates of thrombotic and/or hemorrhagic events related to ACO, certify the effectiveness and the high quality of the AVK monitoring methodology used in our OAC Clinic.

#2130 - Abstract

SUSCEPTIBILITY AND COMPLIANCE TO INFLUENZA AND PNEUMOCOCCAL VACCINATION IN PORTUGUESE PATIENTS WITH HEART FAILURE: THE PITFALL STUDY

Márcia Agostinho Pereira¹, Gisela Vasconcelos², Lígia Rodrigues Santos², Madalena Vicente¹, Joana Duarte³, Francisco Adragão³, Inês Nabais³, Inês Egídio Sousa³, Inês Costa³, Sérgio Maltês, João Presume³, Inês Araújo³, Cândida Fonseca³

¹ Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

² Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal

³ Centro Hospitalar Lisboa Ocidental, Lisboa, Portugal

Background

Heart failure (HF) is a major and raising health problem, with respiratory tract infections being a common trigger of decompensation. Influenza virus and pneumococcal vaccinations are highly recommended in these patients. The aim of this study was to evaluate the vaccination rate for influenza and pneumococcal vaccines in the population with HF and the impact of patient education and active recall in vaccination compliance.

Methods

Prospective interventional study conducted using non anonymized patient survey and electronic health record data of patients seen in a HF Clinic of a general Hospital in Lisbon, between September and December 2018. The knowledge and opinion on those specific vaccines was questioned, as well as previous vaccination status; then, a brief explanation on the importance of vaccination was given; both vaccines were proposed for those not yet immunized. Statistical analysis was carried out using Microsoft Office Excel version 2016 in order to compare vaccination compliance before and after patient education.

Results

186 patients were included, 52.69% male; average age was 74.4 years old; 70.4% had previous compliance to annual influenza vaccination, while only 18.8% was registered for pneumococcal vaccination. Of all patients, 93.5% and only 3.8% were eligible for influenza and pneumococcal vaccinations at no cost, respectively, according to the National Immunization Program (NIP). Nevertheless, in the non compliant groups most patients did not get vaccinated because they "did not think the vaccine was useful", for influenza, and "had never heard of the vaccine", for pneumococcal vaccination. After a brief, one time, educative and active recall, vaccination compliance was 86.0% versus 70.4% (p=0.00027) for influenza vaccination and 83.9% versus 18.8% (p<0.00001) for pneumococcal vaccination.

Conclusion

Insufficient influenza and specially pneumococcal vaccination was registered, despite the high recommendation of both vaccines for HF patients. Among the factors are patient's lack of information, with higher vaccination compliance being achieved after a short

intervention. We hypothesized that pneumococcal vaccination is less recommended by physicians, taking in consideration that few patients knew about its existence. This may be due to the characteristics of the recommendation in the NIP (highly recommended but not free of cost) for that vaccine in HF patients. In a subsequent study we aim to compare the impact of vaccination in HF related events.

#2131 - Case Report

IATROGENIC PERIMYOCARDITIS: A RARE SIDE EFFECT OF MESALAZINE

Diana Vale Carvalho, Pedro Carvalho, Lisa Ferraz, Daniela Meireles, Ana Rafaela Araújo, Ana Raquel Ferreira

Centro Hospitalar Baixo Vouga, Aveiro, Portugal

Introduction

Mesalazine is a widely used drug which is generally perceived as being safe for the treatment of inflammatory bowel disease (IBD). Cardiotoxicity like myocarditis is a rare side effect, present in less than 1% of patients. However, it can be difficult to define the etiology of myocarditis once IBD can lead to myocarditis too.

Case description

A 21-year-old female patient was admitted to our emergency room with chest pain with pleuritic characteristics and palpitations. She had been recently diagnosed with ulcerative colitis and was medicated with prednisolone (15mg/day) and mesalazine 1000 mg twice a day (introduced 15 days before). In the physical examination, she only had fever and she did not show other significant changes. The initial 12-lead electrocardiogram revealed sinus tachycardia. Laboratory tests showed elevated troponin I (297 pg/mL) and C-reactive protein with leukocytosis. The echocardiogram showed a mild depression of the ejection fraction and slight hypokinesia in the basal portion of the inferior wall. She was hospitalized for suspected perimyocarditis and since the patient had been previously medicated with corticosteroids, the dosage was increased to 40 mg/day. Non-steroidal anti-inflammatory drugs or colchicine were not introduced because of the high risk of IBD exacerbation. Since the patient had heart failure mid-range ejection fraction, remodeling therapy was initiated. Cardiac magnetic resonance imaging revealed pericardial effusion, focal ventricular edema, increased ventricular permeability and delayed gadolinium enhancement mainly subepicardial, suggesting focal myocardial fibrosis. Because of mesalazine's cardiotoxicity described in literature, this drug was withdrawn soon after admission. The patient did not show new episodes of chest pain and there was a marked reduction of the patient's troponin levels. The following echocardiogram showed a recovery of the ejection fraction under optimized medical therapy. In the 3-month follow-up, the patient remained asymptomatic.

Discussion

Perimyocarditis is a rare extra-intestinal manifestation of IBD. The differential diagnosis with cardiotoxicity induced by mesalazine

can be challenging in patients with IBD who are treated with this drug. According to literature, mesalazine cardiotoxicity develops about 2-4 weeks after its introduction. In this case, the recent introduction of mesalazine and the clinical improvement after its discontinuation makes it as the most likely etiological agent for perimyocarditis.

POLYSEOSITIS AND PERIMYOCARDITIS WITH DILATED CARDIOMYOPATHY AND PERICARDIAL EFFUSION: WHEN IDIOPATHIC IS NOT THE ANSWER

Ana Craciun, Leila Duarte, Pedro Antunes Meireles, João Madeira Lopes, João Meneses, Rui M. M. Victorino

Serviço de Medicina 2, Hospital de Santa Maria, Centro Hospitalar Universitário de Lisboa Norte, Lisboa, Portugal

Introduction

Many cases of perimyocarditis and pericardial effusion remain idiopathic in developed countries, however it's most often caused by viral agents, followed by other causes. Very few clinical reports have been published about Chlamydia pneumoniae as a cause of perimyocarditis and even less had development of dilated cardiomyopathy.

Case description

A 37-year-old obese male, with no relevant past medical history besides rhinorrhea and odynophagia in the previous 2 weeks, was admitted at Emergency Service with 10-day evolution of daily fever 38.9°C and pain in epigastrium and right hypochondrium. Physical examination was notable for hypophonic and tachycardic heart sounds and tenderness on deep palpation in the painful areas, with no rebound. Blood tests accused leukocytosis 12350/μL, neutrophilia 10100/μL, erythrocyte sedimentation rate 116 mm, C-reactive protein 33.6 mg/dL, fibrinogenemia 1017 mg/dL and troponin 62 ng/L. Chest X-ray revealed great cardiomegaly with blunting of left costophrenic angle. Echography revealed large pericardial effusion with slight collapse of right atrium, coexisting pericardial thickening and bilateral pleural effusion. Pericardiocentesis drained 850cc of serohematic fluid whose cytology showed erythrocytes 4000/μL and cells 596/μL with 60% neutrophils and biochemical criteria compatible with exudative effusion. Echocardiogram and Myocardial Perfusion Scintigraphy showed dilated left ventricular with global hypokinesia and 40% ejection fraction, with no evidence of necrosis. Thoraco-abdominopelvic CT scan was unremarkable, as well as pericardial fluid and blood tests, except for the antibodies anti-Chlamydia pneumoniae IgA and IgG, which revealed positive. As the patient had spontaneous remission of his clinical and analytical condition, he was discharged with diagnosis of polyserositis and perimyocarditis with dilated cardiomyopathy and pericardial effusion. After 4 weeks the serology Chlamydia pneumoniae IgG and IgA continued positive, consistent with chronic infection.

Discussion

More than 50% of adults have *Chlamydia pneumoniae* specific IgG antibodies as a marker of exposure and reinfection is common. IgA antibodies are important to monitor in repeat infections, as they have a half-life of 5 to 7 days. Besides the spontaneous remission observed, as persistence of the short-lived specific IgA antibodies may be taken as an indication of chronic infection, we can't exclude it as the cause of this clinical picture.

PEDICULATED MASS OF THE AURICULAR FACE OF THE ANTERIOR MITRAL VALVE LEAFLET - NOT EVERYTHING IS WHAT IT SEEMS

Mariana Simoes, Viorela-Bianca Cristea, Ana Margarida Monteiro, Maria Sousa Uva, Luiz Menezes Falcao
Medical Center Lisboa Norte, Lisboa, Portugal

Clinical summary

A 71-year-old female patient, with cardiovascular risk factors with target organ lesions was admitted to our department with severe sepsis associated with urinary tract infection with methicillin-resistant *Staphylococcus aureus* in urine culture and bacteremia. Cardiac auscultation showed a mild grade III/VI holosystolic murmur audible throughout the precordium.

Figure #2156.

To exclude infectious endocarditis, a transthoracic echocardiogram was performed and revealed a pediculated mobile mass on the atrial face of the anterior leaflet of the mitral valve, with a fibroelastic appearance, conditioning mild to moderate mitral insufficiency. This mass was not suggestive of vegetation and raised the possibility of a papillary fibroelastoma. The histological examination revealed it to be, after all, a thrombus.

#2162 - Abstract

DIRECT ORAL ANTICOAGULANTS IN OLDER REAL LIFE PATIENTS WITH NON VALVULAR ATRIAL FIBRILLATION

Renato Guerreiro, Susana Quintão, Catarina Bastos, Juliana Campos, Inês Sarmento, Maria João Correia, Catarina Rodrigues, José Guia, Filipa Marques, Inês Araújo, Ana Leitão, Cândida Fonseca

Oral Anticoagulation Clinic, Hospital de São Francisco Xavier, CHLO, Lisbon, Lisbon, Portugal

Background

Direct oral anticoagulants (DOACs) have become the first line therapy for anticoagulation of patients with non valvular atrial fibrillation (AF) over the last decade. Four drugs of this class have been approved: apixaban, dabigatran, edoxaban and rivaroxaban. They share similar indications and contraindications, but have different dosage adjustment algorithm according to patient's characteristics. Considering the heterogeneity between population in different studies, comparisons head-to-head are not possible, neither between trials populations and real life patients. The aim of our work is to evaluate feasibility and safety of DOACs prescription in the patient's with AF to prevent embolic events, and the occurrence of a hemorrhagic event in patients on long-term anticoagulation over 8 years, monitored in our anticoagulation clinic.

Methods

In a population on oral anticoagulation (OAC) with DOACs, patients with AF were systematically monitored through the Gota v.8.1.3 program, in a nursing consultation with medical support, for 8 years, according to the recommendations of the European Heart Rhythm Association (EHRA). Major thrombotic and hemorrhagic events were analysed.

Results

Total of 523 patients with AF on OAC with DOAC were evaluated, 49.33% men, mean age 77 years (SD 9.8). In this population, 127 (24.28%) patients were on apixaban, 125 (23.90%) on dabigatran, 71 (13.58%) on edoxaban and 200 (38.24%) on rivaroxaban, with dose adjustments for comorbidities. Mean age of each group was 79.4 (DP 8.3), 76.4 (DP 9.4), 77.4 (DP 10.4) and 76.4 (DP 10.4), respectively (P: NS). Concerning major ischemic events, there were 3 cardioembolic strokes in the group of apixaban, with none occurring in the dabigatran, edoxaban and rivaroxaban

groups. Regarding major hemorrhagic events, a total of 19 cases (3.6%), respectively: 3, 4, 1 and 11 were observed in the apixaban, dabigatran, edoxaban and rivaroxaban groups. There was a statistically significant difference between the rivaroxaban and apixaban groups (Tukey's test-95% confidence interval [- 0.045 - 0.017], (P=0.02) with respect to the occurrence of stroke. There were no statistically significant differences between the other groups. There was no statistically significant difference between any of the groups for bleeding events.

Conclusion

Our work was able to demonstrate that, in this real life population, the occurrence of cardioembolic / hemorrhagic events was rare, reinforcing the position of DOACs as first-line drugs even in older patient's.

#2169 - Case Report

PULMONARY ADENOCARCINOMA PRESENTING AS BILATERAL INTERNAL JUGULAR VEIN THROMBOSIS

Guilherme Assis, Joana Rua, Daniela Viana, Nuno Ferreira Silva, Romeu Pires, Paula Vaz Marques
Hospital São Pedro de Vila Real, Vila Real, Portugal

Introduction

Multiple conditions can manifest as cervical edema, deep venous thrombosis (DVT) is one of them. Among this group, internal jugular vein thrombosis (IJVT) is a rare primary presentation and its bilateral involvement is even less common. We are reporting a case of spontaneous bilateral IJVT as a presentation of a pulmonary adenocarcinoma.

Case description

A 54-years-old man presented at the emergency room with bilateral cervical edema also involving the right hemiface, with 3 days evolution and associated pain and redness. Over the last 6 months, he described progressive asthenia, cough and night sweats, whilst, with 3 months evolution, he reported insidious dysphagia and reported episodic cervical edema and hoarseness with spontaneous remission. Recently, due to weigh loss, he conducted routine blood tests, upper endoscopy, colonoscopy and chest x-ray: all negative. Background included past smoking (40 UMA), hypertension, hypercholesterolemia, impaired glucose tolerance, alcohol abuse. No relevant family history was found. Cervical CT showed "scarce ganglionic formations on the internal jugular and supraclavicular levels; suspected IJVT". CTA confirmed "bilateral IJVT, distention of the right internal jugular vein, partial occlusion of both brachiocephalic trunks and left pleural effusion". Once admitted, he initiated anticoagulation with enoxaparin 1mg/kg bid. Further tests revealed normal ferritin, homocysteine, protein electrophoresis, autoimmune study and tumour markers – except CA-125 122U/mL. Biopsy of a supraclavicular nodule revealed "carcinoma, TTF1 negative, low probability of primary

thyroid or pulmonary". Abdominopelvic CT added "disperse mediastinal adenopathy and pulmonary nodules". He later conducted a transbronchial biopsy of the largest mediastinal nodule – subcarinal - that, despite the previous immunophenotypic profile, confirmed stage IV primary pulmonary adenocarcinoma.

Discussion

Spontaneous bilateral IJVT is a rare diagnosis. Local causes have to be excluded - infection (Lemierre's syndrome, sinusitis, otitis), central venous catheter, pacemaker and IV drugs abuse – as well as systemic causes - hypercoagulability state, myeloproliferative diseases, oestrogen use, pregnancy, ovarian hyperstimulation syndrome and neoplasia. Regardless of the involved vascular territory, it is important to search for an oncologic cause, frequently associated to DVP.

HEYDE SYNDROME: A DIAGNOSIS TO REMEMBER

Rafaela Pereira, Rosário Blanco, Catarina Cunha, Ana Rita Clara, Alexandra Martins, Mário Lázaro
CHUA Faro, Faro, Portugal

Introduction

Blood loss from gastrointestinal tract is one of the biggest cause of iron deficiency.

Angiodysplasia of the small bowel should be considered in the differential diagnosis of gastrointestinal bleeding (GB) when no source of bleeding was identified after a thorough examination. Bleeding from angiodysplasia in patients with aortic stenosis (AS) is designed Heyde syndrome.

Case description

A 70-years-old male patient, with past medical history of heart failure in the context of severe AS, arterial hypertension, atrial fibrillation anticoagulated with warfarine, type 2 diabetes mellitus and obesity, was sent to an Internal Medicine appointment after multiples episodes of acute heart failure symptoms despite optimal medication.

He referred some episodes of hematochezia and the complete study performed revealed an iron deficiency anemia (hemoglobin 10 g/L). It was assumed to be the cause of recurrent heart failure symptoms. Warfarine was changed to a new oral anticoagulant and was performed an upper endoscopy and colonoscopy that were negatives for bleeding.

Although the adjustment in the medication he was still with episodes of hematochezia and after a week of worsening weakness he was admitted to the emergency department. At the admission his vital signs and his physical examination were normal but laboratory tests showed an hemoglobin even lower (60 g/L). Without no other bleeding source evident, he performed a video capsule endoscopy that was consistent with bleeding angiodysplasia in small bowel and the diagnosis of Heyde syndrome

was made. The patient proceeded to aortic valve replacement and one year later he had normal hemoglobin values without episodes of gastrointestinal rebleeding.

Discussion

The association between AS, iron deficiency anemia, bleeding and angiodysplasia need to be recognized. A possible mechanism by which AS may lead to the development of angiodysplasia is through the development of an acquired form of von Willebrand disease that leads to GB. This case supports that hypothesis because after the valvular replacement none episode of significant bleeding was observed.

Until the valve replacement the management of anticoagulant therapy was challenging. In one hand the anticoagulation was absolutely necessary but, in the other hand, the patient was bleeding and needed to be transfused what represented always a risk due to heart failure. Evidence is lacking to support a specific approach.

PLATYPNEA-ORTHODEOXIA: TWO STORIES, TWO HAPPY ENDINGS...

Daniela Félix Brigas, Francisca Santos, Margarida Madeira, Gonçalo Mendes, Susana Marques, Ermelinda Pedroso
Setúbal Hospital Center, EPE, Setúbal, Portugal

Introduction

Platypnea-orthodeoxia syndrome (POS) is an uncommon condition of positional dyspnoea and hypoxemia, in which symptoms occur when the patient is upright and resolve with recumbency.

We report two different cases that illustrate the challenge of this diagnosis.

Case description

First case is referring to a 77 years old man who was admitted after two months of cough and progressive dyspnoea that improved with lying supine. Arterial blood gas measurement presented O₂ saturation of 84%. Transthoracic echocardiogram documented a paradoxical movement of interventricular septum and right ventricular overload. It was excluded pulmonary thromboembolism and thoracic angiotomography showed only sequelae lesions of fibrotic nature. During hospital stay, it was perceived that hypoxemia was positional, occurring while the patient was upright and resolving while he was recumbent. Transesophageal echocardiogram (TEE) showed interatrial communication, ostium secundum type, with a bidirectional shunting. Posteriorly, patient underwent a successful percutaneous closure of communication, with a final good result and no residual shunting. After the procedure, there was a significant clinical improvement, with no difference of peripheral saturation with positional variation.

Second case is about a 53 years old man with smoking habits who was admitted with a diagnosis of pneumonia. He presented a marked hypoxemia of difficult resolution even after antibiotic

treatment, which worsened with orthostasis. A structural pulmonary disease was excluded, through the performance of computed tomography and bronchofibroscopy. TEE documented a patent foramen ovale with a right-to-left shunting, which was accentuated with 45° head-of-bed elevation, as well as a left atrial appendage (LAA) vegetation. Since *Staphylococcus hominis* was isolated from blood cultures, it was assumed acute endocarditis, which was treated with vancomycin. There was a major clinical improvement and a second TEE showed a free LAA and a bidirectional shunting with no positional variation. It was assumed resolution of POS after treatment of infectious complication, with no need of immediate surgery.

Discussion

These two cases, with very distinctive functional and anatomic components, illustrate the challenge of understanding the exact mechanism by which POS results in clinical symptoms. A suggestive history and positional variation of O₂ saturation are very useful clues for its diagnosis in cases of unexplained hypoxemia.

#2199 - Abstract

READMISSIONS IN HEART FAILURE IN AN INTERNAL MEDICINE DEPARTMENT: A NINE-YEAR COHORT STUDY.

Sílvia Santos Pereira, Rita Homem, Joana Lopes, Eugeniu Gisca, Catarina Valadão, Francisca Delerue, Mário Amaro, Vanda Spencer

Hospital Garcia de Orta, Almada, Portugal

Background

Heart failure (HF) is a chronic and progressive illness with a high prevalence in the elderly. The admissions and readmissions in HF carries out a reduction in life quality, an increase in morbimortality and a burdensome for the healthcare system.

Methods

The authors aim to characterize patients admitted for acute HF in an internal medicine department and the rate of mortality and readmission.

This is a retrospective observational study enrolled all patients discharged from 2008 to 2016 with a primary diagnosis of HF according to International Classification of Diseases (ICD-9). Clinical records and discharged summaries were analysed.

Results

From 2008 to 2016 there were 3190 patients admitted with HF, with a mean age of 77.69 years and 56% of female. In-hospital mortality was 15.5% and the overall mortality in nine years was 54.3%. The most prevalent comorbidity was hypertension, diabetes mellitus and dyslipidaemia.

The readmission rate was 24.3% (775 patients), with a mean of 1.67 readmission per patient (1-19) and the mortality rate in nine years was 51.3%.

Conclusion

The high readmission and mortality rate is due by the temporal inclusion and by the complexity of the patients. It is necessary more studies in HF to understand the real extent of readmissions and to develop measures to decrease it.

INTRACARDIAC MASS: WHEN CLINICAL PRESENTATION DIFFERENTIATE BETWEEN ENDOCARDITIS AND MYXOMA

Paulo Almeida, Diana Carvalho, Tiago Rabadão, Margarida Eulálio, Manuela Vieira, Ana Araújo, Eliana Araújo
Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

Clinical summary

Echocardiography is a valuable method for the differential diagnosis of intracardiac mass. Image 1 - voluminous echodense vegetation, friable and adherent to the ring of the mitral valve in a patient with fever, a grade 3/6 apical holosystolic murmur radiating to the axilla and bacteremia by *Staphylococcus aureus*. The final diagnosis was infective endocarditis. Image 2 - echogenic, filiform, mobile and pediculated image, adherent to the interatrial septum in an asymptomatic patient. It was suggestive of left atrial myxoma. It is understandable that a large vegetation on the mitral valve could mimic a left atrial myxoma, on the echocardiogram because of their similar size and site. However, clinical presentation is essential for the differential diagnosis between a myxoma and endocarditis.

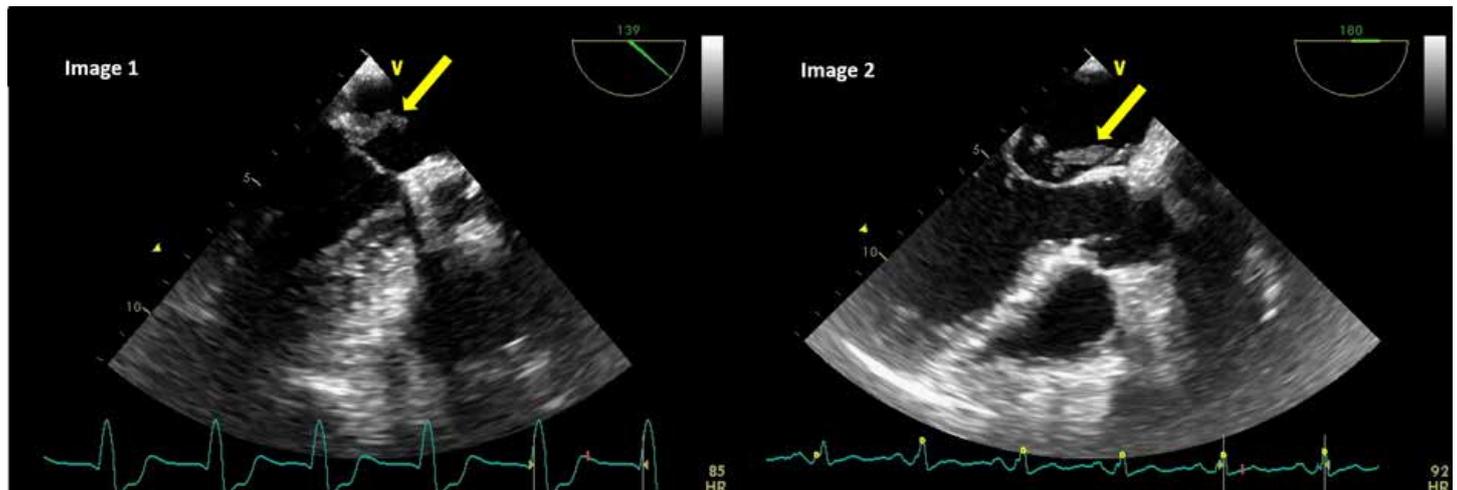

Figure #2209.

#2214 - Case Report

STRESS CARDIOMYOPATHY - THE GREAT IMITATOR

Andreia M. Teixeira, Carla Pereira Fontes, Samuel Fonseca
Centro Hospitalar Entre Douro e Vouga, Santa Maria Da Feira, Portugal

Introduction

Stress cardiomyopathy is characterized by transient regional systolic dysfunction of the left ventricle, but with unobstructed coronary arteries at coronary angiography. The hallmark is the presence of emotional or physical trigger, usual with negative character, which appears to precipitate the event. The pathogenesis is unknown, being postulated mechanisms involving excess of catecholamine, microvascular dysfunction and coronary spasm.

According to literature, it accounts for around 7% of all patients with presumed myocardial infarction and is more prevalent in females.

Case description

A 70 year old man with hypertension and clear cell renal carcinoma was admitted to the emergency room with chest pain and left arm

parathesias one day after initiating treatment with Pazopanib, a tyrosinase kinase inhibitor. He presented with hemodynamic stability and hypofonetic heart sounds on auscultation and no other alterations on physical exam. The electrocardiogram showed 1 mm elevation of ST segment at DI, aVL, v1 and v2 derivations associated with progressive rising of myocardial injury biomarkers with high sensitive troponin I, that raised to 1548.1 ng/L. Echocardiogram showed left ventricle depression (35% by Simpson biplane) and apical left ventricle hypokinesia. Coronary angiography was performed and revealed no coronary obstruction. There was a decrease in troponin I to normal values, electrocardiogram with anterior bundle of left branch block and after 2 days of hospitalization, echocardiogram was repeated and showed recovery of left ventricle function (62% by Simpson biplane) with little regional apical wall abnormal motion.

Discussion

A few cases of reversal ventricular dysfunction by pazopanib are described in literature, although it usually courses with heart failure symptoms and after a short period of treatment, which made it unlikely, in this case, as the symptoms started after one day of therapy.

Stress cardiomyopathy has a clinical presentation that mimics acute myocardial infarction. In most cases the diagnosis is established after a normal coronary angiography, although coronary disease may be present obviating a definitive diagnosis, which raises the suspicion of an underestimated prevalence. Although an increasingly recognized condition, a lot is to uncover in order to establish a consensual approach to this entity.

#2224 - Case Report

PSEUDOANEURYSM OF THE RIGHT SINUS OF VALSALVA

Cátia Carvalho

Centro Hospitalar Universitário de Lisboa Central - Hospital Santo António dos Capuchos, Lisboa, Portugal

Introduction

The pseudoaneurysms of sinus of Valsalva is a serious and rare complication of an infection, trauma or as a complication of a cardiac surgery or procedure.

Case description

We present a caucasian 71 years-old man with hypertensive and valvular cardiopathy (Class III NYHA), under anticoagulation for mechanic valvular prosthesis on both mitral and aortic positions, since 5 years ago. Two days ago, he started with fever and urinary symptoms (pain and sudden urges peeing) and on evaluation he was febrile, hypotensive, pale, without heart murmur, abdominal pain and bilateral oedema of the lower limbs. Laboratory investigation showed neutrophilic leukocytosis (Leu 12,520, Neut 10,150) and a positive c-reactive protein (147 mg/L), an infected urine (40/uL leucocits and presence of nitrites), the x-ray revealed cardiomegaly and electrocardiogram was normal sinus rhythms. It was empirically initiated Ceftriaxone and the cultural exams (blood and urine) revealed an *Enterococcus faecalis* with the increment of Ampicilin due to antibiograma. For the maintaince of the febrile condition, he did a transthoracic echocardiography that showed anterior aortic prosthetic insufficiency, mitral prosthetic valve without alterations, mild hypertrophy of the left ventricle (LV) with dysfunction (ejection fraction: 48%) and inferior septum hypokinesia; which was complemented with a transesophageal ecocardiography that revealed a mitral vegetation (6x4 mm) and a round struture near to the right valsalva sinus (30x30) wich coul be a pseudoaneurysm with a filiform mobile struture (6x2.5 mm) wich could be one more vegetation. He did also a cardiac angioCT that revealed a huge pseudoaneurysm (63x35x48mm) on the LV between aortic and mitral valves, being accepted to cirurgical treatment with the replacement of aortic prosthesis and colocation of Freestyle porcine bioprosthesis on aortic position. He charged one month later, asytmatic.

Discussion

This case re-inforces the team work and the interaction between all the specialities for the great outcome. What seemed to be a urinary infection was a really life threatning clinical condicion.

#2226 - Abstract

NEUTROPHIL-TO-LYMPHOCYTE RATIO AND PLATELET-TO-LYMPHOCYTE RATIO AS PREDICTORS OF VENOUS THROMBOEMBOLISM: A RETROSPECTIVE, SINGLE-CENTER ANALYSIS

João Gramaça, Sara Garez Gomes, Mónica Fidalgo Silva, Teresinha Ponte, Filomena Carneiro, Fátima Campante
Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Background

There is recent data towards a superiority of the neutrophil-to-lymphocyte ratio and the platelet-to-lymphocyte ratio (PLR) as predictors of the presence or absence of deep vein thrombosis (DVT) when compared to the D-dimer test, the former with a 90.2% sensitivity when ≥ 3.4 and the latter with a 89% specificity when ≥ 230 ; when both positive, the data suggests a 100% specificity, a predictive power greater than the aforementioned D-dimer test when ≥ 500 ng/mL. Despite this, the evaluation included only DVT and excluded the many causes for secondary venous thromboembolism (VTE). We retrospectively evaluated the hypothetic value in a real-life setting of these predictive and readily accessible markers.

Methods

Of a sample of 26 patients hospitalized in a medical ward throughout a 2 year span due to VTE or other causes with a diagnosis of VTE during the hospitalization and without clinical signs of infection we retrospectively evaluated the NLR and PLR at the moment of diagnosis. In all of the cases there was a D-dimer test ≥ 500 ng/mL. We included any type of VTE; we excluded patients treated with imunossupressor drugs or with haemotological malignancy.

Results

In the analyzed sample we had 53.85% with a DVT diagnosis, 57.69% with pulmonary embolism (PE) and 11% with VTE at other anatomical sites. 30.1% of the diagnosed VTE had a NLR < 3.4 and only 1 case (3.85%) had a PLR ≥ 230 ; broadening the PLR cut off to 200 increased the percentage to 26.92%. When looking at the cases with a "double positive" ratio, there were 6 cases (including the solitary one with a PLR > 230); there was one instance of a negative NLR and a positive PLR. Interestingly, in the 8 cases with a NLR < 3.4 , there were 6 with only PE or VTE at other site diagnosed and 2 with only DVT diagnosed. When comparing to studies that included just DVT, the NLR ≥ 3.4 was present in 85.71% of the analyzed DVT cases; looking solely at PE cases, the ratio was positive only in 66.67%.

Conclusion

The authors recognise the sample is small, and that there's a selection bias when looking retrospectively only to patients admitted to a medical ward. Nevertheless when applying these markers to a real-life setting by including a more broad group of

patients, as well as both DVT and PE, we distinguish some putative limitations in its use without the backup of other lab tests. Despite this, these ratios could be valuable when included in composite predictive scores, such as Well's criteria for DVT and the Geneva score for PE.

#2231 - Case Report

A RARE CAUSE OF ACUTE HEART FAILURE

Sara Sarmento Rodrigues, Ana Carmo Campos, Isabel Cruz Carvalho, João Freitas Silva, Marco Narciso, Teresa Fonseca
Hospital Pulido Valente, Centro Hospitalar Lisboa Norte, EPE, Lisboa, Portugal

Introduction

The diagnosis of myocarditis is challenging due to its clinical heterogeneity. Although myocardial biopsy is the gold standard in the diagnostic and prognostic evaluation, its rarely done because of its low sensitivity and invasive approach. Myocarditis accounts for about 9%-16% of cases of non-ischemic dilated cardiomyopathy and about 2-42% of cases of sudden death in young adults. The etiology of myocarditis includes infectious and non-infectious causes and toxic myocarditis is rare. Hydrocarbons, present in paints and solvents, are cardiotoxins potentially causing myocarditis, heart failure and sudden death and in rare cases they may be associated with cardiomyopathy.

Case description

We present a case of a 77-year-old man with an history of cardioembolic AIT due to atrial fibrillation, who presented with a 3-week history of palpitations, chest pain, progressive exertional dyspnea, paroxysmal nocturnal dyspnea and peripheral edema. The patient had no previous heart failure (HF), with an echocardiogram with good global systolic function. In the current episode, the patient had a class III NYHA HF, NT-proBNP elevation (3033pg/mL), normal Troponin T (14 ng/L). Transthoracic echocardiography revealed dilated cardiomyopathy, 33% of ejection fraction and diffuse hypokinesia. Of the remaining etiological studies we highlight negative viral serologies (Borrelia, Coxachie, HCV, HBV, CMV, EBV, Adenovirus, Lyme D., Rubeola), normal coronary angiography, normal ventilation/perfusion lung scintigraphy and normal thyroid function. The patient reported an exposure, 2 weeks before, to paints and thinners containing halogenated hydrocarbons in great concentration, without protection of the airway. He denied contact with other substances, drugs or recent infections. Dilated cardiomyopathy was assumed to be in the context of acute toxic myocarditis, and therapy was optimized. The echocardiographic reassessment at 5 months showed an important improvement, with an ejection fraction of 43%, presenting a clinical improvement (class I NYHA).

Discussion

This case presented contemplates the criteria for diagnosis of myocarditis, excluding the most common etiologic causes,

assuming a probable toxic etiology, which is a rare cause of acute heart failure, alerting to the importance of high diagnostic suspicion and an exhaustive context of exposure. Ultimately, the patient was spared a myocardial biopsy and was given a presumptive diagnosis of myocarditis based on the clinical and exposure context.

#2236 - Abstract

CARDIOVASCULAR RISK FACTORS PREVALENCE IN PATIENTS ADMITTED TO THE INTERNAL MEDICINE WARDS IN A UNIVERSITY HOSPITAL

Penelope Almeida, Sara Pires, Luísa Serpa Pinto, Guiomar Pinheiro, Carolina Silva, João Araújo Correia
Centro Hospitalar do Porto, Porto, Portugal

Background

Cardiovascular diseases remain as one of the most important causes of death and morbidity in Portugal despite all efforts. The high prevalence of all modifiable cardiovascular risk factors (CVRF) allied to the progressive population-ageing contribute to this scenario. Therefore all knowledge about the aforementioned CVRF is of great matter for the internal medicine physician.

Methods

Retrospective cohort of patients admitted at the Internal Medicine wards of a University hospital, between January 1st of 2015 and December 31st of 2018. Analysis of demographic characteristics and comorbidities. Categorical variables presented as absolute or relative frequency, continual variables presented as medium and standard deviation. The IBM® SPSS Statistics® software was used (version 24).

Results

Of the 2130 enrolled patients, 1172 (55%) were man and the medium age was 74 years (SD +/- 15.5). The overall mortality rate was 11.3% (n=241). 1686 patients had at least one cardiovascular risk factor (CVRF). These patients presented a medium age of 75.4 years (SD +/- 13.8), the majority were man and the mortality rate in this group was 9.8% (n=186). Arterial hypertension (AH) was the most common modifiable CVRF (n=1353, 80.2%), followed by dyslipidaemia (n=912, 54.1%), diabetes mellitus type 2 (n=659, 39.1%), obesity (n=415, 24.6%), active smoking (n=247, 14.7%) or previous smoking (n=371, 22.0%) and hyperuricemia (n=181, 10.7%). When reviewing data by gender, we verified that the prevalence of AH (84.7% vs. 76.6%, p<0.001), dyslipidaemia (58.6% vs. 50.6%, p=0.001) and obesity (31.6% vs. 19.0%, p<0.001) was superior in woman than in man. On the other hand, woman presented an inferior prevalence of active smoking (5.4% vs. 22.1%, p<0.001) or previous smoking (2.5% vs. 37.7%, p<0.001), and also hyperuricemia (11.5% vs.17.2%, p=0.006). The prevalence of diabetes mellitus type 2 didn't change between genders (40.9% vs. 37.6%, p=0.170).

Conclusion

Interestingly, some of our results are substantially different from what we know about the general Portuguese population. This is probably related to the older medium age of the cohort, the majority being post-menopausal woman, but can also mirror a growing tendency of the prevalence in CVRF in woman.

#2239 - Abstract

EVALUATION OF VENOUS THROMBOPTOPHYLAXIS IN MEDICAL PATIENTS ADMITTED TO A INTERNAL MEDICINE WARD OF A GENERAL HOSPITAL

Gonçalo Miguel Amaral Mendes, Margarida Madeira, Mafalda Figueira, Ana Catarina Emídio, Daniela Brigas, Francisca Santos, Diana Neto, Eugénio Dias, Clara Rosa, Ermelinda Pedroso
Centro Hospitalar de Setúbal, Setúbal, Portugal

Background

Traditionally, venous thromboembolism (VTE), which is defined as a deep venous thrombosis (DVT) and pulmonary embolism (PE), is usually considered a complication of major surgery. However, this view has been changing over the last years. The hospitalization for a nonsurgical acute disease is associated with a rise of the VTE risk. The primary objective of this study was to assess which patients were at risk of a VTE and evaluate if those receiving prophylaxis were receiving the appropriate drug in the right dose and frequency. The secondary objective was to determine if the patients suffered a major adverse event during their stay and up to 30 days after discharge.

Methods

The authors performed a retrospective cross-sectional study involving inpatients in the adult internal medicine ward in January 27, 2019. Patients with length of stay less than 48 hours were excluded. In order to assess the risk of VTE the Padua Prediction Score (PPS) was implemented and patients divided in two categories; low-risk for VTE (<4 points), and high-risk for VTE (≥ 4 points).

Results

Of the 59 patients, 26 patients (44%) were female and 33 (56%) patients were male. The mean age was $80,15 \pm 12,99$ years. Atrial Fibrillation (AF) was present in 22 (37%) patients, with a median HAS-BLED of $3,2 \pm 1,03$, of those, 18 (30,5%) patients were already under hypocoagulation, the majority 77,8% ($n=14$), using direct oral anticoagulants.

When we evaluated VTE risk, 53 patients (89,84%) had a PPS ≥ 4 . 42 (71,2%) patients were under anticoagulation, and from this, 18 (42,8%) were not receiving the correct dose. 15 (83,3%) were having underdosage and 3 (16,7%) an excessive dosage. 17 patients who were not receiving thromboprophylaxis, 12 (70,5%) had a PPS ≥ 4 .

Patients did not have an adverse event during their stay or at 30 days after discharge. We were unable to correctly evaluate and

quantificate minor adverse events like local hematomas, however their presence was frequent.

Conclusion

These results provide insight into prescribing patterns. Thromboprophylaxis was inappropriate in 18 patients, 15 of them underdosed and 3 with an excessive dose. 12 patients that had high risk for VTE were not under hypocoagulation, for unknown reason not presented in the clinical file. In order to improve this outcomes, an internal orientation was approved and another evaluation will be made after its implementation.

INFECTIOUS ENDOCARDITIS : UNUSUAL CAUSE OF LOWER BACK PAIN

Ivan Cadena, Ana Moura, Joana Canadas, Soraia Teixeira, Manuela Grego, Maria Luz Pitta, Luis Siopa
Hospital de Santarem, Santarem, Portugal

Clinical summary

A 78-year-old woman, with biological aortic prosthesis and atrial fibrillation, was admitted due to low back pain for 3 weeks and severe gait limitation. At the physical exam presented degree III/VI systolic murmur and palpation of low back. Lumbar CT scan revealed "multiple osteolytic lesions in the lumbar bodies". After hospital admission there was fever and cutaneous lesions in the foot. *S. epidermidis* methicillin resistant cultured in the blood. Echocardiogram revealed a vegetation on the biological prosthesis in aortic position. MRI lumbar scan showed diffuse alteration of the D12 and L1, translating inflammatory changes in the context of spondylodiscitis. Vancomycin and rifampicin was administered for 6 weeks, before transitioning to linezolid at completion of 12-week for spondylodiscitis.

Figure #2241. Janeway cutaneous lesions in the plantar region of the foot.

LOOKING BEYOND THE RESPIRATORY INFECTION: A DEADLY INTRA-CARDIAC MASS

Vanessa Machado¹, Paulo Ferreira¹, Cristina Ramalho¹, Hilda Freitas², António Cabral², Natália Oliveira²

¹ Trofa Saúde Hospital em Braga Centro, Braga, Portugal

² Trofa Saúde Hospital em Braga Sul, Braga, Portugal

Introduction

Cardiac masses are rare entities that can be broadly categorized as neoplastic or non-neoplastic. Echocardiography is the first-line imaging modality for assessment of intra-cardiac masses. Primary cardiac tumors have a prevalence of 0.001 to 0.03 % in an autopsy series, while metastatic tumors are 20 to 40 times more common. Primary cardiac malignant tumors account for 25% and sarcoma is the most prevalent. Other masses that mimic cardiac tumors include thrombi, pericardial cysts, prominent anatomic structures.

Case description

A 82-year-old man with a medical history of bladder cancer, chronic bronchitis and cardiovascular risk factors was admitted to the Emergency Department of our private hospital with symptoms including cough, mucopurulent sputum and fever. After complementary study, a community respiratory infection hypothesis was assumed and the patient was discharged with empirical antibiotherapy and supportive medical care. A week later, the patient was admitted again to the Emergency Department with maintained cough, mucous sputum expectoration difficult to expel, anorexia and adynamia.

The hypothesis of respiratory infection remained, however because of the presence of elevated inflammatory parameters, anaemia and d-dimer elevation, septic screening was performed and a new antibiotic scheme was started. Computed tomography with angio-tomography was performed. The latter pointed out an intra-cavitary hypodense material (in the right ventricle) with extension to the origin of the pulmonary trunk, possibly related to intra-cardiac thrombus. It also revealed bilateral acute pulmonary thromboembolism, cardiomegaly, bronchiectasis, and pulmonary consolidation. Heparinization was administered. In the attempt to achieve a diagnosis, the echocardiography revealed an intra-ventricular thrombus versus a tumor mass, associated with signs of pulmonary hypertension. Other exams included an urgent request for cardiac magnetic resonance imaging.

The patient presented clinical stability, without complications. The control echocardiography revealed that the intra-ventricular mass had a greater extension, was friable and mobile, conditioning a potential catastrophic embolization. The patient was transferred to a public hospital, evolving briefly to a fatal outcome.

Discussion

The evaluation of cardiac masses may be a diagnostic challenge. We emphasize that it is necessary to valorize the patient's symptoms especially after repeated hospital admissions.

A CASE OF GUILLAIN-BARRE SYNDROME REQUIRING MECHANICAL VENTILATION IN A 86-YEAR-OLD PATIENT

Angeliki Tsifi, Stela Stefanova, Sofia Avgeri, Evaggelia Sergi, Kyriakos Ntorlis, Anastasios Sakkalis
General Hospital of Nea Ionia -Patision Konstantopouleio, Athens, Greece

Introduction

Guillain-Barre syndrome (GBS) is an acute or subacute polyradiculoneuropathy, usually following infections, inoculations or surgical procedures. Rapid diagnosis and early treatment are important in order to improve the clinical outcome and even achieve full recovery.

Case description

We present an 86-year-old female with hypertension and a medical history of breast cancer treated with radiation and hormone therapy after its surgical removal seven years ago. The patient was originally admitted to the neurology department after a recent respiratory tract infection due to limb weakness accompanied by depressed deep tendon reflexes, which rapidly progressed to paralysis. A lumbar puncture was performed. Cerebrospinal fluid (CSF) features supported the diagnosis of GBS, since they exhibited elevated CSF protein with a normal cell count. The patient further deteriorated, she was intubated due to respiratory failure and she was transferred to the ICU after being started on intravenous antibiotics and on iv immunoglobulin (IVIG), which she received for five days. The patient was successfully extubated on day 5 of her ICU admission, her neurological status gradually improved and she was eventually transferred back to the neurology department with minor limb weakness for further management.

Discussion

Respiratory distress is the leading cause of death in GBS. After a correct diagnosis is achieved, supportive measures, treatment with IVIG or plasmapheresis and continuous monitoring of the patient should be implemented in order to avoid further deterioration and death.

VILLARET'S SYNDROME - A RARE PRESENTATION OF SKULL BASE OSTEOMYELITIS

Rahul Unnikrishnan¹, Baiju Faizal²

¹ Rashid Hospital, Dubai, United Arab Emirates

² Lifecare Hospital, Abu Dhabi, United Arab Emirates

Introduction

Skull base osteomyelitis is a lethal condition, especially in immunocompromised and elderly individuals. Here we report a very rare case of skull base osteomyelitis, presenting as Villaret's syndrome. Our patient presented with multiple lower cranial nerve palsies with right-sided Horner's syndrome.

Case description

71 year old male, smoker & diabetic presented with reduced hearing on right side, associated with purulent discharge from both ears (right > left). Two weeks later, he presented with cough, difficulty in swallowing and hoarseness of voice with nasal regurgitation. Symptoms associated with weight loss of 14 kgs over 4 months. Examination revealed right partial ptosis, lateral gaze palsy and miosis. Bilateral loss of gag and palatal reflexes. Right trapezius and sternomastoid was weak with tongue fasciculations. Deviation of tongue to right side on protrusion. Blood investigations revealed high CRP and ESR. CT Brain revealed retropharyngeal/nasopharyngeal hypodense lesion and erosion of right petrous apex. MRI was suggestive of osteomyelitis of petrous and clivus with infection spreading to the nasopharynx. Transnasal biopsy confirmed chronic osteomyelitis

Discussion

Skull base osteomyelitis is a potentially life threatening infection that classically presents as a complication of severe external otitis, middle ear, mastoid or sinus infection and can result in multiple lower cranial nerve palsies as a result of jugular foramen involvement due to widespread involvement of the skull base. Pseudomonas Aeruginosa has been reported as the most common pathogen involved in skull base osteomyelitis. The presentation of skull base osteomyelitis as Villaret's syndrome, as in our case, is extremely rare.

SUBACUTE NEUROLOGIC DETERIORATION. AN UNEXPECTED PATHOLOGICAL FINDING.

Francisco Mula Falcón, Alberto Romero Alonso, Jose Antonio Mira Escarti

Service of Internal Medicine. Hospital de Valme, Sevilla, Spain

Introduction

Osmotic demyelination syndrome (ODS) develops after rapid correction of severe hyponatremia and can result in serious irreversible neurological consequences if it is not early diagnosed. Clinical manifestations of ODS are quite diverse and typically delayed several days after correction of hyponatremia, making diagnosis truly challenging.

We present a case of a patient with family history of neurodegenerative disorders that developed a rapidly progressive parkinsonism syndrome, dementia and altered mental status several days after correction of hyponatremia.

Case description

A 74-year-old woman was admitted for a 2-week history of asthenia, unsteady gait and bradypsychia. Her family history was notable for Parkinsonism and rapidly progressive dementia in her father. Examination was unremarkable except for time and spatial disorientation and bradypsychia. Laboratory testing showed a hyponatremia of 110 mEq/l with serum hypotonicity. Three days later, sodium was corrected to 134 mEq/l and the patient experienced a clinical improvement.

On the fifth day her condition worsened and drowsiness, tremor, rigidity and myoclonus developed. The patient died after progressive neurologic deterioration. Autopsy was performed and showed findings compatible with ODS. 14.3.3. protein in cerebrospinal fluid was negative.

Discussion

ODS can manifest with a great variety of neurological manifestations, some of them serious and irreversible if it is not early diagnosed. Since it usually occurs a week after correcting hyponatremia, it is important to keep it in mind in patients with history of corrected hyponatremia who later develop neurological symptoms. The best treatment is prevention, which is why the rhythm of correction of hyponatremia is crucial.

#108 - Abstract

CLINICAL FACTORS RELATED TO MORTALITY AND DEPENDENCE IN INTRACEREBRAL HAEMORRHAGE – A RETROSPECTIVE STUDY

Tiago Jorge Antunes De Sá, Francisco José Alvarez Pérez

Centro Hospitalar da Cova da Beira, Covilhã, Portugal

Background

Haemorrhagic stroke represents 10% of acute cerebrovascular accidents, with an incidence of 24,6/100000 person-year.

Intracerebral Haemorrhages (IH) are caused by a damage of intracerebral small vessels due to chronic hypertension, amyloid angiopathy or coagulopathies. This disorder has a high mortality rate during acute phase and a high risk of dependence during chronic state.

The main objective of this study is to identify epidemiological, clinical and imaging variables associated with mortality during admission and a worse functional outcome after discharge.

Methods

This was a retrospective study that included patients with IH admitted to the CHCB's Stroke Unit during January 2012-December 2016. Patients with ischemic stroke, subdural hematoma, subarachnoid haemorrhage or brain neoplasm were excluded. The information used for this study was obtained through the patient's clinical processes.

Results

A total of 122 patients were available for analysis, 72 male (59%) and 50 female (41%). Mean age was 73,5±11,78. The locations of hematoma were basal ganglia (n=73), lobar (n=36), cerebellum (n=8), brain stem (n=4) and intraventricular (n=1). Sixty-four patients developed in-hospital complications (32 pneumonia, 31 neurologic deterioration, 17 lower urinary tract infections, 19 hydrocephalus). Twenty-two patients died during admission (29,5%), 52 were dependent after discharge 47 were independent. Variables associated with in-hospital mortality were previous stroke, use of antiaggregants, higher glucose level, higher hematoma volume in CT scan, presence of peri-hematoma oedema, intraventricular haemorrhage, lower Glasgow coma scale score, higher NIHSS score, higher ICH score, occurrence of hydrocephalus and presence of neurologic deterioration.

Variables associated with dependence after discharge were age, higher total leukocyte and neutrophil count, higher neutrophil/lymphocyte ratio, higher hematoma volume in CT-scan, intraventricular haemorrhage, lower Glasgow scalescore, higher NIHSS score, higher ICH score, occurrence of pneumonia, and presence of neurologic deterioration.

Conclusion

The hematoma volumes in CT-scan, the presence of intraventricular haemorrhage, lower Glasgow coma scale score and higher NIHSS and ICH scores were associated with a significant increase of in-hospital mortality and worse functional outcomes.

#151 - Case Report

ALTERED MENTAL STATUS WITH HYPERTENSION: IS POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME ONE OF YOUR DIFFERENTIAL DIAGNOSIS?

Chaozer Er, Navin Kuthiah, Nicholas Wong Wai Cheong

Woodlands Health Campus, Singapore, Singapore

Introduction

There are many causes of altered mental status (AMS). If AMS is coupled with severe hypertension, we ought to consider posterior reversible encephalopathy syndrome (PRES) as one of the differential diagnoses.

Case description

A 60-year-old Malay gentleman with past medical history of hypertension, hyperlipidaemia, diabetes mellitus and previous stroke, presented to us with 1 day history of fever and new onset of confusion. On examination, he was confused and drowsy with no local neurological deficit. The blood pressure (BP) was 210/121 mmHg on admission. Computed tomography of his brain showed diffuse cerebral oedema with no intracranial haemorrhage or acute infarct seen. Empirical intravenous Ceftriaxone, Ampicillin, Vancomycin and Aciclovir were prescribed to treat patient as a case of meningo-encephalitis. He then underwent magnetic resonance imaging (MRI) of the brain which showed extensive, symmetrical white matter changes involving bilateral frontal, parieto-occipital and temporal regions. The changes were in keeping with PRES. He was treated with intravenous labetalol and monitored closely in the high-dependency unit. His systolic BP was controlled at the range of 150-170 mmHg in the first 24 hours of admission. Further history from his wife confirmed that patient has been non-adherent to his hypertension medication for 1 year. His confusion improved with BP control. He was discharged after 2 weeks of hospitalisation.

Discussion

Patients with PRES typically present with acute onset of headache, confusion, seizures and visual disturbances. It is often associated with high BP. There are many conditions such as stroke, meningo-encephalitis, intracranial bleed and venous sinus thrombosis that can present in similar ways. MRI brain classically shows white matter oedema predominantly localized to the posterior cerebral hemispheres. The mainstay of treatment is BP control. Most patients recover within 2 weeks.

#207 - Abstract

CEREBROVASCULAR DISEASE IN ADULTS LESS THAN 55 YEARS OF AGE – A GREAT CHALLENGE?

Sara Lopes Fernandes, Adriana Bandeira, Hélia Martins, Behnam Moradi, Alcina Ponte

Leiria Hospital Center, Leiria, Portugal

Background

Stroke is an important cause of morbidity and mortality. It is more common in men over 65 years of age, however the incidence in young adults has been increasing (5-20% of all strokes). Although less frequent, it will be in this group that presents greater socioeconomic impact, by leaving patients disable during their productive years of life. This study aims to characterize a

population of patients under 55 years of age, in order to improve preventive measures.

Methods

The present study presents a descriptive and retrospective analysis of patients aged ≤ 55 years followed in a Cerebrovascular Risk Consultation, from January 2016 to December 2017.

Results

Of the 183 patients selected, 45 were under or 55 years (25%). The mean age was 48 years, 51% males. The main reason for the appointment was ischemic stroke (53%), followed by transient ischemic attack (29%) and hemorrhagic stroke (7%). Risk factors include dyslipidemia (67%), hypertension (60%), smoking (40%), alcohol (18%), diabetes (11%) and previous ischemic events (13%). The etiological study showed elevation of LDL values in 89% of the patients, changes in thyroid function in 7% and autoimmune analytical disorders in 23%; thrombophilias were positive for at least one factor in homozygosity in 37% and in heterozygosity in 48%; carotid atherosclerosis was identified in 27% of the patients, Patent Ovale Foramen in 28% and atrial fibrillation was diagnosed in 2% of the cases. During follow-up, 7% presented new cerebrovascular events, 4% convulsions and 9% minor bleeding.

Conclusion

About 25% of the patients followed in Cerebrovascular Risk Consultation were ≤ 55 years. There was a huge number of cardiovascular risk factors, making this population a high risk one before the primary event. However, it should be noted that the etiological study identified thrombophilia in about 37% of the patients and Patent Ovale Foramen in about 28%. In order to prevent cerebrovascular events in this population an aggressive medical treatment of risk factors is crucial, however it is also important to identify and treat secondary causes.

#225 - Case Report

HEMOPERICARDIUM WITH CARDIAC TAMPONADE AFTER INTRAVENOUS THROMBOLYSIS FOR ACUTE ISCHEMIC STROKE

Martim Baltazar Alçada, Marina Boticario, Guilherme Violante Cunha, Pedro Manata, Maria Filomena Roque
Hospital de Santarém EPE, Santarém, Portugal

Introduction

Hemorrhage is the major complication of recombinant tissue plasminogen activator (rt-PA) treatment for stroke. We report a case with new onset of cardiac symptoms prior to thrombolysis in whom hemodynamically significant cardiac tamponade occurred after treatment with rt-PA.

Case description

An 59-year-old woman, with history of cognitive impairment,

hyperlipidemia, epilepsy, hypothyroidism and no previous cardiac history, presented with acute right hemiparesis, dysarthria, facial paralysis within two hours of symptom onset (National Institutes of Health Stroke Scale [NIHSS], 11. On arrival to the emergency room, she was tachycardic. EKG showed atrial fibrillation with rapid ventricular response, so she initiated amiodarone perfusion. Head CT revealed neither hemorrhage nor early ischemic changes. The patient met all qualifying criteria for rt-PA. Initially, the patient had a good response to the rt-PA with improvement in function of her right side and speech. However 45 min after stopping the rt-PA the patient became extremely hypotensive with no response to aggressive fluid administration. Emergent bedside pericardial effusion with fibrin clots with evidence of atrial and ventricular collapse. Pericardiectomy was performed with 600ml of blood aspirated from the pericardial sac with rapid recovery of the hypotensive state and no subsequent bleeding complications.

Discussion

The risk of symptomatic intracerebral hemorrhage and systemic bleeding requiring transfusion, surgery or other aggressive management following administration of rt-PA in ischemic stroke has been well described. However, cases of hemopericardium and cardiac tamponade after intravenous (IV) thrombolysis for ischemic stroke are extremely rare. As in our case, small yet available evidence suggesting that acute ischemic stroke patients presenting with cardiovascular signs should receive comprehensive cardiac evaluation including an echocardiogram, prior to the treatment with IV rt-PA.

#227 - Case Report

"HAND KNOB" STROKE

Cátia Ribeiro Santos, Cátia Faria, Maria João Palavras, João Santos, Célio Fernandes

Centro Hospitalar Leiria - Hospital de Santo André, Leiria, Portugal

Introduction

Cortical ischemic stroke affecting the precentral "hand knob" area is well defined as a clinical entity. However, often its clinical presentation as a pure motor deficit without a sensory deficit and absence of cranial nerve deficit mimics a peripheral nerve damage. The most prevalent risk factors are hypertension and atherosclerosis, with embolic etiology being the most likely underlying pathophysiological mechanism.

Case description

This case report describes a male in his late 70s who presented a history of coronary disease and vascular risk factors. Admitted to the emergency department by sudden onset of motor deficit of the left upper limb with an hour and a half of evolution. It performed a cranial CT scan without revealing acute vascular lesions. Blood analyses were not significant and normoglycemia status. For suspected peripheral nerve damage also performed a cervical CT scan that revealed multiple degenerative changes of the cervical spine,

and was observed by neurosurgery that suggested an isolated motor deficit, but clinical picture not compatible with myeloradicular compression. Subsequently, he performed a reevaluation of the neurological examination, with the patient revealing mild left facial paresis, a monoparesis of the left upper limb of distal predominance (proximal grade 2, distal grade 0). Therefore, he repeated a cranial CT scan 12 hours after admission, showing a small cortical hypodensity in the right precentral gyrus, the hand motor cortex "hand knob" area. We assumed the diagnosis of ischemic stroke with clinical presentation of isolated hand paresis (pure motor deficit).

Discussion

The presentation of this case aims to alert to a careful evaluation of the cases of acute motor monoparesis, particularly in the geriatric population with vascular risk factors, including the differential diagnosis of acute neurological syndrome and peripheral nerve damage.

#236 - Abstract

STATINS AFTER ISCHEMIC STROKE: HAVE WE CHANGED OUR CLINICAL PRACTICE?

Luis Castilla Guerra¹, Salvador Perez Galera¹, Maria Del Carmen Fernandez Moreno², Antonio Valenzuela Gonzalez¹, Miguel Angel Rico Corral¹, Miguel Colmenero Camacho¹

¹ Department of Internal Medicine. Hospital Virgen Macarena, Seville, Spain

² Department of Neurology. Hospital de Valme, Seville, Spain

Background

Statins have emerged as guideline therapy for secondary stroke prevention. We investigate long-term trends in statin use after ischemic strokes (IS)

Methods

Retrospective study on patients with IS discharged from the Departments of Neurology and Internal Medicine of the Hospital Virgen Macarena, Hospital de la Merced and Hospital de Valme, Seville, Spain, during two periods: between 1999-2001 and between 2014-2016.

Results

We studied 1575 patients, 661 (42%) women, with an average age of 69 (± 10) years. Comparing the two periods we find that now patients are older (mean age 68 ± 10 vs. 71 ± 11 , $p=0.0001$) and have higher frequency of dyslipidemia (32.5% vs 48.9%; $p=0.001$), and hypertension (67.3% vs 73.8%; $p=0.008$). At discharge statins were used in 18.9% of patients as compared to 86.9% ($p=0.0001$), with an increasing trend (1999 15.2%, 2000 15.5% 2001 24.6%-2014 81.6%, 2015 88.2% 2016 89%). Regarding the statin type: in both periods Atorvastatin was the most common prescribed (80 mg 6% vs. 42.7%; 40 mg 5.1% vs 11.1%), followed by Simvastatin (40 mg 0 vs 13.3%; 20 mg 5.8% vs. 12.1%), pravastatin, and fluvastatin; and

most recently rosuvastatin (2.6%) and pitavastatin (3.3%) ($p = 0, 0001$). High intensity statins was used in 11,1% vs. 54.4% patients ($p=0.0001$), though with similar percentage among statin users in both periods (58.7% vs. 62.6% $p=NS$).

Conclusion

There are significant changes in the use of statins in patients with IS. Currently most IS patients receive statins at discharge, though high-intensity statin treatment is clearly underused.

#257 - Case Report

HEMOCHROMATOSIS AND STROKE: AN EXCEPTION TO THE “IRON HYPOTHESIS”

Mariana Soares, Tereza Veloso, Carmen Corzo, Conceição Barata, Inês Ribeiro, Leila Barrocas
Hospital Espírito Santo de Évora, Évora, Portugal

Introduction

It has been hypothesised that increased iron stores, traduced by increased levels of ferritin, could play a role in the pathogenesis of atherosclerosis, representing an independent cardiovascular risk factor. The mechanism behind this hypothesis relies on the ability of iron to increase oxidation stress and regulate immune responses, affecting all the cells involved in the formation and destabilization of the atherosclerotic plaque. Hereditary hemochromatosis, associated in other studies with increased prevalence of ischemic stroke, seems to be an exception to this hypothesis, assuming a protective role against atherosclerosis. We present a case of stroke in a young adult, whose diagnostic study identified increased ferritin levels and made the genetic diagnosis of hemochromatosis.

Case description

A 48-years-old male presented at emergency department due to vertiginous syndrome. Besides age and gender, he presented other cardiovascular risk factors, such as obesity and smoking. The neurologic exam showed no deficits, but the brain CT showed signs of previous occipital infarcts, so we asked for an MRI of the brain, that showed atrophic areas of the left cerebellar hemisphere, probably associated to vascular etiology. The echocardiogram and the carotid dopplers were normal. We proceeded with the study of stroke in the young adult, revealing negativity of all the prothrombotic markers and a high ferritin level. The genetic test was confirmatory of hemochromatosis. The abdominal MRI showed hepatic hypertrophy and iron overload, coincident with chronic hepatopathy. The patient was referred to hepatology and immunohemotherapy consultations, starting periodic phlebotomies.

Discussion

Hemochromatosis has been postulated as protective against atherosclerosis, due to the effect of the mutation in down-regulating the expression of hepcidin, causing a selective

intra-cellular depletion of iron in macrophages, the main cells intervening in the pathophysiology of atherosclerosis. The studies associating hemochromatosis with higher prevalence of stroke, also showed no increased prevalence of carotid stenosis on these patients, suggesting that the mechanism behind this association does not rely on atherosclerosis, but is still to be unveiled. The presented case shows the importance of including ferritin in the study of patients with cardiovascular events, since it is now suggested as an independent cardiovascular risk factor, possible of being corrected with adequate diet and physical activity.

#286 - Case Report

KLUVER-BUCY SYNDROME AFTER HERPETIC ENCEPHALITIS

Raquel Costa¹, Octávia Costa², Inês Carvalho², Sara Varanda², Célia Machado², Ana Filipa Santos²

¹ ULSAM - Hospital Conde de Bertiandos, Ponte De Lima, Portugal

² Hospital de Braga, Braga, Portugal

Introduction

Kluver-Bucy syndrome is a rare entity that results from bilateral injury of the temporal lobe. It is characterized by severe cognitive and behavioral alterations, namely amnesia, visual agnosia, placidity, hypersexuality, hyperorhythmia and hyperphagia. Herpetic encephalitis is the most common infectious cause.

Case description

A male patient, 21 years old, unemployed with no relevant medical history, is taken to the Emergency Department (EM) due to an inaugural convulsive crisis. At admission he was sleepy, had no focal deficits, had no meningeal signs, and was apiretic. He underwent cranioencephalic tomography that showed no alterations, besides low cerebellar tonsils. During the stay in the EM, he had a new convulsive crisis and started a psychomotor agitation with incoherent speech. T 38 ° C was observed. It was prescribed levetiracetam (3000 mg/d) and, on suspicion of meningoencephalitis, acyclovir (750 mg 8/8hrs), ceftriaxone (2 g 12/12hrs) and dexamethasone (10 mg 8/8hrs). He performed cerebral magnetic resonance imaging that revealed bilateral hypersignal in the temporoinsular and temporomesial regions compatible with herpetic encephalitis. From the analytical study carried out to highlight anti-herpes simplex IgG and IgM antibodies positive. During hospitalization, he started to have behavioral changes, with absence of expression of emotions, hypersexuality, hyperphagia, hyperorhythmia and alotriophagy. Kluver Bucy syndrome was diagnosed. The levetiracetam was replaced by lacosamide (200 mg/d) and risperidone (0.5 mg 3/d) topiramate (100 mg/d) and fluoxetine (20 mg/d) were initiated. Fulfilled 21 days of acyclovir. At the time of discharge, he scored 24 on the MMSE; although there was some improvement of the behavior, it maintained serious alterations, namely alotriofagia.

Discussion

Kluver Bucy syndrome may rarely occur as a complication of herpetic encephalitis. The treatment of this infection with acyclovir should be initiated early and a high index of suspicion is essential. The treatment of Kluver Bucy syndrome is challenging; the existing drugs only help to control the symptoms, and the functional prognosis is reserved.

#357 - Case Report

LIMBIC ENCEPHALITIS: CASE REPORT

Carolina Bologna¹, Gabriella Oliva², Marina Lugara², Pasquale Madonna², Paolo Tirelli², Anna Guida², Maria Antonietta De Sena², Maria Gabriella Coppola², Nunzia Silvestri², Claudio De Luca², Ernesto Grasso²

¹ Sea Hospital- ASL Naples, Naples, Italy

² Sea hospital, Napoli, Italy

Introduction

Title: Limbic encephalitis

Limbic encephalitis is a rare disease often associated with small cell lung cancer and breast cancer, rarely associated with mesothelioma.

Case description

The diagnosis of limbic encephalitis in the elderly multipathological patient admitted to an internal medicine unit may be difficult. Description of the case: a 76-year-old patient with heart failure due to chronic hypertensive ischemic heart disease with hypokinetics and severe depression with EF (35%); mitral valvular disease treated surgically; Permanent FA in TAO; pulmonary asbestosis; Stage III IRC K-DOQI, hospitalized for hyponatremia that could be secondary to high-dose diuretic therapy (at the entrance 114 mEq/l, treated with 3% hypertonic solution).

The correction of sodemia does not resolve the patient's confusional state, which shows signs of rapidly progressive dementia with hallucinations and convulsions. Negative brain CT scan. Haloperidol treatment for hyperactive delirium does not improve the picture. Therefore it requires brain MRI with sequence in DWI showing limbic encephalitis. It then performs lumbar puncture for the detection of anti-HU, anti-Ma, anti-NMDA antibodies. The PET study shows a pathology with high metabolic activity in the pleural lymph nodes and middle lung lobe. The hypometabolism of widespread glucose in the brain center. To the CT solid nodular formation with polylobate margins (Dtrv max 65x48mm; IM: 3-251), corresponding to the medial segment of the LM, poorly dissociable from the parietal pleural profile. Needle aspiration is performed with a 21G needle shows mesothelioma.

Discussion

Discussion: the diagnosis of limbic encephalitis in the hospitalized elderly can be complicated due to the possible concomitance of other reasons of confusional state and delirium.

#367 - Case Report

CAROTID ARTERY DISSECTION: A SUSPICIOUS DIAGNOSIS

Inês Moreira¹, Filipa Guimarães², Joana Martins², Ana Monteiro², Inês Chora², Eduardo Eiras²

¹ Instituto Português de Oncologia Francisco Gentil, Porto, Portugal

² Unidade Local de Saúde de Matosinhos, Hospital Pedro Hispano, Matosinhos, Portugal

Introduction

Carotid artery dissection is an important cause of ischemic stroke in young adults, being responsible for up to 25% of such events in this age group. In the absence of trauma, it typically presents as a constant ipsilateral headache of sudden or gradual onset. As many as 20% of patients can develop ischemic stroke without previous symptoms associated with the dissection

Case description

The authors present the case of a 34 year old woman that presented to the emergency room (ER) with a left sided headache that started 10 days ago and escalated in the past few hours. The pain started suddenly during the night and woke her up, was throbbing, with fluctuating intensity. It alleviated with rest and paracetamol and aggravated with physical effort. This was the first episode of this kind. Associated symptoms were bilateral tinnitus, dizziness, phono and photophobia. No fever, sensitive, muscular or visual alterations were reported. She denied history of trauma, physical exercise or sexual relations the night before the start of the symptoms. Physical and neurological examination in the ER and blood workup were normal. Angio-CT revealed a left cortico-subcortical fronto-insular hypodensity suggestive of an acute vascular ischemic lesion. She was admitted for further study. Viral serologies, immunological and Borrelia studies were negative. Cerebrospinal fluid study was also normal. Echocardiogram demonstrated right-left shunt suggestive of patent foramen ovale. Cerebral angio-MRI confirmed the acute ischemic injury and revealed the presence of dissection of the left internal carotid artery. She was medicated with acetylsalicylic acid. Due to an ambiguous image in the MRI, a thoracic angio-CT was ordered, which demonstrated a solid lesion in the lumen of the right intermediate bronchus. Rigid bronchofibroscopy and pathology results confirmed the presence of a typical carcinoid tumor. She underwent right medium and inferior bilobectomy.

Discussion

The diagnosis of carotid dissection is obvious in the presence of cervical trauma but in its absence a high index of suspicion is required. In this case the patient presented with a typical migraine-like headache without recent history of trauma or arteriopathy. The presence of a carotid dissection could have been easily overlooked and a diagnosis of migraine-type headache established if it were not for the red flags that motivated a more complete study. Carotid artery dissection must always be considered in young adults that present with new onset headache.

CEREBRAL AMYLOID ANGIOPATHY - A RARE RELATIVE TO THE ALZHEIMER'S DISEASE

Cármén Ferreira, Mário Monteiro, Alexandra Dias, Daniela Brito, Fernanda Coutinho

CHMT - Centro Hospitalar Medio Tejo, Abrantes, Portugal

Introduction

Cerebral amyloid angiopathy is characterized by amyloid beta peptide deposits in the small and medium cerebral vessels and leptomeninges. It's caused by intracerebral hemorrhage in the elderly and associated with Alzheimer's disease. Its prevalence is 2.3% in individuals aged 65-74 years, 8% between 75-84 years and 12.1% above 85 years. This disease is uncommon in individuals under 60-65 years and very rare under 50 years.

Case description

A 50-year-old male, with history of difficulty to control blood pressure, obesity and alcoholism. He went to emergency care due to acute changes in language and mental confusion. At admission, he had motor aphasia with blocks, difficulty in pronouncing the word thought, without paraphasia, without alterations of comprehension, repetition or appointment. The cranioencephalic tomography (CT) documented: "left posterior occipital encephalomalacia and left superior parietal intra-axial hematoma of indeterminate origin to demonstrate adjacent hypodensity and partial deletion of the regional grooves, suggesting associated edema". AngioCT revealed: "fair-cortical intraparenchymal hematopoietic focus, with only slight cortical extension in some planes, an aspect that defies the hypothesis of ischemic stroke with further transformation marginal sulcal hyperdensity that seems to translate rupture into the subarachnoid space...without occlusions of large vessels and venous thrombosis...lesions of small and large endocranial vessels, infrequent in this age group, considering the hypothesis of amyloid angiopathy..." The echocardiogram, the 24 hours holter and the doppler of the neck vessels had no alterations. Magnetic resonance imaging (MRI) documented: "multiplicity of intracranial hemorrhagic lesions, in multiple stages of evolution, suggestive of angiopathy with gonadotropin". The neurologist suggested the avoidance of antiplatelet drugs, control of vascular risk factors and alcohol withdrawal. A second CT revealed partial reabsorption of the hematoma, so the patient was discharged.

Discussion

The definitive diagnosis of amyloid angiopathy can only be performed by post-mortem brain biopsy, but a probable diagnosis can be made by MRI identifying 2 or more areas of hemorrhage in typical regions. It's rare in individuals younger than 50 years old. We should consider this diagnosis when neurological symptomatology exists and in order to prevent a significant cognitive deterioration and even the premature development of Alzheimer's disease.

MILD ENCEPHALITIS/ENCEPHALOPATHY WITH REVERSIBLE SPLENIAL LESION - A BENIGN CONDITION WITH NOT SO BENIGN DIFFERENTIALS

Margarida Mouro, Ana Martins, Daniel Coutinho, Sofia Nunes, Jorge Velez

Infectious Diseases Department, Baixo Vouga Hospital Centre, Aveiro, Portugal

Introduction

Mild encephalitis/encephalopathy with reversible splenial lesion (MERS) is a rare clinico-radiological entity, particularly in adults, characterized by the magnetic resonance imaging (MRI) finding of a lesion in the corpus callosum. Patients commonly present with mild central nervous system symptoms and almost universally recover fast and without sequelae. Despite its unknown pathogenesis, some reports identified infections, especially viral, vaccinations and some antiepileptic drugs as potential triggers of MERS. We report the case of a 44-year old patient admitted with this diagnosis.

Case description

44-year old male, previously healthy, presented at the emergency department with sudden onset neurological symptoms (ataxia, myoclonus, dysarthria and headache). He also mentioned nausea, vomiting and dizziness starting the day before and a flu-like syndrome in the previous 5 days, but hadn't measured body temperature. At admission he was afebrile, hemodynamically stable, and exhibited facial myoclonus and global aphasia. Blood workup was normal and a brain CT scan revealed no lesions. A lumbar puncture was then performed and the cerebrospinal fluid revealed lymphocytic pleocytosis (56 cells/ μ L) with mononuclear predominance and increased protein concentration (73.7 mg/dL). Intravenous aciclovir 10 mg/kg every eight hours was empirically started. The following day the patient developed confusion and disorientation, with some sporadic agitation. Viral serologies and an autoimmune panel were negative, and an MRI was performed, revealing a high signal intensity on T2-weighted images in the splenium of the corpus callosum, with diffusion restriction, suggesting a transitory lesion of the splenium. The patient was admitted to the Infectious Diseases ward, aciclovir was stopped, and he fully recovered by day 5. A control MRI performed two months after was completely normal.

Discussion

We report the case of a patient with MERS, a usually benign entity with unspecific neurological manifestations and an imagiological diagnosis. Because of its presentation, the differential diagnosis includes a plethora of not so benign conditions. As in most cases reported in the literature, our patient recovered without any sequelae within few days and a subsequent MRI was completely normal.

#430 - Case Report

GENETIC CAUSES OF STROKE: ABOUT A CLINICAL CASE

Joana Carreiro, Maria Guadalupe Benites, Almerindo Rego
Terceira Island Santo Espirito Hospital, Angra Do Heroismo, Portugal

Introduction

Stroke is a leading cause of death and disability in developed countries. In young age, a stroke is most likely related with heart disease, vasculitis and hypercoagulable states.

Case description

This is a case of 32 years old male with family history of stroke in young age (mother, uncle and cousin) that presented with paresthesias of right hemiface and hand. CT scan showed a thalamic lacunar infarct and leukoencephalopathy and the MRI multiple demyelinating lesions, compatible with multiple sclerosis. In the next years the neurological deficits escalated, with dysarthria, cerebellar ataxia and dementia. At 44 years old, due to cognitive impairment, seizures, tetraparesis and dysphagia, he was hospitalized. MRI showed subcortical and basal ganglia hypodensities and leukoencephalopathy. This associated with the family history and the fact that his younger brother died of an hemorrhagic stroke the year before raised suspicion of a genetic cause. The genetic study revealed a mutation in heterozygosity in exon 4 of the NOTCH 3 gene and he was diagnosed with CADASIL (Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy). Two years later, another two brothers had cerebral ischemic episodes that lead to the diagnosis of CADASIL. The patient died when he was 47 years old.

Discussion

Genetic predisposition to stroke can be categorised in single gene or polygenic disorders, with the first presenting at a younger age, either with stroke or with other clinical features related to the disorder. Like CADASIL, CARASIL (autosomal recessive), Moya-moya disease, Fabry disease and MELAS (Mitochondrial myopathy, encephalopathy, lacticidosis and stroke) may present with stroke in early adulthood.

RADIATION THERAPY CAROTID RESTENOSIS

Marta Soares Carreira¹, Daniela Ferro¹, Andreia M Teixeira², Luís Lemos¹, Margarida Matias¹, Guilherme Gama¹, Paulo Castro Chaves¹, Luísa Fonseca¹, Jorge Almeida¹

¹ Centro Hospitalar Universitário de S. João, Porto, Portugal

² Centro Hospitalar de Entre Douro e Vouga, Santa Maria Da Feira, Portugal

Introduction

Extra-cranial carotid artery stenosis is a well-established vascular complication of radiation exposure which increases the risk of cerebrovascular events.

Case description

A 31-year-old female was admitted to our stroke unit (SU) due to amaurosis fugax (AF) of the right eye. Her prior medical history included a childhood pharynx rhabdomyosarcoma treated with chemoradiotherapy. The patient's recovery period was uneventful, and the cancer did not recur. 22 years later she was admitted to our SU due to a transient loss of vision of the right eye. Extracranial vascular ultrasound examination (EVUE) showed a 75% stenosis of the right internal carotid artery (RICA). The patient underwent carotid artery stenting (CAS) and a 2 months course of dual antiplatelet therapy (DAPT) with acetylsalicylic acid (ASA) 150 mg id and ticagrelor 90 mg 2id followed by monotherapy with ASA. Clopidogrel resistance test was positive. 4 months later she was admitted to our emergency department due to headache. Although computed tomography angiography (CTA) showed narrowing of the RICA, EVUE was normal. A year after CAS, she was again admitted to our SU due to another episode of AF. EVUE showed a 70-80% restenosis of the RICA. CTA confirmed the diagnosis and a balloon angioplasty was performed. Subsequent EVUE showed a stenosis of 50-55%. Aspirin resistance test was positive. She was discharged on DAPT with an higher dose of ASA (250 mg id) and ticagrelor (90 mg 2id). One month after discharge, EVUE showed a similar grade of RICA stenosis.

Discussion

In-stent restenosis is a possible complication of carotid artery stenting which can be managed with interventional procedures such as percutaneous angioplasty with simple balloon. In this case, ASA resistance also contributed to restenosis.

#475 - Case Report

PROBABLE NON-COMPACTED MYOCARDIOPATHY OF THE LEFT VENTRICLE - A LOW FREQUENCY THROMBOEMBOLICAL SOURCE

Rodrigo Rufino, Catarina Carvalho, Alexandra Albuquerque, Fátima Campante

Centro Hospitalar Barreiro-Montijo, Barreiro, Portugal

Introduction

Left Ventricular Non-Compaction (LVNC) is a rare cardiomyopathy, characterized by a prominent left ventricular trabeculae and deep intertrabecular recesses, in the absence of other congenital abnormalities.

LVNC may be of sporadic or familiar nature and its' prevalence is unknown. The main clinical manifestations include heart failure, arrhythmias, cardiovascular arrest and thromboembolic events. LVNC is diagnosed based on clinical and morphological criteria, without a gold standard characteristic, but has several proposed echocardiographic criteria.

Case description

A male 62 year old patient, paraplegic due to a L1 fracture,

goes to the Emergency Department due to paresis of his right upper limb. He was sleepy but easily awakable, disoriented in time, hemodynamically stable, with right central facial and homolateral upper limb paresis. Analytically without relevant alterations and cranioencephalic (CE) computerized tomography (CT) demonstrated bilateral infarcts with inaccurate dating. He was admitted to the Internal Medicine Service for research and rehabilitation for probable ischemic stroke (IS) of the left hemisphere (LH).

During hospitalization, a CE-CT confirmed bilateral border infarcts, suggestive of a cardioembolic source. To complement the study, we performed a 24-hour Holter exam with no alterations, echoDoppler and angio-CT of the vessels of the neck where atherosclerotic plaques were found, with significant stenosis in the right carotid artery, but without urgent surgical indication; and a transthoracic echocardiogram with apical hypertrabeculation, without identifiable thrombi in the left ventricle, suggestive of non-compacted cardiomyopathy. The main diagnosis of stroke in the LH was assumed, with indication for hypocoagulation due to the echocardiographic findings.

The patient remained hemodynamically stable during hospitalization and completed a motor rehabilitation program with improvement of his initial paresis. He is waiting for the results of complementary outpatient exams, namely a cardiac magnetic resonance imaging, and continues investigation in Internal Medicine, Cardiology and Vascular Surgery consultations.

Discussion

This case emphasizes the importance of the etiological investigation of stroke. Analyzing all the possible foci of embolism, namely through the use of echocardiography, allows the diagnosis of rare pathology, as in the likelihood of this case, as we are still awaiting the conclusions of the outpatient study for the definitive diagnosis.

GLIOBLASTOMA MULTIFORME AND LOWER DEGREE GLIOMA

Maria Beatriz Santos, Magda Garça, Pedro Cota, Joana Carreiro, Paulo Ávila, Rita Vitorino Costa

Hospital of the Holy Spirit of Terceira Island, Angra Do Heroísmo, Portugal

Clinical summary

59 years old male patient, personal history of cervical melanoma. Admitted with holocranial headache, urinary incontinence, behavioral changes and left hemiparesis with hypoesthesia with 15 days of evolution. Cranial CT identified two nodular lesions in the right cerebral hemisphere. Cranial MRI revealed "two expansive lesions in the right hemisphere, conditioning moderate mass effect: a frontal parasagittal lesion behaving like glioblastoma multiforme and a thalamic lesion as a lower degree glioma". The patient underwent neurosurgery in a tertiary hospital and adjuvant chemotherapy. Glioblastoma is the most common

malignant primary brain tumor in adults. Patients may present with a wide range of symptoms from unspecified symptoms to focal neurologic signs.

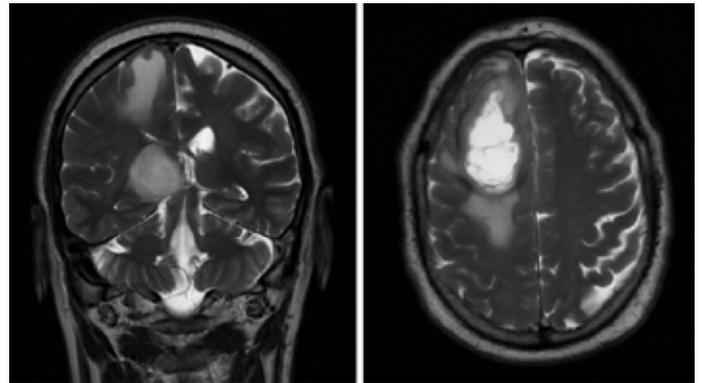

Figure #499. Two expansive lesions in the right hemisphere, conditioning moderate mass effect: a frontal parasagittal lesion (7.1x3.7x5.1cm) behaving like glioblastoma multiforme and a thalamic lesion (2.7x3.6x3.0cm) as a lower degree glioma.

NOT FORGETTING KORSAKOFF

Diogo Faustino, Liliana Antunes, Rita Pocinho, Isabel Baptista
Central Lisbon University Hospital Centre - S. José Hospital, Lisbon,
Portugal

Introduction

Korsakoff syndrome is an uncommon entity, with a reported prevalence 0,5-4,8 per 10000 persons. It typically follows Wernicke Encephalopathy and it represents the irreversible neurologic structural damage secondary to severe thiamine deficiency.

Case description

47-year-old man, with previous history of severe alcohol and tobacco abuse, admitted to the emergency room with severe delirium, ongoing for 3 days with progressive worsening. For the previous months, he had an extremely limited food intake, having isolated himself in his room, only leaving to acquire alcohol (2-3 liters of wine per day) and cigarettes (1-2 packs a day). He was thin, frail with sarcopenia, had visual hallucinations and was disoriented with slowed, disorganized and confabulatory thought. He showed global amnesia, couldn't walk or keep a standing position (neck in anterocolis) and had no abnormal eye movements. Blood analysis showed protein and folate deficiency (Urea 4 mg/dl Creatinine 0.41 mg/dl Albumin 26.0 g/L Hemoglobin 11.2 g/dL Mean Corpuscular Volume 112 fL Folate 1.8 ng/ml), with normal vitamin B12, transaminases and ammonia. Cranial magnetic resonance showed cortical and cerebellar atrophy with widened sulci and an enhanced signal in medial and posterior thalamus

With vigorous and prolonged thiamine and folate supplementation, there was a favorable neurological and cognitive response;

hallucinations ceased and speech coherence was recovered but a profound amnesia persisted, with minor improvement, only recollecting his distant youth.

Discussion

According to the criteria of Caine, the initial clinical picture was consistent with Wernicke Encephalopathy (dietary deficiency together with confusion, disorientation, confabulation and cerebellar dysfunction). The modest improvement of the memory when compared to other cognitive functions, together with the findings on cranial magnetic resonance, suggest the diagnosis of Korsakoff syndrome, with irreversible damage to the thalamus due to prolonged thiamine deficiency.

We highlight the need for an early recognition of Wernicke encephalopathy to ensure prompt and adequate thiamine supplementation in order to avoid the progression to the, mostly irreversible, Korsakoff syndrome, where memory is disproportionately affected when compared to other cognitive functions.

TRANSIENT ISCHEMIC ATTACK VERSUS CONVERSION DISORDER: A CASE REPORT

Miguel Reis Costa, Pedro Pinto, Rosana Maia, Duarte Silva, Irene Miranda, Carmélia Rodrigues, Diana Guerra

ULSAM - Hospital de Viana do Castelo, Viana Do Castelo, Portugal

Introduction

Transient Ischemic Attack (TIA) is defined as a focal and temporary neurologic dysfunction, which is attributable to dysfunction of one arterial territory of the brain. However, there are patients with transient focal neurological symptoms, which are not attributable to focal cerebral ischemia. Psychiatric conditions (like conversion disorder) may imitate a TIA.

Case description

We describe the case of a 62-year-old woman with a medical history of β -Thalassemia and anxiety disorder; family history of sudden cardiac death of a brother. She had an episode of dysarthria, labial commissure deviation to the left side and decrease of strength in the right arm associated with chest pain and fear of eminent death. These deficits were observed by the emergency ambulance crew; however, when in the urgency room she had a normal physical examination – she considered that the deficits had spontaneously resolved in less than 2 hours like had happen before (only this time she decided ask for help). CT scan and CT angiography showed no signs of acute brain injury or vessel alteration. Electrocardiography identified a sinus rhythm associated with few supraventricular premature beats (ectopic atrial escape rhythm was posteriorly confirmed in a 24-hour holter monitoring). Summarized analytics: normal cardiac biomarkers, a hypochromic and microcytic anemia (hemoglobin: 10.3 g/dL), normal electrolytic balance, negative virology serology and a normal lipid panel. Brain MRI revealed

hypersignal focus in periventricular white matter, more prominent in the right frontal lobe probably representing old ischemic infarction areas. Transthoracic echocardiogram identified a slight dilation in the left auricle and signs of left ventricular hypertrabeculation/noncompaction (LVHT), confirmed in cardiac MRI. Electroencephalogram excluded epilepsy. Although the anxiety history and symptoms, considering that the referred deficits had a possible correlation with a vascular area and the confirmation of old infarction regions, the diagnosis of TIA with probable cardioembolic etiology (LVHT) was considered and she began anticoagulation therapy. She had also been referred for a medical genetics consultation.

Discussion

For TIA, the diagnostic challenge is greater, and the “mimic” rate higher, because there is no definitive diagnostic test. Complementary diagnostic procedures may help the diagnosis of TIA; however, clinical judgment remains the cornerstone.

#591 - Case Report

CEREBRAL VENOUS THROMBOSIS - CASE REPORT

Hilda Freitas¹, Natalia Oliveira¹, António Cabral¹, Paulo Ferreira², Vanessa Machado², Cristina Ramalho²

¹ TrofaSaude Hospital Braga Sul, Braga, Portugal

² TrofaSaude Hospital Braga Centro, Braga, Portugal

Introduction

Cerebral vein and dural sinus thrombosis (CVT) is less common than most other types of stroke but can be more challenging to diagnose. The available data suggest that CVT is uncommon. The annual incidence ranges from 0.22 to 1.57 per 100,000, and is more common in women than men, with a female to male ratio of 3:1.

Case description

The authors describe a clinical case of a 66 years old women, autonomous, without known diseases. She went to emergency department sent by Otorhinolaryngology for left temporoparietal headache that started abruptly 15 days before, associated with nausea and vomiting. She had been treated with antibiotics because of sinusitis. Since then she refers attenuation of pain but with maintenance. Neurological examination was normal. She was without fever and with normal blood pressure. Brain Computer Tomography: “The images show left occipital lobar hemorrhage in the resorption phase, surrounded by a halo of vasogenic edema with parietal extension, and the presence of acute subdural blood along the left free border of the cerebellum tent and temporal convexity ipsilateral”. She was hospitalized. She made Computer Tomography Angiography at the admission: “In the study we performed we found asymmetry of the lateral sinuses, due to the lower expression of the left lateral sinus, presenting irregularities in the initial 2/3, coexisting densitometric heterogeneity of the left jugular foramen - partial thrombosis of the left lateral

sinus". Started anticoagulation with Low Molecular Weight Heparin, despite bleeding. At 24h was performed Angio MRI with venoRMN that confirmed de diagnosis and showed favorable evolution. There was a progressive clinical improvement, without complaints on discharge, She kepps maintaining their independence in activities of daily living. Has been accompanied in consultation of Internal Medicine, and is currently asymptomatic. The Study of Prothrombotic conditions, either genetic or acquired thrombophilia, Malignancy, and for inflammatory diseases that can also cause CVT were negative.

Discussion

Although infectious causes of CVT were frequently reported in the past, they are responsible for only 6 to 12 percent of cases in modern-era studies of adults with CVT. Local infections (eg, involving the ears, sinuses, mouth, face, or neck) are typically responsible, although systemic infection is sometimes the only cause. Head injury and mechanical precipitants are less common causes of CVT.

#620 - Case Report

CEREBRAL AMYLOID ANGIOPATHY MIMICKING "TRANSIENT ISCHEMIC ATTACKS"

Carolina Teves Carreiro, Ana Cláudia Furão Rodrigues, Mireille Palmeira, Rui M. Victorino

Hospital de Santa Maria - CHULN, Lisboa, Portugal

Introduction

Cerebral Amyloid Angiopathy is a rare cerebrovascular disease, in which deposition of β -amyloid is found in the media and adventitia of small and mid-sized arteries of the cerebral cortex and leptomeninges. This condition may lead to rapidly progressive dementia, intracranial hemorrhage, or rarely transient neurologic events, although it is often asymptomatic.

Case description

We report a case of a 63 year old man who was admitted to the Hospital Urgency because of a self-limited episodic loss of consciousness. There was a four month history of sudden and transient neurological deficits, namely decreased muscle strength of the left upper limb, dysarthria and blurred vision, associated with subtle new cognitive impairment. The past history included arterial hypertension and septal acute myocardial infarction, two weeks before, on acetylsalicylic acid since then.

On clinical examination, he showed a mild tremor of the left inferior limb in Mingazzini test, without fall, and wide-based gait, with no other alterations. There were no acute findings in CT. He was therefore admitted to Internal Medicine Service, for etiological investigation of recurrent episodes interpreted as transient ischemic attacks.

Cerebral MRI revealed multiple microhemorrhagic foci of peripheral predominance in the right hemisphere, more

pronounced in the cortical and cortical-subcortical frontal regions, as well as in the high left frontal convexity, sparing basal ganglia and brainstem. No evidence of ischemic lesions was found. In conclusion, according to Boston criteria, the imagiological and clinical findings are consistent with the diagnosis of Cerebral Amyloid Angiopathy.

The patient was then followed in outpatients clinic with indication for control of cardiovascular risk factors.

Discussion

This case highlights the importance of considering Amyloid Angiopathy as a differential diagnosis of recurrent transient ischemic attacks, as well as the importance of weighting the risk-benefit of antiaggregation therapy maintenance, in this context considering other comorbidities, because of the high prevalence of hemorrhagic stroke.

#645 - Case Report

THE DIFFICULT DIAGNOSIS OF NEUROSARCOIDOSIS

Karolin Berg¹, Ursula Huber¹, Markus Hofer¹, Sabine Sartoretti-Schefer², Peter E. Ballmer^{1,3}, Eduard Scherer¹

¹ Department of Medicine, Kantonsspital Winterthur, Winterthur, Switzerland

² Department of Radiology, Kantonsspital Winterthur, Winterthur, Switzerland

³ Zürcher RehaZentrum, Davos Clavadel, Switzerland

Introduction

Sarcoidosis is an idiopathic granulomatous multisystem disease with or without involvement of the central nervous system. Neurosarcoidosis occurs in 5-10% of patients of sarcoidosis. A pathological chest X-ray or positive findings in the contrast-enhanced cerebral or spinal MRI is often found. For the definitive diagnosis we need a biopsy with a typical noncaseating granuloma. Neurosarcoidosis is primarily treated with systemic corticosteroids. The second-line treatment includes other immunosuppressive drugs such as methotrexate and infliximab. However, there is no standard recommendation for treatment of refractory neurosarcoidosis.

Case description

A 53-year-old woman was admitted to the hospital because of an episode of vertigo, hypoesthesia in the right arm and leg and a tendency to fall backwards. The general medical examination was normal. A spontaneous nystagmus was revealed on optical Frenzel goggles.

The cerebrospinal fluid revealed increased lactate und protein concentration, a low glucose level and positive oligoclonal bands. Cerebral and spinal MRI showed multiple hyperintense cerebral and nodular meningeal lesions. As differential diagnosis an infectious, a chronic demyelinating, a neoplastic disease or a CNS vasculitis was considered. We found negative liquor

immunoglobulin concentrations for herpes, tuberculosis and borrelia. The FACS analysis was negative and the soluble interleukin-2 receptor was above the reference value. The PET-scan showed multiple active lymph nodes. The biopsy of a paratracheal lymph node revealed single granuloma fragments without necrosis, epithelioid or Langerhans cells. Based on these results, we strongly suspected neurosarcoidosis and a high dose steroid treatment was started, later methotrexate was added.

Discussion

Neurosarcoidosis is a chameleon without pathognomonic clinical symptoms or diagnostic parameters. A definitive diagnosis requires a characteristic clinical picture and a biopsy with histopathological evidence of typical granulomas. Even with nonspecific symptoms, diagnostic tests such as lumbar puncture, contrast-enhanced cerebral and spinal MRI, sIL2-R and PET-Scan can help to diagnose neurosarcoidosis.

It is important to improve more specific diagnostic tools and evidence-based treatments for neurosarcoidosis.

#675 - Case Report

PARANEOPLASTIC NEUROLOGICAL SYNDROME ASSOCIATED WITH ANTI-CV2

Laura Pacho Millan, Marta Parra Navarro, Gabriela Casinos Isart, Paula Fernandez Fernandez, Raquel Aranega Gonzalez, Carlos Lopera Marmol, Montserrat Mauri Plana
Hospital de Mataro, Mataro, Spain

Introduction

Patient of 69 years old, active smoker, with pathological antecedents of COPD, sleep apnea syndrome, a bladder tumor that required transurethral resection (TUR) in 2009 and an incomplete Schatzki ring, that consults for two months of pseudobulbar clinic and toxic syndrome.

Case description

Patient of 69 years, who consults for two months of evolution hiccup with high dysphagia and toxic syndrome, without dysphonia. For a week, he had also non-rotating positional dizziness and progressive drowsiness.

The physical examination revealed a tendency to drowsiness without nystagmus, hypoesthesia in the right hand and dorsum of the foot, unstable gait and positive Dix-Hallpike maneuver to the left.

Tumor markers were performed objectifying positive serum enolase, thoraco-abdominal CT and PET-SCAN without evidence of neoformation, lumbar puncture, serial urine cytologies and cystoscopy without evidence of neoplasia. Given these findings, a neurological paraneoplastic syndrome (SNP) was suspected without evidence of active neoplasia.

Systemic corticotherapy was started at a dose of 1 mg / kg / day and subsequently intravenous immunoglobulins and rituximab with improvement of the pseudobulbar clinic.

During admission, the patient presented hyponatremia secondary to SIADH. The patient was discharged following controls in outpatient clinics of Internal Medicine.

Six months later, a control CT scan was performed that showed an anterior mediastinum mass of 69 mm. Therefore, a new PET-SCAN with hypermetabolic activity of this tumor mass was performed. Finally, a mediastinal biopsy was performed by video-assisted thoracoscopy of the lesion obtaining small cell lung cancer as a primary tumor as the definitive diagnosis.

Discussion

A paraneoplastic syndrome associated with onconeurological antibodies CV2 is a very rare condition. Sometimes the symptoms begin before the appearance of the evidence of an active neoformation as in this case.

The clue in this patient for the diagnosis of the paraneoplastic syndrome was the founding of a SIADH, condition that is frequently related in some tumors, like small cell lung cancer.

It is important to suspect a paraneoplastic syndrome associated with anti-CV2 in patients with bulbar symptoms as dysphagia and drowsiness like this patient and antecedents like active smoking. Also it is important to follow out this patients in outpatient clinics to do an early diagnosis of the possible underlying neoplasia.

#686 - Case Report

FLUCTUATING LEVEL OF CONSCIOUSNESS

María De Los Ángeles Gallardo, Cristina Lojo
Hospital Universitario Virgen de Valme, Sevilla, Spain

Introduction

A 70-year-old male with DM 2 and factor V Leiden heterozygosis carrier (previously two episodes of DVT) anticoagulated with Acenocoumarol was admitted for subacute behavioral disorder that progressively associates altered level of consciousness.

Case description

In Emergency Service he was confused, disoriented and presented fever of 38°C. TAC cranial without findings. Analytically shows PCR > 400, CK elevation and hypertransaminasemia. Lumbar puncture was performed with 9 leukocytes and discrete hyperproteinorrachia. He presents progressive worsening of consciousness level with respiratory failure, requiring intubation and admission to the ICU.

In ICU he has fluctuations of consciousness level with generalized tonic-clonic seizures and clones of right extremities. EEG compatible with moderate grade encephalopathy. Phenytoin is started with poor control requiring associating levetiracetam. Serologies and peripheral blood cultures were negative. Cranial MRI was compatible with diffuse pachymeningitis related to cerebral hypotension secondary to lumbar puncture.

Autoimmune encephalitis is suspected, initiating methylprednisolone boluses. New lumbar puncture with autoimmunity study was negative with Protein 14-3-3 positive

in cerebrospinal fluid (CSF). New EEG with periodic lateralized epileptiform complexes (PLEDS) of short interval. The results of new EEG and the positivity of the protein 14-3-3 in CSF with the symptoms are highly suggestive of Creutzfeldt-Jacob disease.

Discussion

In Creutzfeldt-Jacob disease (CJD), rapidly progressive mental deterioration and myoclonus are the cardinal clinical manifestations. Most of the cases are sporadic. The average age for onset is between 57-62 years and there is no gender predilection. The finding of periodic acute wave complexes in the EEG has a high specificity for diagnosis, as well as the 14-3-3 protein test in CSF. Brain biopsy is the gold standard test, but a typical clinical presentation with findings that corroborate MRI, EEG and CSF is sufficient to exclude other causes and establish it as a probable diagnosis.

#687 - Case Report

SUBACUTE MUSCLE WEAKNESS

María De Los Ángeles Gallardo, Cristina Lojo

Hospital Universitario Virgen de Valme, Sevilla, Spain

Introduction

A 45-year-old male with active smoking (60 pack-year) and drinking habits (40 grams of alcohol a day). He was admitted due to myositis of the lower right limb, two years ago. Analytically there was a CPK elevation with muscle weakness. No follow-up. Not usual treatment.

Case description

Now, he presents progressive muscle weakness of two months of evolution, beginning in lower limbs. Associates anorexia, vomiting and weight loss. In addition, he has predominantly proximal weakness with inability to elevate the members counter-resistance, claudication within a few seconds. Analysis shows a hyponatremia of 117, CPK of 12476, increase of transaminases and INR 1.42.

During admission, he presents progressive worsening, appearing: dysphagia, dysphonia, hypoesthesia and hypoactive ROT. Cranial CT without findings. Lumbar puncture without albuminocytological dissociation. Levels of IgA 226. Electromyogram shows axonal motor polyneuropathy. Later, respiratory failure appears, requiring noninvasive mechanical ventilation and treatment with methylprednisolone (1g bolus) and immunoglobulins. Despite this, poor evolution, requiring intubation and admission to the ICU. CT chest and abdomen scan shows bilateral alveolar condensations; signs of abdominal generalized hypoperfusion with mild ascites; without neoplastic signs. Antibiotic therapy with meropenem and vancomycin was initiated. He remains with hemodynamic instability, lactic acidosis and hepatic failure with coagulopathy. Finally, he died from respiratory septic shock and acute liver failure. The autopsy shows bilateral pneumonia and congested liver. The nerve biopsy is compatible with necrotizing myopathy.

Discussion

The origin of necrotizing myositis is toxic, paraneoplastic or autoimmune. The cases associated with statins persist despite the suspension of the drug. Paraneoplastic myopathy is characterized by a rapidly progressive, symmetric and proximal weakness with severe disability. It is associated with lung, breast and gastrointestinal tract cancers. Antibodies against the particle recognition signal (SRP) and 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) have been found in 2/3 of patients. The absence of antibodies or the presence of HMGCR antibodies seems to confer an increased risk of cancer. The active search for neoplasia is indicated. Corticosteroids combined with other immunosuppressive therapies and the treatment of neoplasia could improve neurological symptoms. Patients with cancer have worse results.

#742 - Medical Image

ANTERIOR MEDIASTINAL MASS PRESENTING AS MYASTHENIA GRAVIS WITH SIGNS OF IRRITATIVE MYOPATHY

Marília Santos Santos Silva, Raquel Rocha, João Martins, Paulo Ricardo Pereira

Hospital Pedro Hispano - Matosinhos Local Health Unit, Matosinhos, Portugal

Clinical summary

A 43 year-old man presented to the emergency department with a four-month progressive evolution of dysarthria, dysphagia, eyelid ptosis and diplopia with afternoon exacerbation. Marked eyelid fatigability was noted on repetitive eye closure. Anti-acetylcholine receptor antibodies were positive while anti-MuSK and LRP4 were both negative. Electromyography demonstrated a decremental response to nerve stimulation and signs of irritative myopathy, a rare but possible finding in Myasthenia Gravis. Symptoms resolved after pyridostigmine and prednisolone initiation. Computed tomography uncovered a heterogeneous anterior mediastinal mass suggestive of thymic carcinoma, that was excised and revealed a type A thymoma on histology. The patient remains asymptomatic 15 months after treatment suspension.

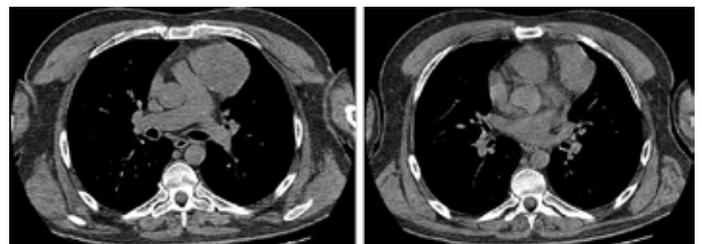

Figure #742. Anterior mediastinal mass - thymoma.

#792 - Abstract

ANALYSIS OF TRIGGERING FACTORS AND MORTALITY PREDICTORS IN A COHORT OF PATIENTS ADMITTED WITH NOT CONVULSIVE STATUS IN AN INTERNAL MEDICINE DEPARTMENT

Lucía Barrera López¹, Alba García Villafranca¹, Ignacio Novo Veleiro¹, Marta Pose Bar², Emilio Manuel Páez Guillán¹, Jonathan Geovany Montoya Valdés¹, Ana Teresa Marques Afonso¹, Néstor Vázquez Agra¹

¹ Internal Medicine Department, University Hospital of Santiago de Compostela, Santiago De Compostela, Spain

² Department of Medicine, Faculty of Medicine and Odontology, University of Santiago de Compostela, Santiago De Compostela, Spain

Background

The non-convulsive status epilepticus (NCSE) is characterized by the association of abnormal electroencephalographic (EEG) activity and subclinical epileptic crisis. It constitutes around 20-30% of the total cases of status epilepticus. Its multiple etiology, variable clinical presentation and the absence of a standardized diagnostic algorithm, makes it difficult to be recognized. The treatment is based on the use of benzodiazepines, antiseizure drugs and general anesthetics. Despite a correct management, NCSE is linked to a high morbidity and mortality and an uncertain prognosis. In this work we aim to characterize the patient diagnosed with NCSE during admission to an Internal Medicine department, as well as to perform an analysis of the potential relationship between clinical-analytical disturbances and the evolution of the status. We also carried out an assessment of the compliance with current recommendations regarding the management of NCSE.

Methods

Cross-sectional observational epidemiological study. All patients diagnosed with NSCE admitted to the Internal Medicine department of the Santiago de Compostela's area between the years 2010 and 2016 were included. Data were analyzed through basic descriptive statistics and univariate analysis.

Results

The sample size was 40 patients (62.5% women) with an average age of 75.86±13.69 years. The most prevalent comorbidity was hypertension (60.55%), followed by chronic kidney disease (51.4%). The most frequent diagnosis at admission was respiratory infection. In 84.2% of patients a brain CT was performed, showing significant alterations in 10.5% of them. At admission, 35% of patients presented changes in the level of consciousness (coma: 3.5%). Focal neurological findings were found in 12.5% of cases. The most used treatment was levetiracetam (71.1%). The use of benzodiazepines was associated with a greater survival, although only a 6.8% of patients were treated with them. None of the patients transferred to the ICU died. During hospital stay, 14 patients died (36.8%). The parameters with a significant higher

frequency in died patients group were hypertension, renal failure, arrhythmias, neuropathy, stroke and levetiracetam treatment.

Conclusion

The NCSE was diagnosed more as a complication than as a reason for admission itself. We found a significant in prognosis regarding the selected treatment, favoring benzodiazepines, despite its low use. The mortality reached the 36.8% and the grade of compliance with current recommendations was low.

VARICELLA ZOSTER VIRUS VASCULOPATHY PRESENTING AS MULTIFOCAL CEREBRAL INFARCTION AND CAROTID ARTERY DISSECTION.

Gregory Offiah, Aine Gorman, Ausaf Mohammad
Midlands Regional Hospital Tullamore, Offaly, Ireland

Introduction

Varicella zoster virus (VZV) can present as a primary or a reactivated latent infection. Rarely, it may reactivate and manifest as vasculopathy.

Case description

A 62-year-old immunocompetent male was admitted with a two-day history of intermittent headache, confusion and fever. Romberg's test was positive, but physical examination was otherwise unremarkable. There was no evidence of a rash. Computed tomography (CT) and magnetic resonance imaging (MRI) of the brain showed non-specific white matter changes in the frontal and occipital lobes. Lumbar puncture revealed a lymphocytic pleocytosis. VZV encephalitis was confirmed by VZV polymerase chain reaction and VZV IgM. He was treated with 21 days of acyclovir.

After initiation of treatment, he complained of diplopia and a right fourth cranial nerve palsy was noted. MRI brain excluded cerebral infarction. One week later, he developed transient left sided paraesthesia. Repeat MRI brain confirmed a subacute lacunar infarct in the right posterolateral thalamus. He was started on methylprednisolone and high dose aspirin. A follow-up MRI brain and angiogram one week later revealed a left internal carotid artery dissection and new right frontal and left anterior thalamic infarcts. He subsequently developed chest pain. CT angiogram confirmed pulmonary embolism. He was treated with a prolonged course of antivirals and steroids for VZV vasculopathy.

Discussion

Greater than 95% of the world's population carry latent VZV with 50% experiencing reactivation. One third of patients with VZV vasculopathy will not present with a rash². It is important to consider VZV in immunocompromised patients presenting with cerebral infarction.

CEREBRAL AMYLOID ANGIOPATHY - A RARE CAUSE OF DEMENTIA

Leonor Naia, Tiago Rabadão, Carlos Rodrigues, Joana Pires, Margarida Eulálio, João Fonseca, Clarinda Neves, Rosa Jorge
Baixo Vouga Hospital Center - Internal Medicine Department, Aveiro, Portugal

Introduction

Cerebral amyloid angiopathy (CAA) is characterized by the accumulation of amyloid substance in small and medium-sized cerebral vessels. Usually asymptomatic, it predisposes to an increased risk of intracranial hemorrhagic events, although ischemic events may also occur. The progressive vascular fragility is responsible for its recurrent and chronic nature.

Case description

Woman, 74 years old, independent in daily life activities, admitted to the Emergency Department for holocranial headache with frontotemporal predominance and short-term memory impairment with 4 months of evolution. Medical history of arterial hypertension, dyslipidemia and hyperuricemia; Medication: omeprazole, olmesartan and atorvastatin. Physical examination: hypertensive (BP 219/96 mmHg), time and space-oriented, with short-term memory impairment and attention deficit, without other neurological deficits. The remaining examination was normal. Cranioencephalic CT scan evidenced numerous infiltrative hypodense areas of the white matter, corresponding to vasogenic edema with bilateral temporo-basal localization, with occipitoparietal and posterior temporal extension. Magnetic resonance imaging (MRI) showed signs of leukoencephalopathy with surrounding edema and multiple supratentorial superficial hemorrhagic lesions, compatible with amyloid angiopathy. The remaining study revealed: hypercholesterolemia (total cholesterol 211 mg/dL and LDL cholesterol 156 mg/dL); 12-lead ECG with sinus rhythm; carotid ultrasound imaging with bilateral carotid atheromatosis, without significant stenosis. During hospitalization, the antihypertensive therapy was optimized, resulting in the normalization of the tension profile and statin treatment was continued. At discharge, the patient maintained short-term memory impairment. The remaining study did not allow to identify other causes for the MRI findings. Given the age at the diagnosis and the exuberance of the lesions, a genetic study (apoE gene) was requested, still awaiting result.

Discussion

CAA is associated with progressive neurological compromise. According to the Boston criteria and given the absence of histopathological confirmation, a "probable" diagnosis of cerebral amyloid angiopathy was admitted. Considering that no treatment is available for CAA and the risk of intracranial hemorrhage, arterial pressure must be controlled and antithrombotic therapy should be avoided. The risks/benefits of statins are still controversial and poorly understood.

POSTERIOR CIRCULATION STROKE: TAKE A HINTS!

Cláudia Oliveira Diogo, Tiago Pais, Ana Ponciano, Bruno Cabreiro, Catarina Faria, Joana Leite, José Leite, Célio Fernandes
Department of Internal Medicine, Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

The main manifestations of impairment of the vestibular system, especially in the acute phase, are dizziness and vertigo. However, the difference between benign peripheral and central causes of vertigo such as stroke remains a clinical challenge. The HINTS exam was developed as a means of assessing patients with the acute vestibular syndrome and consists of three tests: the head impulse (HI) test, characterization of spontaneous nystagmus (N), and test of skew (TS). It is useful to differentiate peripheral and central vertigo and has been shown to have greater sensitivity than neuroimaging in ruling out stroke in patients presenting with acute vertigo.

Case description

We present a case of a 47-year-old otherwise healthy male presented in the emergency department with acute migraine without aura lasting for 9 hours and associated dizziness. Vital signs were stable and clinical examination was unremarkable. Brain computed tomography (CT) did not reveal acute lesions and the patient was diagnosed with peripheral vestibular syndrome. While under observation, he started complaining of nausea, changes in vocal tone and vertigo with imbalance to the left side. He had high blood pressure (BP 151 / 82mmHg) and the monitor showed a heart rate of 73bpm with sinus rhythm. Neurological exam revealed a dysphonia, and a positive Romberg test. Despite being symptomatic, a HINTS test was performed and was positive for skew deviation and non-fatigable bidirectional horizontal nystagmus. Head impulse was difficult to interpret due to lack of patient collaboration. CT Angio showed a foetal emergence of the right posterior cerebral artery and hypoplasia of the left vertebral artery and magnetic resonance of the brain confirmed posterior circulation ischemic stroke.

Discussion

Posterior circulation stroke remains a clinical challenge especially in the acute setting. The HINTS test is quick, non-invasive and can be performed at bedside. Evidence seems to support this test as reliable and effective in differentiating between posterior fossa stroke from peripheral vestibular causes. The presence of one of these subtle oculomotor signs is more sensitive than the combined presence of all other traditional neurological signs to identify stroke as a cause of acute vestibular syndrome. The test provides a clinical tool essential to improve accuracy in diagnosis in emergency setting, making patients eligible for reperfusion therapy and avoiding complications of stroke.

#846 - Case Report

NEUROLOGICAL MANIFESTATIONS OF PRIMARY SJOGREN'S SYNDROME: A CASE OF MONONEURITIS MULTIPLEX

Andreia Freitas, Nuno Leal, Sara Beça, Filipa Borges

Centro Hospitalar Vila Nova de Gaia/Espinho, Vila Nova De Gaia, Portugal

Introduction

Sjogren's syndrome is a systemic autoimmune disease that may affect every organ and system. The involvement of the peripheral nervous system can result in a wide spectrum of neuropathic manifestations. Mononeuritis Multiplex is a rare form of neuropathy characterized by sensory and/or motor deficits in the distribution of an area innervated by individual nerves; pain is common and constitutional symptoms and systemic manifestations of palpable purpura may be present.

Case description

A 71-year-old woman with Sjogren's syndrome began to experience pain in her lower limbs and paresthesias involving the plantar face of the right foot and the 4th and 5th fingers of the right hand. A few days later, purpuric lesions emerged in the lower limbs and paresthesias spread, involving all the right hand with associated pain and paresis. The neurological findings at the emergency service included weakness of the muscles innervated by the right ulnar, medial and radial nerves, and hypoesthesia of the muscles innervated by the sural nerve, bilaterally; the right stilorradial reflex was diminished and both aquilian reflexes were abolished. Petechial lesions were also observed in both legs. Given the severity of the neurological involvement and the patient's personal history, she was admitted to an internal medicine ward. Analytically, the patient presented negative rheumatoid factor, cryoglobulins and serum immunofixation, and normal complement. Thoraco-abdomino-pelvic Computerized Tomography did not show adenopathies. Nerve conduction study was compatible with mononeuritis multiplex. The patient started treatment with 1g/day methylprednisolone at admission and for 3 days, which was switch afterwards to 60mg/day prednisolone. No biopsy of both nerves and muscle was performed because its doubtful utility. The petechial lesions disappeared and symptomatic improvement was obtained. At time of discharge, the patient presented only decreased wrist flexion and manual dexterity of the right superior limb.

Discussion

Peripheral nerve vasculitis appears to underlie mononeuritis multiplex: inflammatory infiltration of the vessel walls leads to endothelial cell destruction with fibrinoid necrosis, vessel lumen occlusion and ischemia. Prompt immunosuppressive treatment is required to prevent permanent axonal degeneration. Aggressive therapy with steroids and immunosuppressive agents (i.e. cyclophosphamide) may be required; however, even combined therapy does not always yield satisfactory therapeutic results.

FAHR'S DISEASE: A CLINICAL CASE

André Matos Gonçalves, Marisa Roldão, Ana Rita Sanches, Sónia

Cunha Martins, Isabel Ambrósio, Margarida Sousa Carvalho

Centro Hospitalar Médio Tejo, Torres Novas, Portugal

Introduction

Familial Idiopathic Basal Ganglia Calcification (FIBGC) also known as Fahr's Disease, is a rare neurodegenerative disease, genetically inherited or sporadic, characterized by abnormal quantities of calcium deposits in the basal ganglia and cerebral cortex. The disease usually manifests itself in the asymptomatic form through the presence of neurological symptoms: progressive deterioration of the cognitive function, changes in the motor functions and speech, muscle cramping, athetosis, chorea, dystonia, ataxia, seizures, and headaches. The diagnosis, although difficult, is based on clinical, analytic (hypocalcemia), and imaging (calcification of the basal ganglia) elements.

Case description

Next it is described the case of a male, 56 years old, autonomous, with prior history of heart failure, benign prostatic hyperplasia, depressive syndrome, history of acute myocardial infarction, and family history of consanguinity. Patient is being followed by Neurology since 02/2019, from where he has been referred for slow gait, involuntary movements of the upper limbs, and memory loss when performing the activities of daily life. Additionally, presented hypocalcemia in a previous analytic study along as an "exuberant basal-basal calcifications and bilateral tachyma (...) probable Fahr's disease" in a previous brain CT scan. During the neurological examination the patient presented a facial amelioration, slow gait, broad base and stiffness on four limbs, with dystonic movements of the lower limbs. A Brain MRI imaging complementary study was performed which confirmed the brain CT scan results. Analytical study also confirmed hypoparathyroidism with hypocalcaemia. In 03/2019 the patient was admitted in Internal Medicine service, where a new analytical study confirmed the previous results. A genetic test (SLC20A2) was performed and awaits results. The patient initiated the calcium replacement with analytical improvement, being maintained as an outpatient. A follow-up is maintained at Neurology and Internal Medicine consultation.

Discussion

Fahr's disease is a rare neurodegenerative disease, which can range from asymptomatic to the presence of nonspecific neurological symptoms. These characteristics contribute to a difficult diagnosis. The recommended treatment consists of calcium replacement. However, such treatment contributes to a deterioration of the cognitive and neurological state, through the progressive deposition of calcium in the cerebral cortex. Therefore, the prognosis is reserved.

#885 - Case Report

BENDAMUSTINE ENCEPHALOPATHY, A RARE ADVERSE EFFECT

Carolina Amado, Mariana Silva Leal, Tiago Valente, Ana Rocha Oliveira, Marcelo Aveiro, Margarida Cruz
Centro Hospitalar Baixo Vouga, Aveiro, Portugal

Introduction

Bendamustine is a chemotherapy agent used in the treatment of non-Hodgkin's lymphoma as a rescue therapy. Known adverse effects are mainly hematologic and gastrointestinal, although there are few reports of neurological toxicity.

The authors present a case of neurotoxicity after bendamustine-rituximab (BR) treatment.

Case description

A 79-year-old man with follicular lymphoma with diffuse large B-cell lymphoma transformation (R-IPI 2, FLIPI 2, Bulky disease) underwent 8 cycles of R-CHOP. Once he presented partial remission, it was followed by 6 BR cycles and 1 cycle of rituximab. After 2 months, the patient presented to our hospital with asthenia, apathy and periodic disorientation, being observed by Psychiatry and assumed reactive depression. Symptomatology got worsened, and the patient was hospitalized. He denied fever or any other symptoms. There was no history of alcohol, tobacco or drugs consumption, nor other relevant medical past history. Physical examination revealed a conscious but slowed down and inattentive patient, without other relevant signs. Blood analysis showed no elevated inflammatory parameters, ionic disturbances or thyroid function alterations; B12 and folate levels were normal; HIV and syphilis serology and auto-immunity study were negative. Cerebrospinal fluid (CSF) analysis were negative and showed no lymphoma or infectious aetiology (bacteria, Herpes simplex 1 and 2 virus, Human herpesvirus 6, John Cunningham virus, Epstein-Barr virus, Cytomegalovirus, Toxoplasma gondii and fungi); serum and CSF anti-neuronal antibodies were negative. Head CT and MRI showed no significant alterations and EEG was compatible with moderate encephalopathy. Thoracic-abdomen-pelvic CT presented stable disease. One month later head MRI, EEG and CSF evaluation were repeated with overlapping results. In light of negative findings from the wide investigation performed, and time causality, it was assumed a severe neurologic sequelae secondary to bendamustine use, enhanced by rituximab. Despite treatment with intravenous steroids and immunoglobulin, the patient died.

Discussion

Bendamustine is generally well-tolerated, although it can cause progressive weakness and encephalopathy. Rituximab is often a cause of chronic encephalopathy and can be considered as an enhancer.

Early drug discontinuation is the first step, but the outcome is variable. Further studies are needed to clarify toxicity mechanisms and rare adverse effects reports are essential to alert physicians to their possibility.

#900 - Abstract

ACUTE ISCHEMIC STROKE IN PATIENTS WITH AND WITHOUT DIABETES MELLITUS

Palmyra Tsiftsi¹, Christina Kotsiari¹, Dimitrios Tsiolpidis¹, Asimina Migdalia¹, Chasan Ali¹, Savvas Katsaridis², Berkay Mollagiousoufoglou¹, Vasilios Tsipizidis¹, Argyrios Tsatsakoulis¹, Theodoros Kostakis¹, Elisavet Makridou¹, Paschalis Karagiozakis¹, Triada Exiara¹

¹ General Hospital of Komotini, Komotini, Greece

² Alexander Technological Educational Institution of Thessaloniki Department of Nutrition and Dietetics, Thessaloniki, Greece

Background

Diabetes mellitus (DM) is a well-established independent risk factor for acute ischemic stroke (AIS). The aim of this study was to identify and compare distinctive patterns between diabetic and non-diabetic population with AIS.

Methods

358 consecutive patients with AIS, who admitted to our hospital during last three years, were studied. Clinical, laboratory and demographical data, risk factors and outcome registered and analyzed. SPSS 20 package was used for statistical analysis.

Results

71(19.8%) patients were diabetic and 287(80.2%) were non-diabetic. The mean age of patients with and without diabetes was 61.4 ± 10.1 vs. 64.2 ± 11.2 , $p=0.034$, respectively. There was no difference between the two populations in the sex ratio. Risk factors in diabetic and non-diabetic population were: hypertension 51 (71.8%) vs 168 (58.5%), $p=0.037$, ischemic heart disease 16 (22.5%) vs 35 (12.2%), $p=0.028$, valvular heart disease 4 (5.6%) vs. 41 (14.3%), $p=0.035$, atrial fibrillation 4 (5.6%) vs. (12.5%), $p=0.048$, renal dysfunction 14 (19.7%) vs. 30 (10.5%), $p=0.022$, previous cerebral infarct 18 (25.4%) vs. 44 (15.3%), $p=0.043$, respectively. The lipidemic profile in diabetic and non-diabetic population was: high density lipoprotein cholesterol (HDL) 36.7 ± 11.4 vs. 51.3 ± 5.4 , $p < 0.001$, low density lipoprotein cholesterol (LDL) 105.3 ± 30.5 vs. 103.7 ± 27.9 , $p=0.83$, triglycerides (TG) 218.3 ± 66.4 vs. 151.3 ± 61.5 , $p < 0.001$, respectively. Complications during the hospital stay were higher in patients with DM. In-hospital outcome, mortality was higher in diabetic patients, 15(21.1%) vs. 35(12.2%), $p=0.045$, respectively.

Conclusion

Patients with DM had higher risk burden for AIS and poorer hospital outcome than non-diabetic patients. Successful control of diabetes and other risk factors is the key to prevent AIS.

#927 - Case Report

SPINAL CORD INFARCTION – ABOUT A CASE REPORT

Marta Dalila Martins, Hugo Pinheiro, Inês Ferreira, João Rocha, Mari Mesquita

Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal

Introduction

Spinal Cord Infarcts are rare and can vary in onset, severity and outcome. The onset of spinal cord infarction is typically abrupt and the consequences are frequently disabling, being largely defined by the vascular territory involved.

Case description

Female, 95 years old and autonomous, with history of hypertension, type 2 diabetes mellitus and anemia. Admitted for study after sudden onset of motor deficits. On the previous day, the patient resorted to the Emergency Service with back pain with anterior bilateral irradiation and supraventricular tachycardia. After adenosine and bisoprolol administration, she returned to sinus rhythm and was discharged. Upon admission, the neurological examination showed mild dysarthria, distal deficits of the upper limbs and absent osteotendinous reflexes other than C5 and C6. Muscular strength in the left lower limb grade 2 and right lower limb grade 3-4, absent osteotendinous reflexes, without urinary retention and with a positive bilateral Babinski sign. Analytically with microcytic anemia and mild renal dysfunction. Brain computed tomography showed incipient signs of atherosclerotic microangiopathic subcortical leukoencephalopathy and discrete bilateral lenticulocapsular lacunar infarcts and non-recent ischemic infarction in the left cerebellar hemisphere. Cervical CT showed degenerative alterations insufficient to justify the clinical presentation. Lumbar puncture was performed and cerebrospinal fluid analysis allowed the exclusion of an infectious etiology of the central nervous system and of Guillain-Barré syndrome. A cervico-dorsal magnetic resonance imaging was then performed, which showed an extensive medullary hyperintense lesion, extending from C6 to D4, presenting central predominance, causing mild spinal expansion. The lesion also presented discrete nodular heterogeneous enhancement. Two diagnostic hypotheses were raised: spinal cord infarction versus longitudinally extensive transverse myelitis. The immunological study was normal with negative anti-neuronal antibodies and aquaporin 4 antibodies favoring the diagnosis of spinal cord infarction.

Discussion

Spinal cord infarction is a rare but often devastating disorder. Patients typically present with acute paraparesis or quadriplegia, depending on the level of the spinal cord involved. Back or neck pain is often present, typically occurring at the level of the lesion. The diagnosis is generally made clinically, with neuroimaging to confirm the diagnosis and exclude other conditions.

#951 - Case Report

VERTIGO: COMMON SYMPTOM, CHALLENGING DIAGNOSIS

Estela Ferrão, Francisca Pulido Valente, Rodrigo Pereira Andrade, Maria José Grade, Luísa Arez

Algarve University Hospital Center; Hospital de Portimão, Department of Internal Medicine, Portimão, Portugal

Introduction

Vertigo and unbalance are common symptoms, responsible for about 3% of the emergency room (ER) visits. Although the majority of their causes are benign, they can represent life threatening situations. About 10% of the cerebellar stroke patients only show vertigo symptoms and the posterior circulation stroke is twice more missed than the anterior one.

Case description

A 67-years-old healthy man, presents to the ER with a sudden onset complaint of vertigo when waking up, imbalance while standing, unsteady walking, nausea, vomiting and occipital headache. The symptoms were worsened by head movement.

He was discharged without being observed by an Internal Medicine specialist, medicated with metoclopramide and betahistine but returned 2 days later, keeping the same clinical picture.

Physical exam: BP 179/117 mmHg. Horizontal right beating nystagmus, not fatigable. Romberg test with preferential leftward fall, ataxic gait, left lateropulsion with gait.

Head CT: without alterations.

ENT observation: Vertigo Syndrome suspicious of a central disorder.

He was admitted with a diagnosis of posterior ischemic stroke, starting therapeutic approach accordingly. Initially he was not able to get out of bed and had a very slow improvement of his disabling symptoms during the hospital stay.

Additional investigation was performed including head MRI, serologies, audiometry and tympanometry, acoustic reflex test, ENT and Neurology observations. Finally, a diagnosis of left vestibular neuritis was made and the patient was discharged with a vestibular rehabilitation program.

Discussion

This case highlights the importance of the Internal Medicine Specialty and its holistic approach to the patient, and also the difficulties when evaluating a patient with complaints of vertigo and dizziness.

Because of the associated high morbidity and mortality, it is crucial to rule-out a stroke in the first place.

Since the imaging tests are not always available or reliable, it is suggested to perform simple tests such as HINTS TEST in the ER setting, to distinguish a peripheral cause from a central cause with a high degree of certainty, in a patient presenting with an acute vestibular syndrome.

The case also emphasizes that even if a preliminary diagnosis is made in the ER, the hospitalized patient should be carefully and

systematically evaluated, because in a high number of cases it may not correspond to the definitive one.

#972 - Case Report

A 78-YEAR-OLD MAN WITH HEADACHE

Flávio Moniz Mendonça, Marina Raquel Santos, [Ana Margarida Temtem](#)

Hospital Central do Funchal, Funchal, Portugal

Introduction

Headache is one of the most common pain symptoms and a frequent cause for doctor visits. A sudden and intense headache can suggest a diagnosis potentially severe more than a recurrent headache. The International Headache Society classifies headache in primary or secondary. Hypnic headache is a rare headache syndrome that may occur either as a primary headache or as a headache secondary to potentially malignant processes. The cause of hypnic headache is not understood. While hypnic headache is rare, the actual incidence and prevalence are unknown.

Case description

The patient is a 78-year-old Caucasian male who presented to an emergency room complaining of a sudden headache that developed only during sleep and causing awakening for minutes to an hour. The patient did not have other symptoms either before or during the event as migrainous symptoms. A careful medical and drug history revealed a known coronary disease approximately for 10 years and had undergone with felodipine/metoprolol, acetylsalicylic acid and simvastatin at that time. There was no allergy history to any drugs. Clinical examination was normal. Highlight the neurological examination did not reveal any change just a probable polyneuropathy from the lower extremities. The patient's laboratory values were normal. Computed tomography of the brain did not show tumors or other lesions, injuries, intracranial bleeding, structural anomalies, infections or other conditions. This case was discussed with neurology, they suggested that was compatible with a hypnic headache. It was prescribed flunarizine and indomethacin once a day, before sleep.

Discussion

This patient's case demonstrates the fundamental importance of the differential diagnosis. An acute, sudden headache can reveal an aneurysm, brain hemorrhage, acute glaucoma, meningitis or even an initial manifestation of a persistent headache as hypnic headache, a rare syndrome headache. This communication is especially important to keep in mind the variety of cases we have to handle in the emergency room.

DOUBLE DISSECTION

Elsa Araújo, [Manuel Barbosa](#), Raquel Costa, Tiago Mendes, Bárbara Sousa, Helena Vilaça

Unidade Local de Saúde do Alto Minho, Viana Do Castelo, Portugal

Introduction

Spontaneous dissection is an important cause of stroke, particularly in young adults.

Neurologic sequelae may result from cerebral ischemia due to thromboembolism, hypoperfusion, or a combination of both.

Common causes include various degrees of trauma or spontaneous events. The proportion of patients with spontaneous artery dissection who are affected by a known connective tissue or vascular disorder is low.

Case description

A 42 year-old female with no pathological history of relevance was transported to the emergency department with impaired speech and strength deficit on the right side of her body. Neurologic examination revealed mutism, conjugate deviation of the left eye, right homonymous hemianopsia, right central facial paresis and right hemiparesis. The brain computed tomography (CT) with no evidence of injury, however, was not performed thrombolysis for being outside the window time. A cerebral CT angiography showed a cervical artery dissection with distal embolization of the M1 segment of the left middle cerebral artery. The patient was transferred to another hospital for an endovascular procedure which underwent successfully.

Etiological investigation was performed during the course of her hospital stay. The patient presented positive rheumatoid factor, antinuclear antibodies and anti-SSA antibodies. After consultation with rheumatology, a primary Sjogren's syndrome (SS) was considered as the most likely diagnose.

Approximately 8 months after the ischemic event, imaging was reassessed with cerebral CT angiography and it documented ectasia of the cervical segment of the right internal carotid artery, aspect, probably resulting from dissection. A diagnostic cerebral angiography was performed and confirmed chronic bilateral carotid dissection.

The patient evolved well under physical therapy, with complete recovery of the motor and language deficits.

Discussion

The patient had a chronic bilateral carotid dissection in which we could not identify any reason for arterial dissection in our patient except for SS. The occurrence of central nervous system (CNS) disorders in association with SS is considered to be rare and the actual prevalence of CNS involvement with SS is unknown. For this reason and because the possibility of recurrence, this patients must be followed closely, in an individualized approach, paying special attention to new signs of disease activity.

MYASTHENIA GRAVIS: AN UNEXPECTED DIAGNOSIS

Palmyra Tsiftsi, Dimitrios Tsiolpidis, Christina Kotsiari, Asimina Migdalia, Chasan Ali, Vasilios Tsipizidis, Bilal Bilal, Argyro Boutali, Paris Poursanidis, Triada Exiara

General Kospital of Komotini, Komotini, Greece

Introduction

Myasthenia gravis (MG) is a rare autoimmune neuromuscular disease characterized by fluctuating weakness of certain voluntary muscles rarely involving the respiratory muscles.

Case description

A 77-year-old female with medical history of hypertension well controlled with furosemide and irbesartan and diabetes mellitus type 2 with metformin, was admitted to our hospital with a three-month history of dyspnea on exertion which had progressed at rest. Drugs or trauma that could ventilatory failure was ruled out. The physical and neurological examination and cerebrospinal fluid analysis were normal. Laboratory evaluation and chest X-ray were normal. There was no evidence of pulmonary thromboembolism on the chest CT scan and no evidence of intracardiac shunting or congestive heart failure on the echocardiography. Cardiac brain natriuretic peptide and the pulmonary function tests were normal. Urine legionella antigen, HIV antibody, ANA titer, hypersensitivity panel and fungal serologies were all negative. The patient's dyspnea resolved with rest and supplemental oxygen. The patient was discharged, but re-admitted in three weeks with recurrence of her symptoms. Due to the fact that her symptoms were relieved at rest and fluctuating, a neurologic etiology was considered. Anti-MuSK antibody level was found to be elevated at 27 nM and she was started prednisone and pyridostigmine with good response to her symptoms. One year later she was asymptomatic.

Discussion

It is important to consider neurological causes when dyspnea is unexplained by cardiac and respiratory causes. Patients with positive Anti-MuSK antibody, have higher risk of respiratory failure, but respiratory failure as the initial presenting symptom is unusual.

#1076 - Abstract

MEAN PLATELET VOLUME IN ACUTE ISCHEMIC STROKE IS NOT ASSOCIATED WITH EARLY OUTCOME

Ana Silva Rocha, Filipa Leal, Luís Nogueira, Anabela Silva, Vitor Fagundes, André Paupério, Juliana Lopes, Helena Vilaça, Mari Mesquita

Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal

Background

Ischemic stroke (IS) is one of the major causes of death and disability in the developed world. Platelets respond rapidly to

vascular injury and larger platelets aggregate more easily. Thus, mean platelet volume (MPV) is a marker of platelet reactivity. MPV and platelet count (PC) are inversely associated so that the total platelet mass remains constant. Some studies have demonstrated an association between IS and MPV. However, its correlation with IS severity or functional outcome has not been established yet.

The objective of this study was to assess whether high MPV was associated with early outcome and hospital mortality in acute IS.

Methods

Observational and retrospective study. Clinical data from hospitalised patients with the diagnosis of IS during the year of 2017 was collected. Demographic information, presence of cardiovascular risk factors (CVRF), functional status and a complete blood count (CBC) on admission were assessed. IS was classified according to TOAST classification and IS severity was assessed by NIHSS on admission. MPV was measured using an automated analyser. Functional outcome was classified according to mRankin scale at discharge.

We defined the following exclusion criteria: thrombocytopenia, medication that could affect PC, known disorders of the platelets, peripheral smear with platelet aggregates and no CBC available at admission. SPSS software was used for data analysis.

Results

Our analysis included 113 patients. PC was inversely associated with MPV ($p < 0,001$) and this association persisted even after a thrombotic event.

There was no statistically significant association between any CVRF and MPV. However, patients with history of smoking presented a higher PC ($p = 0,023$) but similar MPV.

NIHSS ranged from 0-28 but there was no correlation with MPV. Patients with LACI IS presented a higher MPV when compared with other subtypes ($p = 0,041$).

About 23,9% of patients underwent thrombolysis and this group presented a lower MPV ($p = 0,015$).

Mean length of hospitalization was $18,32 \pm 15,33$ days and it was correlated with higher PC ($p = 0,09$). MPV was not associated with mRankin scale score on discharge nor with hospital mortality.

Conclusion

Patients with LACI IS had higher MPV. History of smoking and length of hospitalization were correlated with PC. However, there was no evidence that MPV was associated with IS severity, functional outcome or hospital mortality. Further investigation is needed to evaluate the controversial association between MPV and IS outcome.

#1079 - Case Report

AMYOTROPHIC LATERAL SCLEROSIS - A RARE PRESENTATION

Rosana Maia, Marta Moreira, Duarte Silva, Pedro Pinto, Miguel Costa, Edgar Torre, Carmélia Rodrigues, Diana Guerra
 ULS Alto Minho - Hospital de Santa Luzia - Viana do Castelo, Viana do Castelo, Portugal

Introduction

Amyotrophic Lateral Sclerosis (ALS) is an incurable and progressive neurodegenerative disease, with an annual incidence of 1-3/100,000 cases. It is characterized by the presence of signs and symptoms of first and second motor neurons, simultaneously.

Case description

Female, 72 years old, hypertensive, diabetic, with dyslipidaemia, non-smoker, autonomous, admitted to the Emergency Department due to worsening of the general state, gait slowing and dyspnoea. Asthenia, anorexia and weight loss (33 lbs) in 10 months. After undergoing Holter-24h, electromyography (EMG), echocardiogram, endoscopic study, bone scintigraphy and abdominal ultrasound, with unremarkable results, her family doctor made a diagnosis of Depression. At the physic examination: conscious, cooperative and oriented, with slowed speech, mucocutaneous pallor, blood pressure 185/74 mmHg, oxygen saturation (SatO₂) 86% (FiO₂ 21%). Cardiac Auscultation (A): S1 and S2 present, rhythmic, grade III/VI systolic murmur. Pulmonary A: respiratory sounds diminished, increased expiratory time. Gasometry (FiO₂ 21%), global respiratory insufficiency (RI): pH 7.35, pCO₂ 71 mmHg, pO₂ 51 mmHg, HCO₃ 40 mmol/L, SatO₂ 88%. Admitted to the Internal Medicine Service for hospitalization. Abdominopelvic CT - adenoma of the right adrenal gland. Mycobacteria cultural exam - negative. Despite normal ambulatory exams results, repeated EMG revealed a motor neuron disease, with bulbar attainment. Due to worsening IR, with acidaemia, non-invasive ventilation was started. The patient was later evaluated by Neurology and Pneumology that corroborated the diagnostic hypothesis placed - ALS. Follow-up: Progressive worsening of clinical condition, having died two months later.

Discussion

The authors intend to highlight the atypical presentation of the disease and the inclusion of this type of pathologies in the differential diagnosis of RI. RI is a life threatening symptom and is the most common cause of death in these patients. It may be the first manifestation of the disease, but it occurs more often months or years after the remaining symptomatology.

SPONTANEOUS INTRACEREBRAL HEMORRHAGE IN PATIENTS UNDER ANTICOAGULANT OR ANTIPLATELET THERAPY: DATA FROM AHEPA UNIVERSITY HOSPITAL OF THESSALONIKI

Christos Savopoulos, Georgia Kaiafa, Eleftheria Ztriva, Dimitrios Pilalas, Georgios Polychronopoulos, Areti Sofogianni, Georgios Chatzopoulos, Konstantinos Tziomalos, Thomas Tegos, Apostolos Hatzitolios

A' Propaedeutic Department of Internal Medicine, AHEPA University General Hospital, School of Medicine, Aristotle University of Thessaloniki, Greece, Thessaloniki, Greece

Background

The purpose of this study is to study the incidence of spontaneous intracerebral hemorrhage in patients receiving anticoagulant or antiplatelet therapy for secondary prevention of major cardiovascular events and to evaluate the severity of bleeding complications in these patients.

Methods

18 patient who were hospitalized with intracerebral hemorrhage at the A' Propaedeutic Department of Internal Medicine in AHEPA University Hospital of Thessaloniki, in the year 2018-2019, participated in our study. In order to evaluate the severity of the intracerebral hemorrhage, we used the revised Intracerebral Hemorrhage (ICH) score, which was assessed at the time of the patients' introduction. The score estimates the mortality and the good outcome of patients with intracerebral hemorrhage over the next 30 days and includes the calculation of the NIHSS functional scale, the volume of bleeding, its location and origin, and the age of the patient.

Results

Out of the 18 patients, 13 (72.2%) received anticoagulant and / or antiplatelet therapy - 4 anticoagulants, 7 antiplatelet therapy and 2 anticoagulants and antiplatelet therapy at the same time. Patients receiving anticoagulant and / or antiplatelet therapy had a higher ICH score and worse prognosis as shown from the follow up control. Five patients died within the next 30 days. All of them received anticoagulant or antiplatelet therapy.

Conclusion

Spontaneous intracerebral hemorrhage accounts for 10-15% of cerebrovascular strokes. A large proportion of patients with intracerebral hemorrhage receive oral anticoagulants or antiplatelet therapy for secondary prevention of major cardiovascular events . The progression and prognosis of intracerebral hemorrhage is worse in patients under anticoagulant and / or antiplatelet therapy and this appears to be related to the increased volume and extent of the hematoma. For this reason, new studies focus on the research of agents reversing the action of anticoagulant and antiplatelet therapy in cases of life- threatening bleeding complications.

#1110 - Abstract

ASSOCIATION BETWEEN THE MTHFR C677T POLYMORPHISM AND SERUM TOTAL HOMOCYSTEINE IN PATIENTS WITH EPILEPSY

Karima Sifi¹, Sabah Hanachi², Boulfkhad Assia¹, Karima Benmebarek², Salima Zekri¹

¹ Laboratory of Biology and Molecular Genetics Faculty of Medicine Salah Bounider Constantine 3 University, Constantine, Algeria

² Laboratory of Biochemistry of Constantine University Hospital Center, Constantine, Algeria

Background

The plasma content of homocysteine a pro convulsant depends on many factors, including the methylenetetrahydrofolate reductase (MTHFR) C677T polymorphism. The latter causes severe hyperhomocysteinaemia, especially in the homozygous state. To date, many case-control studies have investigated the association between MTHFR C677T polymorphism and epilepsy susceptibility. However, those findings were inconsistent. The objectives of our work were:

- to evaluate the relationship between the methylenetetrahydrofolate reductase C677T polymorphism and plasma homocystinemia (Hcy) on the occurrence of epileptic seizures in epileptic patients.

Methods

Our study included 101 controls and 100 patients with epilepsy from Eastern Algeria. The C677T polymorphism of the MTHFR gene was investigated by PCR / Digestion with restriction enzyme HinfI. Homocystinemia levels were assayed by chemiluminescence.

Results

Homocystinemia was higher in patients with epilepsy ($16.58 \pm 9.79 \mu\text{mol} / \text{l}$) than in controls ($15.80 \pm 8.41 \mu\text{mol} / \text{l}$), (p -value = 0.13231). In controls, our results did not reveal an increase in homocystinemia associated with mutated genotypes T677T and C677T of the MTHFR p -value = 0.111.

In patients with epilepsy, homocystinemias were significantly higher in the T677T and C677T genotypes than in the C677C genotype with respective p -values of ($p = 0.002777$) and ($p = 0.678769$).

Conclusion

Our results showed a relationship between the MTHFR C677T polymorphism and hyperhomocystinemia, which is in agreement with some data from the literature.

#1145 - Case Report

THE RARE SIDE EFFECTS OF ALCOHOL ABUSE

Marinha Silva¹, Inês Carvalho², Eduardo Freitas³, José Nuno Alves², Ana Filipa Santos²

¹ Hospital Santa Maria Maior, Barcelos, Braga, Portugal

² Hospital de Braga, Braga, Portugal

³ Unidade Local de Saúde do Alto Minho, Viana Do Castelo, Portugal

Introduction

Chronic alcohol abuse is a common disorder. Its effects include neurologic complications through both direct and indirect effects on the central and peripheral nervous systems.

Case description

A 43-year-old man, with chronic alcoholism (over 120 g daily), was brought to the emergency department after a two-week period of behavioural changes and psychomotor lentification. There was no history of illicit drug use. On initial assessment he was disorientated in time and place, with speech output reduced, his motor power was normal, sensitive evaluation disclosed no abnormalities and he had a broad-based stance. His blood pressure was normal and he had no fever. Cerebral computerized tomography revealed a callosal hypodensity and global atrophy, with no acute vascular lesions. Laboratory studies disclosed mild macrocytic anaemia and elevated liver enzymes; renal, thyroid and liver function were normal; systemic inflammatory biomarkers and serum ethanol were negative. Abdominal ultrasonography showed signs of steatosis, with no splenomegaly or ascites. Brain MRI confirmed the callosal lesion, with restricted diffusion and showed T2/FLAIR hyperintensities concerning callosal genu, body and splenium, suggesting Marchiafava-Bignami disease diagnosis. He was started on several vitamin supplementation (including IV thiamine), with good clinical outcome.

Discussion

Marchiafava-Bignami disease is an extremely rare affliction characterized by primary degeneration of the corpus callosum associated with chronic alcohol abuse. It may occasionally occur in patients who are not alcoholic but are chronically malnourished. Clinical manifestations include behavioural changes, cognitive deterioration, seizures, dysarthria, spasticity and gait ataxia. There are no treatment guidelines to date. However, case reports of Marchiafava-Bignami disease have shown a favourable response to thiamine, enhancing the synergism between alcohol neurotoxic effects and hypovitaminosis B1. With this case the authors intend to emphasize the importance of the early diagnosis and treatment to prevent irreversible complications, as this disease is often followed by a poor outcome, with rapid progression to coma or death.

#1151 - Case Report

MENINGIOMA – A PECULIAR CAUSE OF AN ISCHEMIC STROKE AND ORTHOSTATIC HYPOTENSION

Frederico De Almeida Garrett Soares Da Silva¹, Maria Inês Simões¹, Helena Rita¹, Luisa Arez²

¹ Centro Hospitalar Universitário do Algarve - Unidade de Portimão - Serviço de Medicina 3A, Portimão, Portugal

² Centro Hospitalar Universitário do Algarve - Unidade de Portimão - Serviço de Medicina, Portimão, Portugal

Introduction

Meningioma is the most common extra-axial brain tumor in adults and commonly originates in the suprasellar, frontobasal, temporobasal, sphenoid wing, or petroclival regions. Tumors situated in these locations often compromise cerebral blood flow by damaging intracranial blood vessels.

While temporary cerebral ischemia has been recognized as a complication of skull base meningiomas, the amount of documented cases of a meningioma causing an ischemic stroke are scarce.

Case description

This case report documents a woman of 87 years old, with history of hypertension, amaurosis since 1998 and a space occupant lesion discovered in 2016 incidentally by CT-scan after a cranio-cephalic traumatism.

Admitted through the emergency room complaining of headache and mention of prosopagnosia with 1 day of progress, the patient had high blood pressure (200/100 mmHg), with rhythmic pulse, no loss of strength or sensitivity alteration upon neurological examination, and laboratory tests showed no relevant changes.

Cranio-encephalic CT scan on admission described the already known lesion, compatible with a 5,5x3.5 cm meningioma on the anterior base of the cranium, producing a mass effect over hypothalamic structures, optic chiasm, mesencephalon, as well as molding of the third ventricle, arteries of the Willis polygon and carotid siphons. There was also evidence of an acute ischemic stroke in the territory of left anterior cerebral artery.

An MRI of the brain was ordered to clarify a potential relationship between the ischemic stroke and the meningioma, but that could not be recognized with certainty.

No indication for surgical intervention was found after discussion with neurology and neurosurgery, and palliative management was the option taken.

Even with adequate control of blood pressure during the hospital stay, the neurological state persisted. Persistent orthostatic hypotension was recognized during the hospital stay, possibly due to direct compressive effects on the medullary centers crucial for the maintenance of systemic blood pressure.

Discussion

Skull-base meningioma is a rare entity, for which clinicians need to be cautioned, due to the possibility of causing neurological

disorders. If surgical intervention isn't possible, there is the need to regular follow-up, blood pressure control and anticoagulation in some cases, in order to minimize the complications resulting from this condition.

THE VERACITY OF AN ISCHEMIC STROKE DIAGNOSIS

Maria De Araújo Barros Maia, Adriana Watts Soares, Luis Falcão, Virginia Visconti, Luisa Pereira, José Lomelino Araújo
Hospital Beatriz Ângelo, Lisboa, Portugal

Introduction

Ischemic Stroke is one of the major causes of mortality and morbidity in Europe. Hematological causes contribute to 1-4% of all the strokes.

Polycythemia vera is one of the chronic myeloproliferative neoplasms, characterized by clonal proliferation of myeloid cells, clinically distinguished by the presence of an elevated red blood cell mass. 15% or more of the cases can present as ischemic strokes.

Case description

The authors report a case of a 73-year-old caucasian male, with previous history of an ischemic stroke, controlled arterial hypertension, dyslipidemia and smoking habits, that was admitted at the hospital due to sense of imbalance, vertigo, nausea and homonymous left quadrantanopia of sudden onset. The CT scan showed an ischemic lesion of the posterior inferior left cerebellar artery territory. The routine complementary investigation to determine the etiology was inconclusive (normotensive values; low cholesterol levels; sinus rhythm; left atrial dilatation with no thrombus on the transthoracic echocardiography and small calcified atherosclerotic plaque of basilar artery). However persistent erythrocytosis (eryt. 8.04×10^{12}); Hb 17.2 g/dL; Htc 56.8%) and leukocytosis (13,000/L) were noticed, suggesting a possible hyperviscosity syndrome. Further investigation showed normal hemoglobin and protein electrophoresis; microcytosis and hypochromia on peripheral blood smear; iron deficiency (36 ug/dL) and erythropoietin < 0.1 mUI/mL. Polycythemia vera was posteriorly confirmed with identification of the JAK2 V617F mutation. The patient started therapy with phlebotomies and hydroxyurea, with a slow regression of the neurological symptoms and hematocrit correction, until now, with no new events.

Discussion

Although a rare cause of cerebrovascular disease, the importance of this diagnosis relates with the dramatic change of prognosis after correct treatment, with high reduction of future vascular events and with better median survival.

CEREBELLAR ATAXIA, A CHALLENGE

Catarina Carreira Da Costa, Sofia Perdigão, Victor Paz

CHTMAD - Unidade de Chaves, Chaves, Portugal

Introduction

Cerebellar ataxia is an infrequent clinical entity, which possible resolution is dependent on treatment of the lying cause. The fact that there is an extensive list of possible causes, from hereditary, paraneoplastic, toxic, to neurodegenerative conditions, makes the diagnosis and workup a challenge, and not readily accessible to a generalist mind.

Case description

71-year-old woman presented to the emergency department with a 3 days history of confusion and unsteady, wide-based gait, with inability to walk. The patient had previous history of long-term epilepsy medicated with phenytoin 100mg bid. No recent seizures were reported as well as no recent medication adjustment or history of recent viral or bacterial infections. Cranial CT showed marked cerebellar atrophy. The patient was admitted for further workup. As inpatient, a rapidly progressive clinical picture of severe discoordination of both limbs and torso, with periods of severe agitation with incapability of speaking intelligibly was established. Physical restraints and iv neuroleptics were instituted and lumbar puncture was performed. Cranial MRI was not performed due to patient's agitation.

After neurology consult, drugs measurement was made. Blood serum phenytoin levels were 52 ug/mL, being considered toxic levels above 20 ug/mL. Clinical improvement was evident after phenytoin washout. The patient was discharged without any speech impairment, able to walk with aid, and referred to physical rehabilitation.

Discussion

Cerebellar ataxia is a known secondary effect of phenytoin, mainly when toxic levels are achieved, and should have been a high suspicion diagnosis in this patient. The rate of development, the severity of the clinical picture, and the fact that the patient had a long-term controlled epilepsy with no recent medication adjustment, made it fall behind some diagnosis which intervention could be lifesaving. In this case, the discussion with a neurologist was crucial for the resolution of the case.

MULTIPLE EMBOLIC STROKES IN FOCAL SEGMENTAL GLOMERULOSCLEROSIS

WAQAR Haider Gaba, Ahmad Thaer Mahdi, Mariam Ghareeb Al Mansoori

Sheikh Khalifa Medical City, Abu Dhabi, United Arab Emirates

Introduction

Nephrotic syndrome (NS) has been associated with high risk of

thromboembolism (TE) among other complications. Studies have shown that the risk of both arterial and venous TE in NS patients are increased up to eight times compared to general population. Arterial TE is less reported and less understood compared to venous TE. Cerebral arteries are among the least reported sites of TE in NS patients.

Case description

Our patient is 19 years old Emirati male who is known to have horseshoe kidney and was diagnosed with NS due to Focal segmental glomerulosclerosis (FSGS) at the age of 17. His disease was difficult to control with multiple immunosuppressive treatments and high doses of steroids. He developed uncontrolled hypertension and progressive chronic kidney disease. He was admitted with hypertensive emergency and steroids induced psychosis. Later he developed CMV pneumonitis that required 6 weeks of Intensive care unit stay, then was discharged to the medical rehabilitation unit.

After 10 weeks of hospital stay, he complained of sudden bilateral visual loss associated with headache. Physical Examination revealed marked loss of visual acuity bilaterally, other cranial nerves were intact. Power in all limbs was slightly decreased but sensation was intact. MRI Brain showed embolic looking multiple territory infarcts of different ages with micro hemorrhages. Follow up CT head showed progression of the infarcts with regression of oedema. MRA brain showed arterial beading and was suggestive of vasculopathy. Extensive young stroke workup showed elevated total cholesterol and LDL, unremarkable trans-esophageal echocardiography, and negative vasculitis and thrombophilia screen. Our final diagnosis was multiple embolic arterial cerebral infarcts secondary to NS and FSGS. He was managed with aspirin, statins and antihypertensives.

Discussion

NS is associated with a hypercoagulable state which can lead to ischemic stroke. In a literature review of 30 cases reported as cerebral arterial TE in NS, the mean age of patients was 40.7 years, and the diagnosis of FSGS was in only 2 of these cases. Our patient is unique in that he is the third case reported to have cerebral arterial TE secondary to FSGS, and the youngest among them. Role of anticoagulants and antiplatelets in primary or secondary stroke prevention for NS remains undetermined. We believe that understanding the risks and morbidity of NS in young strokes is very important in the early detection and prevention of significant morbidity.

ANCA-NEGATIVE EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS PRESENTING AS MULTIPLE CEREBRAL INFARCTION

Regina Costa, Diogo Carneiro, Bruno Silva, Gustavo Cordeiro

Coimbra Hospital and University Centre, Coimbra, Portugal

Introduction

Eosinophilic granulomatosis with polyangiitis (EGPA) is a multisystemic autoimmune vasculitis which essentially affects small and medium vessels mostly of the lung and skin. It is frequently followed by peripheral eosinophilia and the extrapulmonary involvement is frequently associated with higher morbidity and mortality.

Case description

72 year-old woman admitted to the Emergency Room with left hemiparesis and altered state of consciousness with 12 hours of evolution. She had previous history of asthma diagnosed at age 40, hypothyroidism and dyslipidemia and she had discontinued oral corticoid intake for facial angioedema 4 days ago. Her cerebral CT scan showed a right occipital hypodensity compatible with a subacute vascular lesion but the CT angiography showed absence of any abnormal enhancement. Brain MRI showed multiple subacute occipital ischemic lesions and bilateral hemispheric microbleeds, which pointed to a vasculitic process. Cardioembolic sources were excluded. Patient also presented with eosinophilia of 35.80%. Chest CT was performed showing ground glass areas but no pleural effusion. Autoimmune screening was carried out and was negative, namely anti-neutrophil cytoplasmic antibodies (ANCA). Despite a Five-Factor-Score (FFS 2011) of zero points, due to the neurological involvement it was decided to initiate methylprednisolone in 1g bolus for 3 days, followed by methylprednisolone 1mg/kg/day with progressive improvement of neurological deficits.

Discussion

Despite presenting manifestations for several years, only in this hospitalization it was possible to diagnose the EGPA of this patient who meets 4/6 diagnostic criteria proposed by the American College of Rheumatology. Central Nervous System involvement in EGPA is rare and is more commonly related to cardioembolic stroke. ANCA's are indeed an aid in the diagnosis of EGPA, but their absence should not exclude the diagnosis, since they are present only in about half of the patients.

The prompt diagnosis of the neurological manifestations of EGPA allows an adequate treatment with a significant improvement of the prognosis of the patient. Once diagnosed, patients should be treated readily to prevent relapses and neurological sequelae.

EXUBERANT HYDROCEPHALUS

Mariana Silva Santos, Daniela Luz Silva Rodrigues, Rodrigo Rufino, Catarina Carvalho, António Cardoso, Fátima Campante
Centro Hospitalar Barreiro-Montijo, Barreiro, Portugal

Clinical summary

A hydrocephalus is a condition caused by a disturbance of cerebrospinal fluid formation, flow or absorption, leading to an increased volume of this fluid.

Female, 45 years old, prior history of spina bifida causing paraplegia, nephrectomy, chronic kidney disease and several pressure ulcers. The patient was admitted with urosepsis and aggravated renal function, and had been stable for several days. Due to altered state of consciousness, a CT scan was performed and identified an enormous ventricular enlargement, apparently stable and probably related to a Chiari malformation. It should be noted that the patient's neurological exam was normal and there was no apparent cognitive impairment. Also, to our knowledge, the patient had never performed a CT scan.

Figure #1206. Exuberant hydrocephalus.

#1213 - Abstract

DETECTION OF ATRIAL FIBRILLATION IN THE POST-STROKE SETTING – EXPERIENCE OF A PORTUGUESE HOSPITAL

Cecília Moreira, Magda Ventura, Emanuel Ferreira, Sara Salvador, Ana Rita Pais, Mário Fontes, João Rosinhas, Adriana Alves
Hospital Pedro Hispano, Matosinhos Local Health Unit, Matosinhos, Portugal

Background

Atrial fibrillation (AF) affects up to 3% of the population over 20 years and can lead to cardioembolism, responsible for about 30% of ischemic strokes. Despite the diagnostic workup, around 30% of the ischemic events remain of unknown etiology - perhaps due to paroxysms of AF. The identification of these events is of major therapeutic importance, favouring hypocoagulation. Currently there are recommendations for continuous ECG monitoring in the initial 24-48 hours. There is no clear evidence for cardiac monitoring afterwards.

Objectives

To describe the type of in-hospital and outpatient monitoring performed in individuals with cryptogenic stroke and to assess when and which exams to perform.

Methods

Retrospective observational study of all patients with a diagnosis of stroke in 2012 and a 5-year retrospective cohort of the ones discharged without etiologic diagnosis according to TOAST classification. In this last cohort, we calculated the rate of AF detection in 3 stages: 1st - admission (ECG upon admission), 2nd - hospitalization (external electrocardiographic continuous monitoring) and 3rd - 5-year monitoring in outpatient setting (ECG or Holter-24h). In the 2nd stage we also calculated the average number of hours until AF detection. SPSS Statistics 25.0 was used for statistical analysis and $p < 0.05$ was considered statistically significant.

Results

In a total of 259 patients included, 42% remained of unknown etiology at discharge. In the 1st stage, AF was detected in 7.8% and, in the 2nd stage, in 9.1% (>50% detected within the first 72h). A total of 88 patients completed the 5-year outpatient follow-up and 7 of these didn't repeat any type of electrocardiographic monitoring. AF was detected in 8.9%, with 50% of the cases detected in the first 12 months. The electrocardiographic reassessment was performed with ECG in 100% of the cases and only 25% did an additional Holter-24h. The diagnostic yield was 6.3% and 9.5% respectively.

Conclusion

The rate of AF detection in our study is similar to other studies and reinforces the need of prolonged cardiac monitoring in order to maximize AF detection. The highest yield was found during the first 72h of hospitalization and within the 1st year of outpatient follow-up, during when the Holter-24h seems to be the most helpful procedure.

The present study shows that there is no standardization in the type or timing of electrocardiographic monitoring but pointed out important information that enabled us to elaborate a protocol of performance.

NEUROINVASIVE WEST NILE VIRUS INFECTION: REPORT OF TWO CASES

Maysam Jeridi^{1,2}, Yosra Cherif^{1,2}, Maroua Mrouki^{1,2}, Fatma Ben Dahmen², Meya Abdallah^{1,2}

¹ Tunis El Manar University Faculty of Medicine of Tunis, Tunis, Tunisia

² Regional Hospital Ben Arous, Internal Medicine Department, Ben Arous, Tunisia

Introduction

Since its discovery in 1999, West Nile virus (WNV) has been associated with a wide spectrum of clinical features. It's a potentially fatal infection. We report 2 cases of WNV infection with neuroinvasive conditions.

Case description

Case 1

A 26-year-old patient with no medical history was admitted to our department of internal Medicine for lymphocytic meningitis. Physical examination revealed meningism, photophobia, muscle weakness. Laboratory tests showed hemoglobin 13.2 mg/dl, creatine kinase level 1400 U/l (normal range: 125–220 U/l) and C-reactive protein 48.06 mg/l (normal range < 8 mg/l). Cerebrospinal fluid (CSF) analysis showed 165 cells, glucose of 3.7 mmol/l and protein of 0.47 g/l (reference range: 0.15-0.45 g/l). Bacterial blood and CSF cultures were negative. All the serologies of Herpes simplex, Human immunodeficiency virus, hepatitis B, hepatitis C and varicelle Zona virus were negative. The serology of West Nile virus was positive. WNV-IgM and IgG antibodies detection was performed in serum and WNV-IgM tested positive 15 days apart. Magnetic resonance imaging (MRI) showed mild thickening and contrast enhancement of cauda equina nerve roots. Our patient was diagnosed with acute polyradiculoneuropathy due to WNV in an immunocompetent patient. He was treated with Aciclovir during 21 days. Muscle weakness and limb pain improved progressively.

Case 2

A 70-year-old patient with a medical history of diabetes mellitus presented to emergency department with 5 days of fever and headache. Physical examination showed an altered mental status, quadriplegia and aphasia. Laboratory analysis revealed neutropenia and elevated C-reactive protein 78 mg/l. CSF culture was negative. WNV-IgM antibodies tested positive in serum and cerebral MRI showed T2 and FLAIR signal hyperintensity in deep and subcortical white matter of the bilateral parietal lobes. Our patient was diagnosed with acute WNV encephalitis. He was discharged after 21 days with cognitive impairment and residual quadriplegia.

Discussion

In both reported cases WNV infection was revealed by neuroinvasive condition: acute polyradiculoneuropathy and acute encephalitis. Even though rare, neuroinvasive WNV infection should always be suspected during the WNV transmission season. It seems to be potentially fatal in elderly patients.

#1264 - Case Report

GANGLIONOPATHY AND PRIMARY SJÖRGREN SYNDROME: A NEW CASE REPORT

Amal Beya Chatti^{1,2}, Yosra Cherif¹, Maroua Mrouki^{1,2}, Mohamed Sami Zrida^{1,2}, Fatma Ben Dahmen², Meya Abdallah²

¹ Tunis El Manar University Faculty of Medicine of Tunis, Tunis, Tunisia

² Regional Hospital Ben Arous, Internal Medicine Department, Ben Arous, Tunisia

Introduction

In addition to glandular manifestations of Sjogren syndrome (SS), neurological manifestations can involve both peripheral and

central nervous systems. Sensitivomotivo polyneuropathy is by far the most common manifestation found in 60% of peripheral nerve damage. Pure sensory neuronopathy (SN) or ganglionopathy is rarely described. We report a new case of ganglionopathy revealing primary SS.

Case description

A 27 year-old patient with a history of Hashimoto thyroiditis, presented with abolished tendon reflexes, a tendency to fall on standing position and distal dysesthesias of the left arm initially and later progressing to bilateral lower extremities within 6 months. She plained of dry eyes and the Scirmer test was positive. The biological analysis, including diabetes, Hepatitis C, hepatitis B, HIV, anti-neutrophil cytoplasmic antibody, Vitamin levels, and Lyme disease were unremarkable. Electrodiagnostic studies revealed severe sensory neuronopathy (ganglionopathy) in all 4 limbs. Cerebral and spine magnetic resonance imaging revealed T2 hyperintensity in posterior cord. The search for anti-neuronal antibodies was negative. The immunological assessment revealed positive antinuclear antibodies, positive anti-Ro/SSA, anti-La/SSB and anti-RO52 and positive rheumatoid factor. The patient was later tested for paraneoplastic syndrome antibodies, which were negative. Our patient was diagnosed with ganglionopathy Sjörgen and was treated with corticosteroid during 1 year. Electrodiagnostic studies 1 year later showed similar results.

Discussion

We would like to report this case as their ganglionopathy Sjörgen is rare in clinical practice. Nevertheless, other differential diagnosis especially malignancies should be ruled out

#1267 - Case Report

ACUTE POST-INFECTIOUS CEREBELLITIS

Bárbara Pedro, Margarida Monteiro, Catarina Pereira, Tereza Patrícia, Fernando Aldomiro
Hospital Professor Doutor Fernando Fonseca, Amadora, Portugal

Introduction

Acute cerebellitis is a rare neuro-inflammatory syndrome, that occasionally follows systemic viral or bacterial infections, with the majority of cases described in children. But while in children it has been widely studied, less is known about acute cerebellitis in adults, due to the small number of cases reported.

Case description

A 52-year-old woman presented on emergency department with odynophagia, cough and fever with one week of evolution. Since three days, the patient had mild tandem gait difficulty, associated with occipital headaches and vomiting. Neurological examination did not show nystagmus, with postural tremor of both upper limbs, with an intentional component and slight dysmetria, associated with a broad base gait, impossible without support, with tendency to retropulsion. Computerized tomography (CT)

scan of the brain and cerebrospinal fluid (CSF) examination were normal. Serology, viral polymerase chain reaction (PCR) and cultures of CSF were normal. It was assumed an upper airway infection and amoxicillin-clavulanic acid and clarithromycin were started and maintained for 7 days. Blood serology for EBV, CMV, Influenza, HIV, Mycoplasma Pneumoniae, Chlamydia Pneumoniae and Legionella were negative. Brain magnetic resonance imaging (MRI) was normal. The patient's condition improved with motor rehabilitation, and after 2 weeks she was discharged.

Discussion

Acute cerebellitis in adults is a rare entity with a wide range in etiology, clinical presentation and outcome. This case aims to highlight the need for a high index of suspicion for diagnosing this condition in patients who present with an acute cerebellar syndrome in the setting of a febrile illness. Since in the literature, only a few cases of acute cerebellitis in adults have been described, further studies are necessary to establish diagnosis and treatment guidelines.

#1274 - Case Report

AN APHASIC EPILEPTICUS SYNDROME

Catarina Sousa Gonçalves, Nuno Reis Carreira, Marisa Teixeira Silva
CHULN, Lisboa, Portugal

Introduction

An epilepsy syndrome refers to a cluster of features incorporating seizure types, electroencephalographic and imaging features. It may also have distinctive comorbidities such as intellectual and psychiatric dysfunction. Aphasic epilepticus syndrome is a rare condition and it is characterized by aphasia without impairment of other cognitive functions, which is usually associated with structural brain lesions such as stroke, brain tumor and trauma. We report an epilepsy syndrome associated with aphasia in a patient with an acute subarachnoid hemorrhage who presented initially with nonketotic hyperglycemia.

Case description

A 73-year-old woman under anticoagulant therapy with rivaroxaban suffered a head injury after falling. One week later presented an alteration of the state of consciousness and was taken to the emergency room. The lab tests showed nonketotic hyperglycemia and an HbA1c quantified in 14,5%, as well as an acute non aneurysmatic subarachnoid haemorrhage in the left frontotemporal region shown on the tomography. On the third day of hospitalization, after the initiation of the correction of hyperglycemia, the patient was presented with Broca's aphasia, and therefore the EEG concluded a status epilepticus. After introduction of antiepileptics the clinical features disappeared and the following EEG showed absence of epileptic activity.

Discussion

Aphasia is a common symptom of seizure in post-ictal period. Ictal

aphasia prolongation is a rare condition called aphasic epilepticus syndrome. Usually these patients have lesions around and/or on the language cortex. There are also some reports of aphasic epilepticus syndrome in metabolic disorders. Furthermore, focal motor seizure and epilepsy can occur in 25% of nonketotic hyperglycemia. The presentation of aphasic epilepticus syndrome is not common in these patients. Even though it is well known, isolated aphasic epilepticus syndrome is rare and its diagnosis is not easy.

#1291 - Case Report

STROKE OF THE YOUNG ADULT – OCCULT, MULTIFACTORIAL OR CRYPTOGENIC ETIOLOGY?

Filipe Bessa, Pedro Silva Gaspar, Pedro Meireles, João Meneses, Rui Victorino, Catarina Mota
Centro Hospitalar Lisboa Norte - Hospital de Santa Maria, Lisboa, Portugal

Introduction

Ischemic stroke in the young adult requires an exhaustive diagnostic exercise with a wide range of possible etiologic factors. As such, it is increasingly common that some cases have more than one identifiable cause, with different prothrombotic factors that overlap leading to an increased thrombotic risk.

Case description

A 45 year old caucasian woman with no relevant medical background and on oral contraceptives, was admitted with language and writing alterations preceded by lipothymia. On neurologic examination, right central facial paresis and paraphasia with phrase repeating errors were found. The initial CT scan showed a left fronto-opercular sequelae cortico-subcortical lesion and 24 hours after it showed a recent left posterior insular cortico-subcortical lesion, suggesting ischemic lesions on two left median cerebral artery territories. The following investigation revealed a heterozygotic mutation of factor V Leiden and a positive Lupus anticoagulant test, the last not confirmed 12 weeks later. The remaining study of hereditary and acquired thrombophilias were negative. 24-hour Holter ECG was normal. Although asymptomatic, cerebral MRI showed new ischemic lesions on the semioval center and superior frontoparietal white matter. Transcranial and carotid triplex Doppler ultrasound showed the presence of frequent microembolic signs which intensified with Valsalva maneuver and transoesophageal echocardiogram was compatible with right-left shunt. Right heart catheterization was performed, but no patent foramen ovale was found. The contribution of cumulative prothrombotic factors in a young patient (factor V Leiden, oral contraception) was assumed, with concomitant paradoxical embolism due to Right-to-Left shunt of occult origin. The patient was started on anticoagulation with vitamin K antagonist, remaining without new events.

Discussion

The diversity of recognized etiologies for cerebrovascular events in young people requires a thorough investigation and careful follow-up. In addition to the events of undetermined etiology, to which occult sources of embolism frequently contribute, there is an increasing recognition of multifactorial etiology that hinders therapeutic decisions and secondary prevention strategies.

FACIAL PALSY AND VESICULAR RASH - A CASE OF RAMSAY HUNT SYNDROME

António Epifânio Mesquita^{1,2}, Andreia Fernandes³, Lara Câmara¹, Francisca Martins¹, Catarina Patrício¹, Vítor Brotas¹

¹ Serviço de Medicina 2.3, Hospital Santo António dos Capuchos, Centro Hospitalar Universitário de Lisboa Central, Lisboa, Portugal

² Departamento de Fisiopatologia, NOVA Medical School, Universidade Nova de Lisboa, Lisboa, Portugal

³ Serviço de Neurologia, Hospital Santo António dos Capuchos, Centro Hospitalar Universitário de Lisboa Central, Lisboa, Portugal

Clinical summary

A previously healthy 77 year old woman presented with a 2 day history of difficulty closing her left eye and facial asymmetry. She reported left sided ear fullness but denied ear pain or rash, hearing loss, vertigo, tinnitus or otorrhea. She denied other neurological symptoms, fever, headache or recent tick bite. There was no history of trauma. On physical examination left sided peripheral facial nerve palsy was evident. Inspection of the left external ear revealed vesicular and crusted rash. Neurological exam was otherwise normal. A clinical diagnosis of Ramsay Hunt Syndrome was made. The patient was prescribed with oral course of prednisone and acyclovir. Two months after the diagnosis the rash has resolved. Facial palsy improved but the patient still needs physical therapy.

Figure #1324. Left sided facial palsy; vesicular and crusted rash on left external ear.

SPONTANEOUS INTRACRANIAL HYPOTENSION - CLINICAL CASE

Hilda Freitas¹, Antonio Cabral¹, Natalia Oliveira¹, Paulo Ferreira², Vanessa Machado², Cristina Ramalho²

¹ TrofaSaude Hospital Braga Sul, Braga, Portugal

² TrofaSaude Hospital Braga Centro, Braga, Portugal

Introduction

The diagnosis of spontaneous intracranial hypotension should be considered in patients who present with positional orthostatic headache, with or without associated symptoms, perhaps in the setting of minor trauma, and in the absence of a history of dural puncture or other cause of cerebrospinal fluid (CSF) fistula. Confirmation of the diagnosis requires evidence of low CSF pressure, most often by MRI (eg, pachymeningeal enhancement) or by radioisotope cisternography, and/or evidence of a CSF leak on other neuroimaging studies, mainly computed tomographic (CT) myelography.

Case description

The authors describe a clinical case of a 40 years old women, autonomous, no known diseases or chronic medication. She had headaches with about 1.5 months of evolution. She reported daily holocranial headaches that improved when she lay down. No previous head injury; without Anterior Lumbar Puncture; No history of otitis, and no nasal loss of CSF. Went to the Emergency Department by the intensity and persistence of headache. Se performed brain resonance (MRI) that revealed "subdural suffers, bilateral hemispherical, associated with engorgement of the venous sinuses. The cerebellar tonsils pop up the plane of the magnum hole.". During the hospitalization she made MRI of the cervical-dorsal-lumbar and sagittal column: "Discus prothusions. "Given a clinical suspicion, was performed Isotopic cisternography, which revealed bilaterally D5-D6 fistula. It was observed and oriented in addition by Neurosurgery. She presented a favorable clinical evolution, presenting asymptomatic to the discharge date. Epidural blood patch was performed later. She Has been followed up in consultation of Internal Medicine, being without headache, and asymptomatic.

Discussion

The authors intend with this case to call attention to the diagnosis for a rare pathology, which can often go unnoticed if we do not think about her, and whose diagnosis allowed the patient to solve the problem.

THE HEADACHE THAT WON'T GO AWAY

Ana Figueiredo Albuquerque, Maria João Palavras, Juliana Silva, Flávia Santos, Helena Carrondo, Célio Fernandes

Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

Cerebral Venous Thrombosis (CVT) is an uncommon disease, with an annual incidence that ranges from 0.22-1.57 per 100,000, representing only 0.5-1% of all strokes. CVT refers to any clot in the cerebral venous system and it is divided into deep, superficial, and dural venous sinuses thrombosis. Several causative conditions have been described in CVT, such as thrombophilia's, inflammatory diseases, trauma and some medications are the main etiologic determinants of CVT.

Case description

We present the case of a woman with 38 years-old of age that came for the third time to the ER with 3-day evolution of occipital headache, photophobia, dizziness and one episode of vomits, with no neurological deficit. The patient had history of recurrent migraine, without other known diseases. Medicated with oral contraceptive since the last 9 months. The physical examination only revealed a discrete right central facial paresis.

The blood analysis showed a leukocytosis $12,8 \times 10^3/\mu\text{L}$, and an elevation of dimers ($=1207 \text{ ng/mL}$). A brain computed tomography without contrast was performed and displayed hyperdense signs in superior longitudinal sinus, with ischemic lesions on both the occipital and parietal lobes. The patient was medicated with a therapeutic dose of low-molecular weight heparin (LMWH; enoxaparin) 1 mg/kg/12h subcutaneously. Later on, the thrombophilia study revealed a MTHFRA1298C homozygous mutation.

Discussion

Cerebral venous sinus thrombosis is an uncommon and delicate condition with unpredictable presentation and prognosis. With this clinical case the authors intend to demonstrate the need to have a high index of suspicion to diagnose the CVT in a patient with migraine, otherwise it may have catastrophic outcomes. This patient had two predisposal factors, the mutation and the oral contraceptive medication, that lead into having a thrombotic event.

#1402 - Abstract

ATRIAL FIBRILLATION AND STROKE - A CHICKEN AND EGG EQUATION?

Mário Bibi, Sara Moreira Pinto, Alda Tavares, Rute Ferreira, Cristina Rosário

ULSM, Porto, Portugal

Background

The interplay between atrial fibrillation (AF) and stroke can be complex. It is well established that AF can lead to ischemic stroke (IS). However, there is a new concept of "neurogenic AF" in which AF appearing after a stroke can rather be a manifestation of the stroke and not the cause of it. This correlation is being investigated and is dependent on the localization of the cerebral injury.

Methods

A retrospective study was conducted, among patients admitted in an Internal Medicine Ward, between April of 2014 and June of 2015. The patients with AF were selected and epidemiological, clinical and analytical data was collected and analysed. The objective was to compare patients admitted with AF to those admitted with AF and stroke. Focus on the characteristics of the AF and underlying cardiopathy and decision to initiate anticoagulation. Statistical analysis was performed with SPSS software v25; values of $p < 0,05$ were considered statistically significant.

Results

A total of 236 admissions and 214 patients were examined. The median age was 77 years and 66% of patients were women. Sixteen individuals also had a stroke in the same hospital admission. There was more inaugural AF diagnosed in patients with stroke than those without (75% vs. 25%; $p = 0.004$). We observed a trend in patients with stroke to had less frequently known cardiopathy (25.0% vs. 56.8%, $p = 0.014$), as well as smaller atriums (median 43.0mm [35,49] vs. 45.4 mm [29-64]; $p = 0.302$). The subgroup of AF plus stroke was less frequently anticoagulated (31% vs. 59%, $p = 0,251$) and had a greater mortality (31% vs. 7%, $p = 0.014$). Readmissions at 12 months were similar.

Conclusion

AF is a known cause of IS and anticoagulation should be initiated when appropriate. However increasingly evidence suggests different mechanisms of AF, including the possibility of a neurogenic AF.

Our data suggests a difference between the AF in stroke and non-stroke patients, which can point to two different types of AF: a cardiogenic-related and a neurogenic-related. It is necessary to further study the AF that happens after an IS and to quantify its recurrence, risk of further strokes and anticoagulation need. Until then, the same indications to anticoagulation should be kept as in "general" AF.

#1433 - Case Report

SUDDEN ABDUCENS NERVE PALSY

David Prescott, Ana Isabel Brochado, Margarida Pimentel Nunes, Inês Branco Carvalho, Isabel Montenegro Araújo, Beatriz Donato, Rita Sérvio, José Luís Ferraro, Vasco Evangelista, António Martins Baptista, José Lomelino Araújo

Hospital Beatriz Ângelo, Loures, Portugal

Introduction

Pituitary macroadenomas represent up to half of suprasellar masses and are larger than 10 mm in size. They may be asymptomatic but generally present with cranial nerve defects, mainly optic chiasm compression with anopsia and sometimes oculomotor palsy. Isolated eye movement nerve palsies are rare, especially when affecting the trochlear and abducens nerves.

However, these changes may happen following cavernous sinus invasion, wall displacement or pituitary apoplexy.

Case description

In this case report we present the case of a fifty-six year old man who presents with a four day acute headache, followed by a two day isolated abducens nerve palsy, with complaint of horizontal diplopia and limited levoersion of the left eye. There were no other neurological changes, namely visual field defects. CT and MRI imaging identified enlargement of the sellar loca due to a left median and paramedian intra-sellar mass measuring approximately 12 by 14 mm, without evidence of haemorrhage, vascular lesions, cavernous sinus displacement or invasion. The mass was causing optic chiasm compression and hormonal dysfunction due to hyposecretion, with asymptomatic secondary hypothyroidism and hypogonadism in biochemical testing. After multidisciplinary discussion with Ophthalmology, Endocrinology and Neurosurgery, the patient was discharged after 8 days on levothyroxine and corticosteroid therapy, referenced to Neurosurgery and Neuroendocrinology follow-up.

Discussion

Ophthalmoplegia usually happens late in the natural history of the tumour and typically after and in conjunction with optic nerve defects, mostly affecting the third cranial nerve. Isolated palsy of the abducens (sixth) cranial nerve is even rarer due to its relatively protected placement inside the cavernous sinus, and therefore is generally affected only after the third and/or fourth cranial nerves. In this case, abducens palsy was seen without optic chiasma or oculomotor defects, even though the tumour was in contact with the optic chiasma and there was no identifiable invasion of the cavernous sinus. There was also no evidence of pituitary apoplexy. Pituitary tumours are a challenging diagnosis, and the differential has to be made with other possible central nervous system changes, namely other tumours and vascular lesions. Treatment is usually by trans-sphenoidal resection, with symptom and hormonal correction in most patients, and imaging follow-up at 3 months' time and then yearly.

#1475 - Case Report

FAHR'S DISEASE: A DIFFERENTIAL DIAGNOSIS OF EPILEPTIC SEIZURE

Gabriela Pereira, Ana Ferreira, Laura Castro, Magda Fernandes, Glória Alves, Jorge Cotter

Hospital Senhora da Oliveira, Guimarães, Portugal

Introduction

Fahr's disease is a rare neurological disorder characterized by abnormal calcified deposits in basal ganglia and cerebral cortex, commonly affects young to middle aged adults and clinical manifestations incorporate a wide variety of symptoms, ranging from neurological symptoms of extrapyramidal system to neuropsychiatric abnormalities of memory and concentration to movement disorders.

Case description

A 52-year-old female presented with sudden onset of generalised tonic-clonic seizure to the emergency department. Diazepam was given as the first-line antiepileptic drug, and the seizure was responsive to the treatment. After the patient regained consciousness, a neurological examination was performed. Abnormal neurological signs including dysarthria, sixth nerve palsy of the right eye and generalised neuromuscular irritability such as muscle cramps and tetany were found. Chvostek's sign and Trousseau's sign were positive. Over the past month, the patient family reported episodes of tonic-clonic movements of the limbs, progressive deterioration of mentality and audio-visual hallucinations with psychomotor agitation.

Laboratory studies including serum calcium 4.9 mg/dl (normal 8.4-10.6 mg/dl), phosphate 7.8 mg/dl (normal 2.3-4.7 mg/dl) and parathormone level 3.1 pg/ml (normal 15-65 pg/ml) demonstrated idiopathic hypoparathyroidism. Additional diagnostic laboratory tests including thyroid hormones and vitamins were within normal range.

Cranial CT scan showed extensive symmetrical intracerebral calcifications in both basal ganglia and radiated crown.

Sonographic examination revealed normal thyroid gland and parathyroid glands.

Parenteral calcium, calcitriol supplementation and intravenous fluid support were started with a favourable outcome.

Discussion

In conclusion, this is a case of a rare neurological disease with a variable prognosis and hard to predict. There is no reliable correlation between age, extent of calcium deposits in the brain, and neurological deficit. A slowly progressive course is usual and there's no standard treatment.

MULTIFACTORIAL ENCEPHALOPATHY: CHRONIC INTOXICATION BY LITHIUM AND SEPSIS

Maria Duarte¹, Raquel Rocha², Miguel Silva², Susana Marques De Sousa¹, Inês Amaral Neves¹, Filipe Correia²

¹ Centro Hospitalar Póvoa de Varzim/ Vila do Conde, Vila Do Conde, Portugal

² Hospital de Pedro Hispano, Matosinhos, Portugal

Introduction

Lithium is indicated to treat bipolar disease, especially for acute mania and maintenance treatment. However, its mechanism of action has not been fully elucidated. The excretion is renal and, although freely filtered, about 60% is reabsorbed in the proximal tubules. Volume depletion and renal damage are associated with increased reabsorption, leading to chronic intoxication with neurological, cardiac and renal manifestations.

Case description

We present the case of a 67-year-old woman living in a nursing home, dependent on external help for routine daily activities, with history of heart failure, chronic kidney disease (CKD) and bipolar disorder under lithium therapy, 400 mg bid. She was admitted to the hospital for fluctuations in mental status and myoclonic jerks with 10 days of evolution. Brain computed tomography was normal. Serum lithium dosing revealed toxic levels (3.96 mmol/L) and was discontinued. Empirical antibiotic therapy with ceftriaxone was started due to nosocomial urinary tract infection and the patient was transferred to an Intermediate Care Unit for sepsis with haematological, metabolic, neurological and renal dysfunctions. On admission, physical examination showed marked fluctuations in alertness and attention status, oromandibular dyskinesia and upper limbs and palpebral myoclonus. The electroencephalogram revealed diffuse cortical dysfunction without epileptic activity. The patient improved gradually after escalation of antibiotic therapy, adequate hydration and hemodialysis for lithium clearance.

Discussion

Older adults are especially vulnerable to lithium toxicity due to reduced glomerular filtration rate and volume of distribution. In this case, there was already a known CKD and chronic intoxication by lithium led to the initial neurological findings of encephalopathy and neuromuscular excitability, thus emphasizing the importance of clinical and analytical monitoring of patients under narrow therapeutic window drugs. The worsening of neurological status was multifactorial with septic encephalopathy contributing to the greater severity.

MANAGEMENT OF ASYMPTOMATIC CAROTID STENOSIS IN A PATIENT WITH RECENT ACUTE MYOCARDIUM INFARCTION AND ISCHEMIC STROKE

Maria Duarte¹, Raquel Rocha², Joana Ricardo Pires³, Filipe Correia²

¹ Centro Hospitalar Póvoa de Varzim/ Vila do Conde, Vila Do Conde, Portugal

² Hospital de Pedro Hispano, Matosinhos, Portugal

³ Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

Introduction

Atherosclerosis is a systemic inflammatory disease that mainly affects large and medium-sized arteries. Atherothrombosis of the extracranial carotid arteries may result in ischemic stroke, either by embolism of thrombotic material or low blood flow due to stenosis with inadequate collateral compensation.

Case description

We report the case of a 65-year-old woman with metabolic syndrome and a history of two lacunar strokes and two episodes of acute coronary syndrome without ST-segment elevation:

the first at 63 years of age, treated with coronary artery bypass grafting; the second treated with angioplasty and stenting just three days before new admission in the emergency department, this time due to imbalance. Neurological examination showed nystagmoid saccades in the horizontal pursuit eye movements, mild flattening of the left nasolabial fold and right hemiparesis due to prior stroke, with no other remarkable changes. Brain magnetic resonance imaging revealed multiple ischemic lacunar lesions in the right side of the pons, one of which was acute. Carotid and transcranial Doppler ultrasonography revealed left internal carotid artery stenosis >90 percent and occlusion of the left vertebral artery. Therefore, the patient had a carotid stenosis that did not contribute to the vertebrobasilar stroke but was severe and progressing compared to previous exams. She underwent carotid artery stenting, which occurred without intercurrents.

Discussion

In patients with asymptomatic carotid stenosis (≥ 50 percent), the annual risk of ipsilateral stroke is 0.5-1.0 percent, being recommended intensive medical treatment. For patients with stenosis of 60 to 99 percent and high risk of stroke, revascularization by carotid endarterectomy may be considered. Despite evidence of similar long-term outcomes, carotid artery stenting appears to be associated with a higher risk of periprocedural stroke and death. However, in this case of a patient who had recently undergone coronary artery stenting, the risks of discontinuation of dual antiplatelet therapy for endarterectomy clearly outweighed those of angioplasty.

#1528 - Abstract

STROKE MIMICS ADMITTED TO A STROKE UNIT: A ONE-YEAR CASE SERIES

Margarida Massas, Vera P Sarmiento, Vasco Neves, Ana Bernardo, Maria Piteira, Tereza Veloso, Carmen Corzo, Sílvia Lourenço, Conceição Barata, Luísa Rebocho
Hospital do Espírito Santo de Évora, Évora, Portugal

Background

The differential diagnosis of cerebrovascular diseases (CVD) can be challenging. Several disorders may present similarly to a stroke, prompting the same management, including admission to a Stroke Unit. We aimed to determine and analyse the proportion of cases admitted with non-CVD to a Stroke Unit by any hospital physician in an acute stroke-ready hospita

Methods

We have reviewed the discharge notes of all patients admitted to a six-bed stroke unit during 2018, selecting those with non-CVD as their main diagnosis. We then fulfilled a previously designed database with socio-demographic and clinical variables. We have analysed the data descriptively.

Results

There were 323 patients admitted to the stroke unit during 2018, from which 55 (17%) were diagnosed with non-CVD. Of these, 31 were women (56%). The mean age was 61 ± 16 y.o. The 55 patients were admitted for a mean of 3.7 ± 2.4 days. Almost half the patients ($n=28$) presented with motor and/or sensitive deficits. Other common presenting symptoms were confusion ($n=10$), headache ($n=8$), decreased level of consciousness ($n=8$), vertigo ($n=8$) and speech changes ($n=7$). Only 9 (16%) had Cincinnati criteria for fast-track activation and none was submitted to thrombolysis. NIHSS at admission ranged from 0 to 8 pts (median 2.1, IQR 0 - 3.8), with 47 patients presenting with up to 4 pts. The most frequent diagnosis was epilepsy ($n=9$), followed by headaches ($n=8$). Seven patients had psychiatric disorders, whilst five suffered from global transient amnesia. Four cases were peripheral vertigos and three patients had facial palsy. Three cases were due to side effects of medications, whilst two were caused by low sodium level. Two patients presented with hypertensive crisis. There were seven patients with other less common disorders, and five patients still warrant further investigation.

Conclusion

The rate of patients with non-CVD admitted to this stroke unit is similar to that reported by other units around the world. The great majority of these patients present with diseases that do not benefit from this highly specialized level of care. Nonetheless, it is arguable whether this rate can be decreased, given the need for specialist testing that is not available at the A&E. It would be interesting to study the effectiveness of a stroke team in improving the diagnostic accuracy of stroke in the A&E setting.

#1551 - Case Report

TAKOTSUBO SYNDROME AND CEREBROVASCULAR DISEASE: A CASE ON AN UNCOMMON ASSOCIATION

Margarida Massas, Vera P Sarmiento, Diana Coutinho, Tereza Veloso, Carmen Corzo, Sílvia Lourenço, Conceição Barata, Luísa Rebocho
Hospital do Espírito Santo de Évora, Évora, Portugal

Introduction

Reports of thromboembolic complications in patients with Takotsubo cardiomyopathy have been increasing, being stroke the most common type of thromboembolic complications. However, neither the timing nor the treatment of the thromboembolic event resulting from Takotsubo cardiomyopathy have been well described.

Case description

Female patient, 48 y.o., treated for arterial hypertension and depression, with a two-week history of retrosternal pain with cervical radiation. She was admitted to the A&E department 1h30m after the sudden onset of facial asymmetry and decreased left

muscle strength. On neurological examination: left homonymous hemianopia, left central facial paresis, decreased muscle strength 3/5 and sensitivity of the left arm, dysmetria on the left finger to nose test. NIHSS at admission of 7 pts. After excluding intracranial hemorrhage and contraindications for thrombolysis, the patient was started on alteplase. The contrasted head CT revealed a thrombus in the M2 segment of the right middle cerebral artery (MCA), and she was immediately transferred to the reference hospital for thrombectomy. This was complicated by severe vasospasm of the M1 segment, with complete occlusion of the M2 branch. She was admitted to the Stroke Unit with a NIHSS of 16. Further exams showed inverted T waves on the EKG precordial leads and an increased troponin level. On the echocardiogram there was a marked apical ballooning of the left ventricle with a large thrombus inside (36x25 mm). The coronary angiogram suggested a possible spontaneous coronary dissection of the distal anterior descendant coronary artery. Hence, a diagnosis of an embolic ischemic stroke of the right MCA territory on a patient with a Takotsubo cardiomyopathy, possibly secondary to a spontaneous coronary artery dissection, was assumed. The patient was transferred back to the referring hospital with a NIHSS of 12, which remained unchanged. She was kept anticoagulated and discharged after regression of the LV thrombus.

Discussion

Intracardiac thrombus formation is a relatively common complication of Takotsubo cardiomyopathy, and the incidence of embolic stroke due to this syndrome is low (0 to 9.5%). The association between this heart disorder and cerebrovascular disease still warrants further investigation, considering it seems to be both a cause and a consequence of stroke. In this case, there is a complaint of chest pain two weeks prior to the stroke, making the Takotsubo cardiomyopathy the most likely cause of the stroke.

#1553 - Medical Image

CEREBRAL VENOUS THROMBOSIS: DIAGNOSIS WITH A NONCONTRAST CT

Margarida Massas, Vera P Sarmiento, Vasco Neves, Ana Bernardo, Tereza Veloso, Carmen Corzo, Sílvia Lourenço, Conceição Barata, Luísa Rebocho

Hospital do Espírito Santo de Évora, Évora, Portugal

Clinical summary

Man, 28 years old, history of arterial hypertension, obesity, hypercholesterolemia, smoking habits and alcohol abuse, presented to the A&E with a worsening intense headache over the course of 5 days. On the neurological exam a left horizontal nystagmus was detected. Head CT revealed a spontaneous hyperdensity of the superior sagittal sinus (red arrow head), with a dense delta sign (red arrow), adjacent cortical veins (blue arrow) and right lateral sinus, suggestive of acute venous thrombosis. Cerebral Venous Thrombosis represents approximately 0.5% to 1% of all strokes, with just 25% of these presenting with

headache only. Anatomic variability of the venous sinuses makes CT diagnosis of CVT insensitive without contrast, with abnormal findings present in less than 1/3 of the cases.

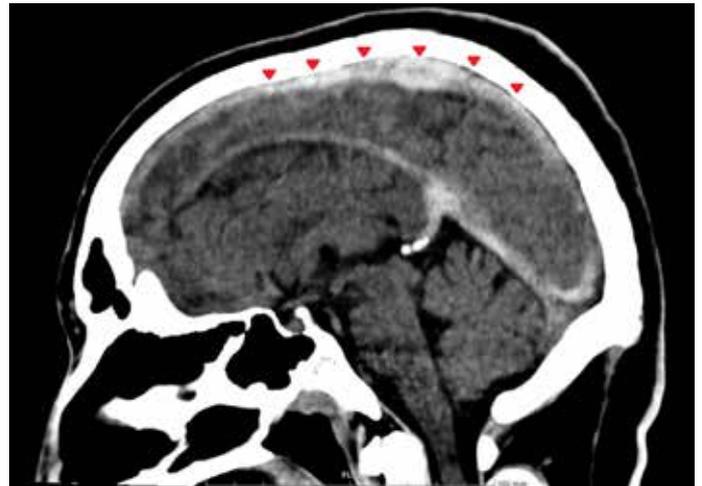

Figure #1553. Sagittal view of a noncontrast head CT. Red arrow head: hyperdensity of the superior sagittal sinus.

#1572 - Case Report

GIANT CELL ARTERITIS IN A 79 YEARS OLD MALE: A CASE REPORT

Ricardo Gomes¹, Ana Patrícia Gomes¹, Isabel De La Cal Caballero, José Proença¹, Ana Campelos², Leopoldina Vicente¹

¹ Internal Medicine Service - Centro Hospitalar Universitário Cova da Beira, Covilhã, Portugal

² IPATIMUP - Institute of Molecular Pathology and Immunology of the University of Porto, Porto, Portugal

Introduction

Giant cell arteritis (GCA) is a chronic inflammatory disease involving large/medium-sized arteries and the greatest risk factor is aging. The diagnosis should be considered in patients from 60 to 80 years old with de novo headaches, abrupt onset of visual disturbances, transient monocular visual loss, jaw claudication, unexplained fever, anaemia, and/or high serum erythrocyte sedimentation rate (ESR) and/or high C-reactive protein (CRP). Given the irreversible pattern of visual loss in most cases, when there is a strong suspicion, prompt treatment might be needed.

Case description

A male patient 79 years old reached the emergency service complaining of severe left occipital headaches, dizziness, asthenia and transient jaw claudication with more than 1 month of evolution. He had been evaluated 3 days earlier with the same complaints and fever with about 8 days of evolution and treated with ciprofloxacin, trazodone and iron supplements due to anaemia. Other symptoms were absent. He had controlled arterial hypertension (telmisartan/hydrochlorothiazide suspended 5 days earlier). The physical examination revealed tenderness of the left temporal artery. Neurological examination and cranial

tomography scan without relevant findings. Without postural hypotension. Lumbar puncture negative to central nervous system infection. Blood results showed anaemia (Hb: 9.8 g/dL) normocytic/normochromic, CRP 25.0 mg/dL and ESR: 110 mm/H. The patient began empirical ceftriaxone (7 days total). After 4 days in the hospital, he claimed sudden visual loss and was evaluated by an ophthalmologist that found cataracts on both eyes. Due to aggravating symptoms we began treatment with 70mg of prednisolone/day with improvement around 48 hours after the visual loss. The vasculitis, bacteriological and viral studies were negative. The histology of biopsy fragment of superficial branch of the left temporal artery revealed giant cell arteritis. The only relevant finding after discharge was transient hyperglycaemia due to corticoids.

Discussion

The diagnosis is based on histopathological or imaging exams (most commonly the temporal artery) given the potential complications related to high dose glucocorticoids. Although the tissue was collected 24h after glucocorticoid therapy, biopsy was positive. Treatment was instituted promptly once the diagnosis of GCA was strongly suspected. Although some studies defend treatment with pulses of intravenous corticoids, we opted for a more conservative approach with 70 mg/day orally.

#1588 - Case Report

SIMULTANEOUS ACUTE HEMORRHAGIC STROKE AND MYOCARDIAL INFARCTION: A MANAGEMENT CHALLENGE

Carlos Candeias, Marco Fernandes, Maria João Correia, João Pedro Marto, Nuno Ferreira, Teresa Mesquita, Luis Campos
Stroke Unit - Hospital S. Francisco Xavier - Centro Hospitalar Lisboa Ocidental, Lisboa, Portugal

Introduction

Simultaneous occurrence of acute myocardial infarction (MI) and Intracerebral hemorrhage (ICH) is uncommon among patients admitted to Emergency Room (ER). Both medical conditions are life-threatening, with a narrow therapeutic time. Even though the acute management of both clinical conditions is well documented in the literature, the management of both conditions, simultaneously, represents a challenge.

Case description

We report the case of a 73 year old male, admitted due to shortness of breath, dyspnea and chest pain lasting 48 hours. In the several hours preceding admission, it was noted he had altered mental status and a blood pressure (BP) of 250/110 mmHg. Physical examination showed a heart rate of 89 bpm, BP of 233/166 mmHg and a pansystolic murmur. Neurological examination revealed that the patient was confused, disoriented and with reduced sensation in his left lower limb and loss of sensation down the left-hand side of his body. He was also noted to have a left sided hemianopia.

Laboratory findings showed a troponin 841 µ/L. Non-contrast CT head showed an acute right parietal ICH, and his ECG showed ST segment elevation with T wave inversion V2-V6 and Q wave in anterior leads. Transthoracic Echocardiogram revealed a left ventricular thrombus and apical aneurysm. Patient was initially treated with non-fractionated heparin (NFH) and strict blood pressure control, as assessment by the cardiology team deemed him unfit for coronary intervention. For the first seven days in the stroke unit the patient had neurological improvements even with NFH treatment. At day eight of hospitalization the patient had a cardiorespiratory arrest but return of spontaneous circulation was achieved following CPR and defibrillation. The patient was then transferred to the coronary intensive care unit and underwent coronary angioplasty and stent placement. Following this the patient was treated with double antiplatelet therapy (APT) and anticoagulant therapy (ACT) with favorable clinical response.

Discussion

A delayed intervention in MI or ICH may result in permanent irreversible morbidity, disability, or even death. But the use of APT and ACT, that are a standard component of acute MI management, may risk worsening the patient's neurological condition. Since there is no clear evidence-based guideline or clinical studies that have addressed the optimal management of this rare co-occurrence, a multidisciplinary team approach is essential to manage these complex patients.

CEREBRAL POSTERIOR STROKE

Nuno Bernardino Vieira, Alexandra Avila, Vanda Conceição, Maria José Grade, Luísa Arez
Serviço de Medicina 3 - Unidade Hospitalar de Portimão do Centro Hospitalar Universitário do Algarve, Portimão, Portugal

Clinical summary

An 72-year-old man former smoker was admitted with transient episode of syncope, diplopia, unilateral limb weakness and gait ataxia. On admission, he was alert but he maintained the diplopia and the imbalance. The CT scan doesn't reveal any new vascular lesions. The CT angiography revealed intracranial occlusion of the vertebrobasilar system (right and left vertebral arteries and the proximal third of the basilar artery). A couple of hours after the patient admission, presented clinical worsening with respiratory difficulty, decreased consciousness and left hemiparesis and he needed mechanical ventilation for his transportation to a differentiated unit where he received successful endovascular treatment.

Figure #1595.

#1631 - Case Report

CENTRAL VENOUS THROMBOSIS IN A YOUNG FEMALE

Margarida Gaudêncio¹, João Sousa², Bruno Silva², Ricardo Veiga³, Bruno Rodrigues², Isabel Bessa¹

¹ Internal Medicine Department, District Hospital of Figueira da Foz, Figueira Da Foz, Portugal

² Neurology Department, Coimbra Hospital and University Centre, Coimbra, Portugal

³ Neuroradiology Department, Coimbra Hospital and University Centre, Coimbra, Portugal

Introduction

Central venous thrombosis is an increasingly frequent pathology, which is organized by the presence of thrombotic phenomena in the venous sinuses and cerebral veins. Responsible for 1% of all strokes, turning primarily to young adults. It presents a high variability in its clinical presentation, mode of installation but also etiology.

Case description

The case being reported is of a 46-year-old female patient that was referred to the emergency department for headache with 14 days of evolution, progressive, without photophobia or phonophobia, associated with nausea and paresthesia of upper limb and right hemiface. With a personal history of migraine and abnormal uterine bleeding. Medicated with oral contraceptives. At physical examination, was hemodynamically stable, conscious, oriented and cooperative, with right Barré and non-upper limb myotatic hyperreflexia. Without facial dysmetria and no change in eye movements.

Computed tomography (CT) angiography and venography of brain have shown venous thrombosis of 1/3 of the right transverse sinus, 1/3 posterior of the superior longitudinal sinus, as well as, 1/3 of the upper longitudinal sinus. Analytical exclusion of autoimmune pathology and thrombophilia. Accompanied in consultation of Vascular Risk, having completed 6 months of hypocoagulation

initially with warfarin but for labile INR, changed to edoxaban (60 mg daily).

In elective diagnostic cerebral angiography, was identified a dural arteriovenous fistula that results of the anastomosis of external carotid artery, muscular ramifications of the right vertebral artery, meningeal branches of right upper cerebellar artery with anterograde traction for the left transverse sinus and reflux to the superior sagittal sinus.

She underwent elective endovascular therapy, without intercurrents.

Discussion

Intracranial arteriovenous fistulae constitute a heterogeneous group of vascular malformations, constituting 15% of all malformations. From the anatomopathological point of view, they correspond to the anastomosis between the male arteries and the dural venous sinus. Clinically, this type of malformation may present with more aggressive symptoms to intracranial hypertension, relatively benign symptomatology or even incidental findings. In the literature, this malformation is present in about 1.6% of patients with central venous thrombosis.

WERNICKE'S ENCEPHALOPATHY – THE CLASSIC TRIAD

Vânia Mendes Junqueira¹, Tânia Lampreia², José Vale²

¹ Centro Hospitalar do Oeste - Hospital de Caldas da Rainha, Caldas Da Rainha, Portugal

² Hospital Beatriz Ângelo, Loures, Portugal

Introduction

Wernicke's encephalopathy (WE) is a neurological disorder characterised by a triad of oculomotor changes, ataxia, and confusion. Is caused by thiamine deficiency mostly due to chronic alcoholism, but other etiologies have been described. Neuropathology shows a hemorrhagic necrosis in the mammillary bodies, tegmentum of pons, periaqueductal area and the dorsal medial nucleus of the thalamus.

Case description

The authors present the case of a 37 years old male, who was brought to the ER because of strange behavior. He had an important history of chronic alcohol consumption and a mild depressive syndrome in treatment. He referred a generalized fatigue that began 2 weeks before and since that wasn't able to get out of his home. In consequence no alcohol or food intake occurred during this period.

At admission the patient was awake, bradypsycic and unable to sustain attention. He had an ataxic gait, an exuberant horizontal-rotatory nystagmus and a franc limitation in abduction and adduction of both eyes. He reported distal hypoesthesia of the four limbs. Apart from dehydrated and malnourished, the physical examination was normal. Blood tests showed a slight leukocytosis.

Brain CT-scan showed no abnormal findings. At this point WE was very likely so the patient begun immediately thiamine EV. The following diagnostic workup showed a normal serum thiamine level (8.9 mcg/dL), but after thiamine supplementation had began; a folic acid and vitamin B12 deficit; and a negative screening for HIV and syphilis. The lumbar puncture showed no albuminocytological dissociation or pleocytosis. Anti-GQ1b IgG antibody and the microbiological study of CSF was negative. A Brain MRI was unremarkable

We also performed an EMG with the results suggesting a moderate left carp tunnel syndrome and a bilateral L3-L4 and L5-S1 neurogenic compromise. The CT scan of the lumbar spine showed some degenerative alterations without neurologic compression.

A remarkable improvement was seen during hospitalization, presenting at discharge only a slight limitation at abduction of both eyes, a minor nystagmus and the gait ataxia had also diminished.

Discussion

This classic triad in this clinical context should prompt immediately to IV thiamine as WE is associated with a high mortality rate with delayed treatment. Brain MRI can be normal. The frank improvement after a few days of treatment also corroborates our hypothesis. No full recovery was seen probably because of the delay in searching medical advice.

#1721 - Case Report

HYPERBARIC OXYGEN THERAPY IN THE TREATMENT OF CENTRAL RETINAL ARTERY OCCLUSION: A CASE REPORT

Helena Greenfield¹, Cátia Gaspar², Rita Gonçalves¹, Óscar Camacho¹, Lílíana Carneiro¹

¹ Hospital Pedro Hispano, Matosinhos Local Health Unit, Matosinhos, Portugal

² Instituto Português de Oncologia, Porto, Portugal

Introduction

Acute persistent visual loss, defined as a sudden deficit in visual function lasting more than 24 hours, can be caused by etiologies in three main categories: media, retinal, or neural pathway problems. An etiological determination is essential, since some causes, such as central retinal artery occlusion (CRAO), require immediate treatment.

Case description

The authors present the case of a 21-year-old male, who reported to the Emergency Room with sudden, painless vision loss of the right eye (OD), which had started 1 hour previously. His best visual acuity (VA) was hand motion of the OD, preserved in the left eye. Relative afferent pupillary defect was excluded. Biomicroscopy of both eyes was normal. Optical coherence tomography revealed incipient edema of the internal retinal layers of the OD. Retinography with retinal paleness. No further alterations on neurological examination were documented.

Cranial computed tomography angiography scan was normal. A clinical diagnosis of central artery branch occlusion was made, intravenous thrombolytic therapy was performed, with no objective improvement in VA and the patient was referred to hyperbaric oxygen therapy (HBOT), which was started within 7 hours of symptom development. There was a clear notion of VA improvement and upon ophthalmologic evaluation after 5 sessions with VA 3/10 OD and Goldmann visual field (GVF) with central scotoma OD. He completed HBOT with total VA recovery, and GVF with marked improvement.

Discussion

CRAO is an ophthalmological emergency, with longer blood flow interruption leading to severe retinal damage and irreversible vision loss. Therefore, prompt diagnosis and intervention are vital. Traditional therapies, however, have no proven clinical benefit HBOT has emerged as a potential sight-saving procedure when employed in the acute phase, the rationale for its efficacy is related to the retinal dual blood supply. Current knowledge suggests an early administration of HBOT is essential, with the time between onset and the start of oxygen therapy being critical in preserving visual acuity. There is a threshold beyond which retinal cells can no longer recover, so patients presenting within the first 24 hours of symptom onset should be promptly referred to HBOT. A recent meta-analysis of HBOT was shown to achieve visual acuity improvement and was associated with favorable critical outcomes. The authors present this case report as further evidence of HBOT efficacy.

#1726 - Case Report

A 35-YEAR-OLD MALE WITH CLINICALLY ISOLATED SYNDROME OF MULTIPLE SCLEROSIS

Ricardo Gomes¹, Isabel De La Cal Caballero¹, José Proença¹, Luís Abreu², André Leitão², Marta Arenga², Leopoldina Vicente¹

¹ Internal Medicine Service - Centro Hospitalar Universitário Cova da Beira, Covilhã, Portugal

² Neurology Service - Centro Hospitalar Universitário Cova da Beira, Covilhã, Portugal

Introduction

Multiple sclerosis (MS) is the most common immune-mediated inflammatory demyelinating disease of the central nervous system (CNS). The cause of MS remains unknown and there are no unique clinical manifestations but a typical patient is a young adult with one or more episodes of CNS dysfunction, such as unilateral optic neuritis, focal brain syndrome, focal brainstem or cerebellar syndrome, or partial myelopathy during more than 24 hours and without infectious or traumatic cause.

Case description

A male patient 35 years old reached emergency service complaining of sudden decrease of strength on the right

hemibody causing gait impairment and transient dysarthria with 24 hours of evolution. Complaints of diplopia, headache, visual changes, trauma, fever or constitutional symptoms were absent. The neurological exam revealed right central facial palsy, mild dysarthria, right hemiparesis (muscle strength on MRC scale: 3 proximally, 4 distally), generalized myotatic hyperreflexia, right hemiplegic gait and flexor cutaneous plantar reflexes bilaterally. Brain CT-Scan revealed white matter hypodensities bilaterally more evident on the right corona radiata and juxtatrigenal. On the 5th day, brain and spinal cord MRI revealed: «Intense signal in T1 after contrast in juxtaventricular and juxtatrigenal location, left internal capsule, with diverse dimensions as in left corona radiata, hyperintense in T2 and hypointense in T1, some lesions were gadolinium-enhanced. In the C1-C2 segments was seen a small hyperintense lesion in T2 and T2 STIR revealing the right lateral area with well-defined limits and without mass effect signifying probable active inflammatory disorder. Lumbar puncture showed oligoclonal IgG bands, absent in the serum. Infectious CNS and vascular studies were normal. Assuming MS we began acute relapse treatment with 1000 mg methylprednisolone intravenous for five days with almost complete remission of the symptoms while following motion rehabilitation daily.

Discussion

MS is a heterogeneous disorder with variable clinical and pathologic features reflecting different pathways to tissue injury. The diagnosis of MS can be made when they present with a first clinical attack (id est, a clinically isolated syndrome) if a single MRI obtained at any time shows dissemination in space and, as evidence for dissemination in time, by the simultaneous presence of gadolinium-enhancing and nonenhancing lesions. Intravenous high doses steroids are the most used treatment in acute relapses of MS.

#1731 - Case Report

HEMIBALLISM AS A PRESENTATION OF ACUTE STROKE IN YOUNG ADULT

Joana Fontes, Inês Grenha, Elsa Araújo, Manuel Barbosa, Joana Silva, Bárbara Sousa, José Carlos Veloso, Paula Brandão
ULSAM - Hospital Conde de Bertandos, Ponte De Lima, Portugal

Introduction

Movement disorders are a rare presentation of acute stroke with an estimated prevalence at approximately 1%. The most common vascular dyskinesia is hemiballism/hemichorea.

In most cases, the lesions are due to small vessel cerebrovascular disease in the middle or posterior cerebral artery territories, involving the contralateral subthalamic nucleus (STn). Occasionally, lesions are found outside of the STn, including the caudate nucleus, putamen and thalamus.

Case description

A 45-year-old man, with a past medical history of dyslipidaemia, hypertension, alcohol abuse and smoking, presented to the

Emergency Department (ED) with a history of sudden onset of involuntary, irregular and high-amplitude movements of his left upper extremity for around 2 hours with posterior transitory paraesthesia of his left hand.

In the ED, the patient was hemodynamically stable and afebrile. Neurological examination was normal. His laboratory results, including blood sugar were normal, the ECG was in sinus rhythms and the computed tomography scan of the head didn't reveal any acute ischemic lesion. For the clinical suspicion of transient ischemic attack, the patient was treated with one dose of aspirin 300 mg. He was hospitalized in a stroke unit for further investigation.

During the hospitalization, the neurologic deficits did not recur. The complementary laboratory study revealed hyperlipidemia and excluded inflammatory/infectious or hematologic disorders. The electroencephalography didn't show epileptiform activity and the carotid ultrasound was normal. In the magnetic resonance imaging was described ischemic lesions in the right middle cerebral artery territory involving the posterior limb of internal capsule and the caudate and lenticular right nucleus. Echocardiogram didn't detect any potential cardiac source of stroke and holter monitoring didn't identify occult paroxysmal atrial fibrillation.

The aetiology of this acute ischemic stroke presented as hemiballism was established as cerebral small vessel disease. The patient was discharged to home with aspirin 100 mg and high potency statin and motivated to change his lifestyle habits. No further episodes occurred at 1-year follow-up.

Discussion

We report a case of a hemiballism resulting from an acute unilateral caudate lesion which improved spontaneously and didn't require pharmacotherapy. Long-term prognosis in post-stroke hemiballism is generally good and the control of vascular risk factors is crucial in reducing the recurrence.

#1744 - Case Report

DIAGNOSIS DIFFERENTIAL OF A CONVULSIVE STATUS EPILEPTICUS

Giovana Clare Sousa Ennis, Joana Silva Marques, Joana Correia, Bruno Barbosa, Inês Barros, Ana Albuquerque, Rui André
Tondela-Viseu Hospital Centre, Viseu, Portugal

Introduction

The authors present a clinical report of a female patient admitted in the Intensive Care Unit (ICU) with the diagnosis of convulsive status epilepticus, and the diagnostic rationale behind the therapeutic choices that led to her clinical recovery.

Case description

The authors present the case of a 70 year-old female patient, with a history of hypertension, atrial fibrillation and depression and no history of epilepsy or seizures during infancy. In the three previous weeks before hospitalization, she had experienced

adynamia, apathy, memory loss and mood changes, being mainly more depressed having been recently medicated with fluoxetine 20mg. The patient had been hospitalized with the diagnosis of symptomatic normovolemic hyponatremia in the form of generalized tonic-clonic seizures. Although the ionic disorder was corrected the patient maintained frequent seizures, culminating in the absence of recovery of the state of consciousness and transfer to the ICU. The electroencephalogram (EEG) performed was suggestive of status epilepticus. As the patient presented a maintained status epilepticus despite the correction of the hyponatremia, a thorough aetiological study was performed, including a cerebral MRI that excluded structural causes and ruled out central pontine myelinolysis. Cerebrospinal fluid study, including biochemical analysis and virus and bacterial identification was negative. Antiepileptic medication with levetiracetam, sodium valproate and clonazepam was titrated with no new epileptic events or epileptic activity in EEG. Due to neurological stability, weaning of sedative medication and extubation was performed successfully. However, the patient presented an oscillating state of consciousness, ranging from coma to spontaneous reversal, without new alterations in EEG or imaging tests. At this stage the authors suspected of paraneoplastic or autoimmune encephalitis. Given this hypothesis, treatment trial with 1 g of methylprednisolone daily was initiated with significant neurological improvement, and no new episodes of altered state of consciousness.

Discussion

The exclusion of infectious, structural and ionic causes for status epilepticus in adults with no history of epilepsy, should lead to consider the existence of less frequent causes, namely autoimmune or paraneoplastic aetiologies. In clinical practice, diagnostic confirmation isn't usually available before initiating treatment, so diagnostic suspicion is essential for adequate treatment of these patients.

#1752 - Case Report

BRAIN TUMOUR, THE ETERNAL DOUBT: PRIMARY VERSUS SECONDARY?

Miguel Borges Da Silva, Albina Moreira

Hospital Pedro Hispano, Unidade Local de Saúde de Matosinhos, Matosinhos, Portugal

Introduction

Primary tumours of the central nervous system (CNS) have a low incidence in adults, while brain metastases account for more than half of the brain tumours in this age group. Clinical manifestations are diverse depending on the site of the invaded brain. Treatment and prognosis are dependent on the histology of these tumours.

Case description

A 74-year-old woman hospitalized for the study of brain lesions suggestive of neoplasia. The patient presented a clinic with a

2-week evolution of behavioural changes (adynamia, emotional lability, apathy and mnemonic alterations) associated with intense bilateral frontal headaches. Documented at the objective examination: bradifrenia, poor speech, inattention, signs of frontal (palmomentonian on the left and bilateral grasping), some neglect of the left hemibody and ideomotor apraxia in the left limbs. During hospitalization, the patient maintained the same clinical manifestations with increasing adynamia and apathy. She performed nuclear magnetic resonance imaging (MRI) that showed several intracranial lesions (at the level of the corpus callosum and cortico-subcortical and periventricular regions of right predominance) suggestive of primary cerebral neoplasm (glioma), and it was not possible to exclude brain metastases. The study for primary systemic neoplasm as well as cerebrospinal fluid cytology was negative. Stereotactic biopsy showed glioblastoma multiforme.

Discussion

The study of brain tumours in the older population almost always involves the exclusion of primary systemic neoplasm. Although imaging techniques often provide information suggesting a specific histology, biopsy remains essential for the diagnosis and therapeutic orientation of primary CNS tumours. This clinical case is intended to highlight this fact.

#1753 - Case Report

MAGNETIC RESONANCE IMAGING (MRI) TOO SOON – A CASE OF SPORADIC CREUTZFELDT-JAKOB DISEASE (CJD) WITH NORMAL MRI

Pedro Leite Vieira¹, Mariana Ribeiro Santos², Margarida Rodrigues², Álvaro Machado², Sofia Rocha²

¹ Amato Lusitano Hospital, Castelo Branco, Portugal

² Braga Hospital, Braga, Portugal

Introduction

CJD is the most common human prion disease. With a prevalence of 1:1000000 worldwide is a rare, fatal, neurodegenerative disorder included in the group of spongiform encephalopathies, counting the sporadic form (sCJD) for 85-90% of the cases. Typically affects patients in the 70th decade, but could be seen in younger or older (>80s) ones. The most frequent clinical presentation is a rapidly progressive cognitive decline associated with other neurologic manifestations (ataxia, myoclonus, akinetic mute state) according to the location of lesions. The mean survival is 6 months and over 90% of patients die within a year of symptoms onset.

Case description

82-year-old man, previously independent, with history of type 2 diabetes, arterial hypertension, dyslipidaemia and treated prostate adenocarcinoma was admitted to emergency room. His daughter referred a 4-week history gait ataxia, dysarthria and lack of memory for recent facts. At that moment, was unable to drive or walk and needed total help on his daily life activities. Neurologic

examination: disoriented, bilateral intention tremor, finger to nose test dysmetria, stood on a broad base and was unable to walk, despite support. No further changes on physical examination and laboratory tests. The first MRI showed cerebral atrophy and T2 unspecific hyperintensities of subcortical frontoparietal white substance bilaterally. Electroencephalogram: basal activity α 8Hz and no paroxystic activity. Positron emission tomography suggested Alzheimer Disease or Lewy body dementia. Neoplasm, infection, autoimmune diseases, ammonia encephalopathy and lesions of posterior column of spinal cord were excluded. Given the patient clinical deterioration, aphasia, myoclonus and totally bedridden, MRI was repeated and revealed areas of hyperintensity in T2/FLAIR and diffusion restriction on basal ganglia and both thalamus. Tau protein 3800 pg/mL (N<335 pg/mL), phospho-Tau protein 85.3 pg/mL (N<51 pg/mL) and 14.3.3 protein weak positive. As expected, patient died after 4 months.

Discussion

The case reported meets the diagnostic criteria for definite sCJD: clinical, laboratory and imaging findings. It is a very uncommon presentation due to patient's age, but mostly due to the late imaging findings. It also shows the extreme importance of family symptoms description, patient's clinical evolution, as well as clinical suspicion of the most likely diagnosis.

ISCHEMIC STROKE, BLAME THE INFECTED HEART

Alexandra Prizal Pousinha, Madalena Paulino, Ana Palricas, Ana Nunes Rocha, João Seabra Barreira, José Barata
Hospital Vila Franca de Xira, Vila Franca De Xira, Portugal

Introduction

Infective endocarditis is associated with significant cardiac and noncardiac morbidity. Among many complications, septic embolism has the potential of causing devastating sequelae and even life-threatening clinical situations. As the case presented, ischemic stroke, is frequently a result of embolization to the middle cerebral artery, although any arterial cerebral territory may be affected.

Case description

A 75 years old woman, presents do the Emergency Department with fever and prostration.

Relevant past medical history was hypertensive cardiomyopathy and breast cancer in remission. She was admitted to the enfermary with respiratory infection, and on the fourth day, Escherichia coli came positive on blood cultures, sensible to antimicrobial therapy. During the period of hospitalization, a severe clinical deterioration was observed, with loss of conscience and conjugate gaze palsy to the right, as well as right leg paralysis.

The brain computerized tomography imaging showed right medial temporal and occipital corticossubcortical hypodensity, suggestive of acute ischemic lesion of the right posterior cerebral artery.

Attending the isolation of E.coli in blood cultures, a transthoracic echocardiography was performed, which revealed an image suggestive of a vegetation on the posterior mitral valve leaflet (>12 mm in size), without significant functional repercussion. She was then transferred to the Stroke Unit in the Hospital, and went through magnetic resonance imaging which demonstrated multiple cerebral supra and infratentorial infarctions, whose major lesions were seen in right occipital area, as well as left cerebellum hemisphere, suggestive of cardioembolic origin.

Atransesophageal echocardiogram was contraindicated by the time, given the clinic instability, as the patient developed acute cardiac insufficiency. The cardiac surgery team was also approached for the possible removal of the cardiac vegetation, but the deteriorating status, with respiratory failure and increased oxygen uptake, was decided that any intervention should be delayed. The clinic state aggravated and the patient died on the 22^o day of hospitalization.

Discussion

This case demonstrates that septic cerebral embolization, manifesting as an ischemic stroke, is the most frequent neurologic complication of the infective endocarditis. Many of these lesions are usually asymptomatic, since they are only visible in magnetic resonance imaging (gold standard diagnostic imaging) which can delay the diagnosis.

#1820 - Case Report

A CASE REPORT OF MARCHIAFAVA-BIGNAMI DISEASE

Ivo Castro, Adelaide Figueiredo, Maria Cristina Esteves, Luís Siopa
Hospital Distrital de Santarém, Santarém, Portugal

Introduction

Marchiafava-Bignami is a rare disease characterized by demyelination of the corpus callosum and high mortality rate. It is associated with toxics exposure or nutritional deficit and it's present at patients who have chronic alcohol abuse. Clinically this disease is more frequent in male patients, older than 45-years-old and manifest itself with neurocognitive defects or seizures and goes from mild deteriorating to comatose state. MRI is essential for diagnosis.

Case description

We present a case of a 55-years-old men with history of chronic alcohol abuse with epilepsy associated. Other comorbidities were arterial hypertension, dyslipidemia and insulin-treated type 2 diabetes. The patient was admitted at the hospital with a progressive aggravation in the previous three months with the ascites, asthenia, food refusal, prostration and slow speech, confusing state. After an initial study that presented normal levels of INR, AST, ALT, LDH and ammonia at analytical serum study, normal lumbar puncture and normal head CT scan, the patient was admitted to the ward where he was treated with thiamine and supportive therapy. More studies were conducted as a magnetic resonance imaging which demonstrated changes compatible with

the progression of atrophy and demyelination of the body callus known as Marchiafava-Bignami. The patient died 33 days after in a comatose state and with hospital acquired pneumonia.

Discussion

Although Marchiafava-Bignami's disease is rare, it is associated with high mortality. So we should be aware when patients with a history of alcohol abuse present with neurological changes that are not compatible with clinical and laboratory status.

MOYAMOYA DISEASE

Cátia Carvalho, Daniana Condado, César Vieira, Joana Diogo, Rita Monteiro, Carolina Coelho, Rita Bizarro, Angela Ghilechi, Maria Helena Pacheco, Lurdes Venâncio Pereira, Conceição Loureiro
Centro Hospitalar Universitário de Lisboa Central - Hospital Santo António dos Capuchos, Lisboa, Portugal

Clinical summary

MoyaMoya Disease, also known as spontaneous occlusion of the circle of Willis, is a rare chronic cerebrovascular disease of unknown etiology and is an important cause of non atherosclerotic intracranial arterial disease, characterized by steno-occlusive changes at the terminal portion of the internal carotid artery and an abnormal vascular network. The clinical manifestations include ischemic or hemorrhagic vascular events, seizures, involuntary movements, headache and cognitive impairment. These images are from an 58 year-old portuguese female with a transient involuntary movements of the upper limbs and progressive cognitive impairment. The AngioMR that reveals vascular alterations in agreement with the typical MoyaMoya alterations. Nowadays she is waiting for surgery.

#1886 - Case Report

REVERSIBLE POSTERIOR LEUKOENCEPHALOPATHY SYNDROME (RPLS) - A CASE REPORT

Sofia Ramos Gonçalves, Rafael Dias, Patrício Freitas, Rafael Freitas, Pedro Balza, Maria Luz Brazão
Hospital Central do Funchal, Funchal, Portugal

Introduction

Reversible posterior leukoencephalopathy syndrome (RPLS) is a clinical radiographic syndrome of heterogeneous etiologies. The

syndrome is not always reversible, and it is often not confined to either the white matter or the posterior regions of the brain. Case series suggest that it is more common in women. The symptoms of RPLS evolve rapidly over hours to days. Hypertension is frequent but not invariable. The hypertensive crisis may precede the neurologic syndrome by 24 hours or longer. The clinical syndrome of RPLS is characterized by headaches, altered consciousness, visual disturbances and seizures. Neuroimaging is essential to the diagnosis of RPLS.

Case description

62-year-old female with a history of arterial hypertension and chronic obstructive pulmonary disease. She presented in the emergency department with complaints of severe headache, over the previous 20 minutes. She mentioned headaches over the previous week. On observation her blood pressure was 197/112 mmHg. While being evaluated the patient presented deviation of both eyes to the left and involuntary movements of the superior upper limb, that rapidly evolve to a generalized tonic-clonic seizure. A noncontrast head computed tomography scan (CT) was performed and showed no significant alterations. She was admitted in the acute stroke unit and performed a noncontrast brain magnetic resonance imaging (MRI) which showed presence of bilateral parietal subcortical and periventricular focal areas of enhanced signal, compatible with RPLS. Over the first days of hospitalization she maintained elevated blood pressure with need for high doses of antihypertensive medication and altered state of consciousness alternating between periods of mild somnolence and periods of confusion and agitation. On the tenth day of hospitalization, another brain MRI was performed and it showed enlarged areas of enhanced signal on the left cerebellum, suspected of being in relation with a stroke/irreversible lesion. After stabilization and improved clinical status, she was transferred to the neurology department.

Discussion

RPLS should be promptly recognized, since it is usually reversible with appropriate management. Clinicians should have a high clinical suspicion, recognize the neurologic syndrome and evaluate for RPLS with brain magnetic resonance imaging (MRI), particularly when evaluating this patients in the emergency department.

#1894 - Case Report

RECURRENT NEUROLOGIC SYMPTOMS - WHAT IS THE CAUSE?

Sofia Gonçalves, Pedro Balza, Luz Brazão
Hospital Central do Funchal, Funchal, Portugal

Introduction

Brain tumors originate in different cells of the central nervous system (CNS) or in systemic neoplastic cells that metastasize to the CNS. The signs and symptoms may be caused by compression of adjacent structures or by increased intra-cranial pressure. High-grade gliomas are malignant and rapidly progressive brain tumors.

Case description

49-year-old female, previously healthy. She was taken to a primary health care facility due to complaints of paraesthesias of the upper right limb and right hemiface, with spontaneous regression. On suspicion of a transient ischemic event she was medicated with clopidogrel. Six days after this event, she presented recurrence of the symptoms. Ten days after the initial episode, she presented

in the emergency department of a central hospital complaining of recurrence of the symptoms but this time associated with dizziness and decreased muscular strength in the right upper limb. Neurological examination performed showed a decrease in muscle strength in the right upper limb (grade 3+/5). A cranioencephalic computed tomography scan was performed and revealed a "left, cystic-necrotic lesion of aggressive characteristics and significant perilesional cerebral edema compatible with glioblastoma". She was admitted to the Neurosurgery department in order to perform diagnostic brain magnetic resonance imaging and surgical planning. The examination of the brain tissue excised during the surgery revealed it to be a glioblastoma multiform (grade IV).

Discussion

Symptoms caused by high-grade gliomas usually develop over days to weeks and, at an early stage, may mimic other pathologies (such as cerebrovascular disease). Therefore, the authors believe they should be taken into account when evaluating patients with neurological complaints.

#1911 - Case Report

VENOUS SINUS THROMBOSIS IN CEREBRAL VEINS AND VENOUS HEMORRHAGE IN POSTPARTUM PERIOD

Lauma Dobelniece^{1,2}, Nauris Zdanovskis¹, Ligita Belasova²

¹ Riga Stradins university, Riga, Latvia

² Vidzemes Regional Hospital, Valmiera, Latvia

Introduction

Compared to arterial diseases, cerebral venous sinus thrombosis (CVST) is rarely seen cause of cerebral infarction. The diversity of clinical symptoms, etiology and radiology findings, makes it less recognizable at the initial presentation. The risk factors of CVST described in literature are trauma, surgery, infections, malignancy, transitory hypercoagulation states (dehydration, oral contraceptives, pregnancy), or permanent hypercoagulability from genetic causes, or it can occur spontaneously.

Case description

A 31-year-old patient, woman, 17 days postpartum, complained about severe headaches for a week and nausea with vomiting. Patient referred that the headaches were the "worst ever" she experienced. For the last 3 days before arriving at the emergency room (ER), the pain was localized more on the left side of the head. A head CT scan was performed and small arteriovenous malformation on the left temporal lobe was described by radiologist. No signs of thrombosis or hemorrhage were seen. Patient was discharged home to continue treatment and examination on outpatient basis. Three days later, she was re-admitted to ER with aphasia (motor>sensor), right side dysmetria and continuous headaches on the left side. Glasgow coma scale – 13/14 points, NIHSS – 6/7 points, mRS – 3 points. MRI head scan revealed sagittal sinus thrombosis, venous hemorrhagic infarction

on the left temporal lobe, small subarachnoid hemorrhage. Patient was hospitalized in neurology ward stroke unit. The laboratory results showed anemia (9.5mg/L), positive ANA, ENA, elevated APCR levels, positive SS-A/Ro60, questionable results of SS-A/Ro52, cytosin in CSF – 12/mm³ with raised lymphocyte count. Patient had no records of other diseases or positive family history, but she had home labor with serious blood loss with no further hospitalization. Patient received anticoagulants, symptomatic therapy, physiotherapy and rehabilitation. Systemic lupus erythematosus diagnosis was suggested by rheumatologist and therapy with hydroxychloroquine was started. Patient had a good recovery with no known neurological deficit and symptom recurrences.

Discussion

Cerebral venous thrombosis is a challenging diagnosis for both – radiologists and clinicians. The changes in CT scan are not always properly seen or interpreted, but the availability of MRI scan usually in ER stage is limited. The proper anamnesis and possible risk factor clarification could help to overcome these difficulties.

#1948 - Case Report

POSTPARTUM STATUS EPILEPTICUS – WHAT IS THE CAUSE?

Sofia Gonçalves, Rafael Dias, Pedro Balza, Duarte Noronha, Teresa Carolina, Armando Morganho, Orlando Sousa

Hospital Central do Funchal, Funchal, Portugal

Introduction

Cerebral vein and dural sinus thrombosis (CVT) is less common than most other types of stroke but can be more challenging to diagnose. Because of its myriad causes and presentations, CVT is a disease that may be encountered not only by neurologists and neurosurgeons, but also by emergency clinicians, internists, amongst others. It is more common in women than men and both pregnancy and the puerperium are amongst the most frequent risk factors for CVT. The pathogenesis of CVT remains incompletely understood and it has a highly variable clinical presentation, headache being the most frequent symptom.

Case description

27-year-old female, previously healthy, presented to the emergency department, one week after delivery, with complaints of paresthesias of the right upper limb of spontaneous resolution and subsequently two, short duration, episodes of seizure, with slow recovery of the state of consciousness, over de previous 24 hours. She also reported cervical-occipital pain that worsened with the supine position and improved when lying down, ever since the postpartum, with no response to analgesia. Neurological examination she presented mydriatic and slowly reactive pupils and unintentional spontaneous movements of the four limbs. A cranioencephalic computed tomography scan was performed and revealed “extensive venous thrombosis of the longitudinal sinus

with venous ectasias in their proximity”. After the examination, the patient presented two generalized tonic-clonic convulsive seizures and one focal convulsive seizure, without complete recovery of the state of consciousness between them and therefore considered to be status epilepticus. Given that the patient was sub-febrile and the study of group B streptococcus, performed peri-partum, was positive, a lumbar puncture was performed and a central nervous system infection was excluded. Anti-epileptic medication and hypocoagulation with enoxaparin was initiated. During hospitalization, transition to warfarin was performed, with a good response. From the etiologic study carried out, the authors highlight the presence of a heterozygotic mutation in the prothrombin gene.

Discussion

Although uncommon, CVT is an important diagnostic to be considered in the etiologic evaluation of recent onset headache. Therefore, the authors consider essential that a thorough, holistic and multidisciplinary approach should be implemented in the treatment of these patients.

#1963 - Case Report

AUTONOMIC DYSREFLEXIA: A FORGOTTEN BUT POTENTIALLY LIFE-THREATENING CONDITION

Alexandre N. Fernandes¹, Maria Inês Vicente^{1,2}, Fredo Renato Silva¹, Ana Paula Antunes¹, Tânia Strecht¹, Carolina Sepúlveda¹, Jana Zelinová¹, Mónica Bettencourt¹

¹ Hospital de Cascais, Cascais, Portugal

² IPO Lisboa, Lisbon, Portugal

Introduction

Autonomic dysreflexia (AD) is a potentially life-threatening syndrome that develops as a complication after spinal cord injury, usually at or above the level of T6. This clinical entity is a paroxysmic dysregulation of the autonomic nervous system due to unmodulated sympathetic reflexes below the injury level in response to noxious or innocuous stimuli. In 85% of cases, the triggers are related with bladder distension and fecal impaction. AD consists of a constellation of signs and symptoms that culminate in marked hypertension. If not recognized and promptly treated it can lead to serious complications, such as seizures, cerebral hemorrhage and eventually death. Several studies showed that medical staff knowledge and awareness is severely lacking in this area.

Case description

A 47-year-old male, residing in a long-term care facility, with medical history of spinal cord injury (C4 level), with subsequent spastic paraplegia, was admitted to our emergency department with a pulmonary infection with global respiratory failure and was given IV antibiotic. Four days after admission he had an episode of severe anxiety associated with diaphoresis and feeling of

impending doom. During this episode he sustained a rise in blood pressure of 177/107 mmHg, with a pulse of 86 bpm and pulse oximetry of 74% saturation. Physical examination and laboratory findings were unremarkable. He was administered captopril and ventilatory support and the episode resolved in half an hour. The following day, he had a similar episode and was managed the same way. Since he had no previous history of hypertension no further evaluation was performed and a diagnosis of AD was made. At this time we realized that the patient had been constipated for 4 days. He was given laxative treatment and normal bowel transit was established. Until he was discharged he didn't experience any similar episode.

Discussion

Spinal cord injury is a devastating health problem that poses particular challenges to the physician. It has been observed that the higher the spinal cord injury level occurs, the greater the risk of AD, with up to 90% of patients with cervical spinal or high-thoracic spinal cord injury being susceptible. Identification and elimination of specific triggers is considered the first line of treatment and the use of antihypertensive drugs should be considered a last resort. The authors highlight with this interesting case the importance of the awareness of this condition, to ensure proper and timely management.

#1985 - Case Report

ARNOLD-CHIARI SYNDROME AS A DIFFERENTIAL DIAGNOSIS OF RECURRENT SYNCOPE

Marta Arriaga Rocha, Joana Maurício, Martim Trovão Bastos, Susana Bastos Heitor

Hospital Prof. Doutor Fernando Fonseca, Amadora, Portugal

Introduction

Arnold-Chiari is a group of deformities of the hindbrain. Issues range from herniation of the posterior fossa contents outside of the cranial cavity to absence of the cerebellum with or without other associated intracranial or extracranial defects. Clinical manifestations are varied, and some patients remain asymptomatic until adults. The most common symptoms are neck pain, headache, muscle weakness, numbness, altered sensitivity and imbalance. Syncope is an unusual manifestation but during a valsalva manoeuvre, intracranial pressure increases and syncopes may occur secondary to vertebrobasilar artery compression. The neurological examination helps in the diagnosis and confirmed by MRI.

Case description

A 19-year-old girl, without relevant personal and family medical history or regular medication was hospitalized by episodes of dizziness and repetitive syncope, after physical effort. At admission she was hemodynamically stable, eupneic and without alterations in cardiopulmonary auscultation. A summary

neurological examination showed tactile and painful hyposthesia of the left hemiface and left limbs; fall of the left upper and lower limb in the extended arms and Mingazzini test with muscular strength score 4/5; left dysmetria and adiadococynesia. Analytically within the reference values. Holter, Echocardiogram and Ecodoppler of the vessels of the neck showed no alterations. CT-cranial-encephalic (CE) revealed cerebellar tonsils insinuating themselves in the occipital foramen, with partial erasure of the regional liquor circulation spaces. For clarification, MRI-CE showed ectopy of the cerebellar tonsils, about 6 mm caudal to the anatomical plane McRae. The Arnold-Chiari syndrome was diagnosed. The patient was discharged with indication to avoid physical effort, particularly isometric exercises or associated with Valsalva maneuver. The patient was referenced to neurosurgery consultation for evaluation of surgical necessity.

Discussion

Arnold-Chiari syndrome is a rare entity of great clinical interest due to the diagnostic difficulty since it mimics other conditions in which cerebellar pathologies are involved. Arnold-Chiari malformations should be considered in the differential diagnosis of recurrent syncope, especially if accompanied by headache, vertigo, or transient sensory or motor symptoms in arms or legs. This case report reinforces the importance of a systematized approach to a common symptom.

#1994 - Case Report

SPONTANEOUS HAEMATOMA CAUSING FEMORAL NERVE PALSY – A COMPLICATION IN THE SETTING OF ANTICOAGULATION

Cátia Fava Gaspar, Helena Greenfield, Liliana Carneiro

Hospital Pedro Hispano, Matosinhos, Portugal

Introduction

Haemorrhage is one of the most well-known adverse events associated with anticoagulation, occurring in 1-4% of patients. When it occurs in locations enriched with nervous structures, such as the iliacus muscle, the consequences could be catastrophic.

Case description

The authors present the case of a 64 year old woman, with prolonged hospitalization due to severe rheumatic mitral and aortic valve disease awaiting valvular replacement surgery. She had a history of dyslipidaemia, first-degree atrioventricular block and atrial fibrillation under anticoagulation with warfarin, which was altered during the inpatient period to low molecular weight heparin adjusted to the patient weight. The patient developed symptoms of right groin pain with lower limb irradiation, without any trauma associated. A computed tomography showed iliacus muscle haematoma with 79x49x119mm. An immediate non-surgical drainage was performed as well as suspension of anticoagulation. During the subsequent days, the patient developed progressive weakness of the right lower limb, attributed

to the nerve compression/strain, which was re-evaluated, due to doubts of the necessity of surgical intervention. A conservative approach was decided on, because of the high risk of more vascular/nervous damage due to the local inflammatory process. On imagiological re-evaluation there was reabsorption of the haematoma which permitted reintroduction of anticoagulation, with no further episodes of haemorrhage documented. However, despite the recovery, an electromyography showed very severe axonal damage of the right femoral nerve and the patient presented no clinical recovery during the rest of her hospital stay, being unable to walk autonomously even after the initiation of a tailored rehabilitation program.

Discussion

The ageing of the population is leading to greater co-morbidity in patients and to a higher percentage of anticoagulated patients. This case shows the importance of being alert to the potential adverse effects of this therapy and of the need to be alert to clinical signs that can make us suspect of complications, such as, haematoma formation and of the need for a close collaboration between medical and surgical specialties in order to detect early complications, which allow us to avoid permanent damage, which, was unfortunately not possible in the case presented above.

#2009 - Case Report

INTERAURICULAR SEPTUM ANEURYSM: A RISK FACTOR FOR CRYPTOGENIC STROKE

Pedro Ribeiro Soares, Margarida Mesquita, Tânia Proença, Carla Andrade, Diana Ferrão, Catarina Pereira, Fernando Nogueira, José Marques, Jorge Almeida
Centro Hospitalar de São João, Porto, Portugal

Introduction

Stroke is the second leading cause of death and the third leading cause of disability worldwide. The presence of interatrial septum aneurysm is a rare malformation that is associated with an increased risk of cardioembolic stroke and is more prevalent in patients less than 55 years of age. The main manifestations of this anomaly are arterial embolism and atrial arrhythmias.

Case description

52-year-old male with type 2 diabetes mellitus, hypertension, dyslipidemia, smoking history and rheumatoid arthritis with complaints of left hemiface and left upper limb paresthesias that had spontaneous resolution in less than 24 hours. He performed a CT scan which was consistent with a lacunar ischemic infarction. Transthoracic echocardiogram showed normal cardiac chambers and the presence of interatrial septal aneurysm, multiperforated, without associated thrombi and a positive right-left shunt. The findings were confirmed by transesophageal echocardiography. He started antiplatelet and statin therapy and was discharged from the ward with indication to perform percutaneous correction of the interatrial septum aneurysm.

Discussion

Anomalies of the atrial septum are associated with a higher prevalence of cardioembolic stroke. The presence of uncomplicated atrial septal aneurysm alone does not require specific treatment and only appropriate follow-up. However, the presence of other anomalies (including patent foramen ovale) or paradoxical embolism should be the subject of an individualized evaluation, namely for percutaneous treatment. The increasing recognition of this pathology and its potential association with cryptogenic stroke is critical for the appropriate treatment of these patients.

AN IMAGE IS WORTH A THOUSAND WORDS

Ana Isabel Rodrigues, Rita Martins Fernandes, Domingos Sousa, Nuno Mourão Carvalho, Hugo Calderon, Cristina Granja
Centro Hospitalar Universitário do Algarve - Unidade de Faro, Faro, Portugal

Introduction

An altered state of consciousness (ASC) involves a variable combination of inattention, incoherent speech, disorientation, psychomotor agitation, hallucinations, and disturbance in the sleep-wake cycle.

The differential diagnosis in ASC is a great clinical challenge.

Case description

A 69-year-old woman with a past history of hypothyroidism and arterial hypertension presented to emergency department with a 3-day history of headache, dizziness and nausea.

She brought the result of a head magnetic resonance imaging (MRI), performed in another hospital, reporting acute ischemic injury in the cortex of the insula and in the cortex of the right temporal lobe.

On physical exam she was confused, febrile (39.5°C) and with loss of balance. She was admitted to the ward with the diagnosis of ischemic stroke.

On the fourth day of hospitalization her state of consciousness worsened evolving to a score of 5 in the Glasgow Coma Scale (GCS). A lumbar puncture was performed and the cerebral spine fluid (CSF) analysis showed glucose 85 mg/dl, protein 121 mg/dl and white blood cell count 261/mm³ with lymphocytic predominance. Empiric broad-spectrum were started as well as intravenous acyclovir for suspected encephalitis. She repeated the imaging study supporting the hypothesis of herpetic encephalitis. Two days later the Intrahospital Emergency Medical Team was contacted for a seizure. The patient was then admitted to the intensive care unit with coma of unknown origin probably secondary to encephalitis.

The electroencephalogram (EEG) showed neurophysiological aspects supporting the clinical hypothesis of herpetic encephalitis and a follow-up EEG 9 days later showed worsening of epileptiform activity, even after optimization of antiepileptic

therapy. After completing 21 days of acyclovir and suspension of the sedoanalgesia there was no neurological recovery. The patient remained with a GCS of 3 eventually dying at the 24th day of hospitalization.

Posthumously, the CSF analysis utilizing polymerase chain reaction of herpes simplex virus (HSV) type 1 was found to be positive, confirming the diagnosis.

Discussion

HSV encephalitis is associated with a high morbimortality rate and diagnosis should be made promptly, as the early start of treatment has prognostic implications.

This case report is relevant because the first diagnosis was influenced by an imaging exam that masked the viral encephalitis hypothesis and delaying the vital treatment, highlighting the importance of correct imaging in modern medicine.

MILLER FISHER SYNDROME: CASE REPORT

Raquel Costa¹, Ana Oliveira², Mariana Santos², Joana Braga³, Ana Filipa Santos²

¹ Hospital Conde de Bertiandos, Ponte De Lima, Portugal

² Hospital de Braga, Braga, Portugal

³ Hospital de Santa Maria Maior, Barcelos, Portugal

Introduction

Miller Fisher syndrome (MFS) is a rare variant of Guillain-Barré syndrome (GBS), observed in 1 to 5% of the cases. It is characterized by the acute development of ataxia, ophthalmoparesis, and areflexia.

Case description

A 57-year-old male was admitted to the emergency department with one-day history of progressive gait disorder, dysphonia, dysphagia and paresthesias of the hands. In the week before onset of symptoms he had a mild upper respiratory infection. The patient denied other infectious illnesses or diarrhea. He had no recent vaccinations or travel history, head trauma or unknown bite. There was no history of fever. He had no sphincter dysfunction or diplopia. His past medical history was significant for a monoclonal gammopathy that was being studied for the past 6 years and dyslipidemia medicated with statin. On neurological examination, he was fully alert and oriented to time, place, and person with an intact memory. He had bilateral ptosis and severe supraversion palsy. No facial muscle asymmetry was noticed. His soft palate elevated poorly and he had no gag reflex. There was no sensory or motor deficit in the limbs. A global areflexia was present. The plantar response was flexor. He displayed significant dysmetria on heel-to-shin testing, with gait unsteadiness. Laboratory studies revealed normal complete blood count, comprehensive metabolic panel, thyroid stimulating hormone and cardiac markers; the erythrocyte sedimentation rate was 36 mm/hour. A lumbar puncture was performed, and the cerebrospinal fluid (CSF) analysis

was normal. A possibility of MFS was entertained and intravenous immune globulin (IVIG) was started. Investigation was completed with brain magnetic resonance that showed no evidence of acute infarction or other alterations, and electromyography that revealed signs of axonal sensory neuropathy. The test for anti-GQ1b antibodies and campylobacter were being analyzed at the time of discharged. The patient completed IVIG for 5 days and significant clinical improvement was noticed. At the time of discharged he had normal neurologic exam, being able to ambulate alone.

Discussion

The authors intend to emphasize the importance of an early diagnosis, since if MFS is identified and correctly treated the prognosis is good.

THE CHALLENGING DIFFERENTIAL DIAGNOSIS OF DEMYELINATING DISEASES

Mariana Ferreira De Almeida¹, Pedro Oliveira Monteiro¹, João Calvão¹, Daniel Ferreira², Maria Inês Matos¹, Luís Nogueira-Silva^{1,3}, Maria Teresa Cardoso¹, Jorge Almeida¹

¹ Internal Medicine Department, Centro Hospitalar São João, Porto, Portugal

² Neurology Department, Centro Hospitalar São João, Porto, Portugal

³ CINTESIS - Center for Health Technology and Services Research, University of Porto, Porto, Portugal

Introduction

Acute disseminated encephalomyelitis (ADEM) is a rare autoimmune demyelinating disease, frequently triggered by viral infections or vaccination. An acute and often rapidly progressive cerebral and spinal cord inflammatory reaction occurs, leading to severe morbidity if not promptly treated.

Case description

A 37-year-old woman, with a history of conization for cervical high-grade squamous intraepithelial lesion, recently vaccinated against human papillomavirus and that reports a respiratory tract infection in the previous month, was brought to the emergency department due to a 3-day headache, urinary retention and constipation. Her husband reported progressive confusion and imbalance.

Her neurological examination showed motor aphasia, inferior limbs paraparesis (proximal dominance) and progressive dysesthesia from T6 level to inferior limbs. The bloodwork was unremarkable; besides a slight protein elevation, the cerebrospinal fluid cytology was normal and the viral meningoencephalitis panel was negative. The cerebral CT scan revealed multiple white matter hypodense lesions, interpreted as meningeal carcinomatosis, reason why she was admitted the Internal Medicine Department. Subsequently, a brain and spinal MRI depicted inflammatory/demyelinating lesions in both cerebral hemispheres, with medullar extension between

T6 and T12 levels, compatible with the diagnosis of ADEM (not suggestive of multiple sclerosis (MS), not excluding neuromyelitis optica (NMO)). Immunologic study (ANA, ANCA, anti-neuronal antibodies, anti-ENA antibodies) was negative; however anti-AQP4 and anti-MOG antibodies are still pending.

Immunosuppressive therapy was instituted with methylprednisolone pulses for 5 days, followed by six daily plasmapheresis sessions. The patient had notorious clinical improvement and was discharged without significant aphasia, able to walk unassisted. Nevertheless, disautonomic manifestations were still significant and the patient started self-intermittent bladder catheterization and sphincter control training.

Discussion

ADEM is a rare demyelinating disease posing a challenging differential diagnosis approach, namely with MS and NMO. Although the majority of patients improve significantly after immunosuppressive therapy, full recovery is less frequent and occurs in less than a half of patients. ADEM most frequently presents as a monophasic disease but recurrences and progression are frequent in MS and NMO.

#2113 - Case Report

IT IS NOT ALWAYS A TIA

Catarina Teles Neto, Marta Valentim, Ana Gameiro, Luís Siopa
Hospital Distrital de Santarém EPE, Santarém, Portugal

Introduction

It is estimated that up to 60% of patients referred with a diagnostic hypothesis of transient ischaemic attack (TIA) do not have this diagnosis confirmed. Any causa of transient neurologic symptoms such as migraine, metabolic disorders, drugs, among others, may mimic a TIA.

Case description

A 75 year-old male with systemic hypertension and chronic obstructive pulmonary disease due to smoking, was brought to the Emergency Room because of an acute confusional síndrome lasting for 1 hour. There was no history of trauma or alcohol/drugs consumption. He was conscious and cooperative, but disoriented in person, time and space and dysarthric speech, but no other neurologic déficit; his vital signs were stable and remaining physical exam was unremarkable. Stroke protocol was activated and his head and neck vessels angio-CT had no acute changes. Arterial blood gas and blood tests were within normal parameters, including negative etanol levels. Because of a NIHSS score of 2 he was not submitted to thrombolytic therapy and was admitted to neurological surveillance. Urinalysis then revealed positive for amitriptyline that he had started the week before. Along with drug suspension, progressive clinical improvement was seen over the first 24 hours. Head MRI was performed without any evidence of vascular lesions, so it was considered as a confusional síndrome associated with amitriptyline.

Discussion

Amitriptyline is a tricyclic antidepressant that inhibits serotonin and norepinephrine reuptake; it also has high affinity to histamine H1 and muscarinic M1 receptors. Although rare, the possibility of an acute confusional síndrome associated with the anti-cholinergic effects of this drugs has been described. It is fundamental to look for any iatrogenic cause when we are before a transient neurological condition.

KLEBSIELLA PNEUMONIAE OTOMASTOIDITIS AND MENINGITIS

Inês Vieira Santos¹, Isabel Montenegro Araújo², Catarina Lameiras³, João Gonçalves⁴, Rodolfo Gomes², Rita Faria², Patricia Patricio², António Messias²

¹ Hospital Espírito Santo de Évora, Évora, Portugal

² Hospital Beatriz Ângelo, Lisboa, Portugal

³ Hospital Fernando da Fonseca, Lisboa, Portugal

⁴ Hospital Luz Arrábida, Porto, Portugal

Clinical summary

75-year-old male, history of hypertension and diabetes mellitus, was admitted to the hospital due to a state of consciousness (GCS 10) and fever. Cranioencephalic computed tomography (CE-CT): obliteration of the mastoid and tympanic cavity by tissue component. Lumbar puncture: purulent cerebrospinal fluid (CSF), elevated protein concentration 546mg/dl, hypoglycorrhachia 2mg/dl, and pleocytosis. Evolution in septic shock. Admitted bacterial meningitis and started Ceftriaxone, Ampicillin, and Vancomycin empirically. Subsequently with identification of *K.pneumoniae* in CSF. CE-CT reassessment with otomastoiditis and osteomyelitis with isodense levels of the occipital horns and hydrocephalus. He subject to mastoidectomy with the closure of the liquor fistula with favorable evolution.

TO ANTIPLATELET OR NOT ANTIPLATELET, IS THAT THE QUESTION?

Rita Ribeirinho Duarte, Ana Sousa, Francisco Dias Cláudio, Tiago Tribolet Abreu, Margarida Jacinto
Hospital Espírito Santo de Évora, Évora, Portugal

Clinical summary

A 72-year-old man presented to the emergency (ED) with a 12-hour-long headache and diminished strength in his right leg. 3 months earlier, the patient had a loss of conscience and left body hemiparesia. CT and MRI had no acute changes, a diagnosis of acute ischemic stroke was made and he was discharged with clopidogrel. 1 month later, he suffered a small energy trauma, with no injury. The patient had a GCS of 15 and diminished strength on his right arm and leg. CT revealed chronic left frontoparietal subdural hematoma, a right subphalcial hernia and deleted left cisterns. The patient underwent hematoma drainage. Antiplatelet is a well established therapy, but it is not without risks. If stroke diagnosis is not straightforward, one should consider if risks might outweigh the benefits.

Figure #2168. CT Scan with frontoparietal hematoma and deleted left cistern.

#2170 - Case Report

INFLUENZA H3N1 ENCEPHALITIS – CAN FLUE TAKE OVER YOUR BRAIN?

Rúben Reis, Francisco Pulido Adragãos, Inês Nunes, Armindo Ramos
Hospital de Cascais, Cascais, Portugal

Introduction

Influenza virus infection can have a range of presentations, from asymptomatic to life-threatening disease. Most commonly presented as malaise, myalgia, fever and upper airway symptoms, but it can also present as pneumonia, myocarditis, acute renal failure, liver failure and encephalitis. We report an influenza pneumonia and encephalitis case.

Case description

The authors report a case of a 57 year old woman with history of hypertension, obesity, type 2 diabetes and schizophrenia. Chronically medicated with clozapine 200 mg/day, biperiden 4 mg/day, simvastatin 20 mg/day, indapamide 1.5 mg/day and metformin 1000 mg/day. The patient presented with a week history of flu like symptoms with altered mental status (Glasgow coma score 10), fever (38°C) and dyspnea. Laboratory results showed an elevated C reactive protein (15.85 mg/dL), acute kidney injury (Creatinine 2.04 mg/dL) and positive rapid influenza antigen, arterial blood gas revealed type 2 respiratory failure, and urine and blood tests were negative for benzodiazepine, ethanol and tricyclic antidepressants. Chest X-ray was compatible with pneumonia and head computer tomography was normal. Initially admitted as pneumonia with altered mental status (sepsis) and medicated with oseltamivir and ceftriaxone. The patient's mental status deteriorated to a GCS 3 within 2 days and eventually transferred to the ICU where she was mechanically ventilated. During the ICU stay the patient developed a generalized tonic-clonic seizure after the suspension of propofol. EEG showed epileptiform activity and a lumbar puncture was performed: high opening pressure, glucose 131 mg/dl, white cell count 1/microl; protein 61 mg/dL. Search for inotropic viruses and head magnetic resonance were requested. Both CSF and blood Influenza RNA test were positive for Influenza A H3N1 and oseltamivir was continued for 15 days. Due to improving mental and cognitive status, the isolation of the influenza virus and seizure control with valproic acid and levetiracetam, the brain MRI request was cancelled. The patient made a full recovery by the 30th day of ICU and was transferred to the medicine ward.

Discussion

Although rare, influenza encephalitis should be considered in some specific settings, such as its seasonal epidemics (winter) or in some pandemic settings (H1N1 pandemic in 2009). Even though the symptoms may differ from patient to patient, this diagnosis should be considered when altered mental status or new neurologic symptoms appear in the settings described above.

#2172 - Case Report

FROM A “STROKE” TO AN OVERWHELMING DIAGNOSIS

Salomé Marques, Daniela Neto, Vitor Macedo Silva, Clarisse Neves, Emilia Lopes, Jorge Cotter
Hospital da Senhora da Oliveira, Guimarães, Portugal

Introduction

Glioblastomas are malignant brain tumors with poor prognosis. Its presentation usually occurs in the 70th decade of life and is characterized by symptoms associated with the mass effect of the fast-growing tumor. Some forms of presentation may arise as focal neurological symptoms or as seizures.

Case description

54-year-old male, with no known cardiovascular risk factors, presented with a 3-day history of intermittent paresthesia and paresis of the hemiface and upper limbs. During the hospitalization, some of these episodes were observed and there was also labial commissure deviation. A mild insular hypodensity and ipsilateral parietocorticossubcortical hypodensity were demonstrated in the CT-CE with suspicion of hyperdensifying focus in the M2 segment of the left middle cerebral artery. The analytical study, doppler US of neck vessels and transthoracic echocardiogram showed no significant alterations. However, transesophageal echocardiography revealed a FOP with right-to-left shunt. The patient was discharged from hospital without any neurological deficit, oriented to the Internal Medicine and Cardiology consultation and started hipocoagulation with a NOAC. At one month follow-up, he maintained episodes of paresthesia and paresis of right hemiface and upper limb. Ten days after, he was admitted to the ER due to convulsive crisis and a brain MRI was performed. It showed multiple corticosubcortical frontal-temporo-insular infiltrative lesions (with extension to the lenticular nucleus), parieto-temporal on the left side, with hyposignal at T1, hypersignal in the sequences with long RT and heterogenous enhancement after gadolinium. These lesions also comprised cystic/necrotic areas in frontal location and conditioned focal parenchymal expansion and mass effect with left lateral ventricle compression. These aspects suggested a high-grade multicenter glioma, likely glioblastoma multiforme. The patient was transferred to Neurosurgery care and was submitted to craniotomy with awake-asleep-awake anaesthetic technique. The affected tissue was only partially removed due to development of transient dysarthria. On the first postoperative day there was a sinking of the patient's state of consciousness due to intracerebral haemorrhage with deviation of the midline structures. Histological analysis of the tissue removed confirmed the diagnosis of high grade glioma

Discussion

High-grade gliomas are characterized by rapidly growing lesions and may be confused in an early stage with cerebral ischemic lesions.

#2213 - Case Report

DID COCAINE PLAYED A ROLE? - CASE REPORT

Rafaela Pereira, Ana Varela, André Florêncio, Motasem Shamasna, Conceição Viegas, Ana Paula Fidalgo
CHUA Faro, Faro, Portugal

Introduction

Drug consumption increase the risk of ischaemic and haemorrhagic stroke. Therefore, cerebrovascular disorders contribute to the morbidity and disability associated with illicit drug use.

The most commonly drugs associated with stroke are amphetamine and cocaine.

Cocaine use is associated with both intracerebral haemorrhage

and subarachnoid haemorrhage. As with ischaemic stroke the exact mechanism involved is not fully understood though may involve cocaine-induced haemodynamic changes in susceptible individuals. Potential causes include cerebral vasospasm, increased platelet aggregation, acute hypertension, dysrhythmias, embolization caused by infective endocarditis, vasculitis and exacerbation of pre-existing vascular disease.

Case description

A 56-year-old male patient, with a history of alcohol and tobacco abuse, was admitted to the hospital reporting blurred vision and gait disorder since he woke up. He mentioned that he had consumed cocaine the day before. On physical examination he had a blood pressure of 129/71 mmHg and the neurological exam revealed left homonymous hemianopsia. The brain Computed Tomography Scan (CT Scan) demonstrated an intracerebral hemorrhage in the right parietal lobe. Brain Magnetic Resonance Imaging (MRI) revealed a right parietal hemorrhage with 48 mm diameter and excluded subjacent lesions. The blood tests performed were unremarkable. The urinalysis exam, to determine the presence of toxic substances, revealed the presence of cocaine.

Discussion

We present a case of a hemorrhagic stroke possibly associated with cocaine use. Drugs use should always be considered as a possible cause of stroke, especially in young people and in patients who lack other vascular risk factors. However, it is impossible to prove that the cause was exclusively due to drugs.

Due to the short half-life of cocaine, high arterial blood pressure may no longer be found in the initial evaluation of the patient. Indeed, this patient presented normal blood pressure values.

The authors want to emphasize to always consider a toxicology screening for drugs in young patients with stroke and no obvious cause or if suggested by clinical history or examination.

#2238 - Case Report

A RARE TYPE OF STROKE, WHEN ONE-SIZE-FITS-ALL APPROACH DOESN'T WORK!

Rita Amorim Costa, Marta Gomes Rodrigues, Isabel Taveira, Raul Neto, Pedro Salvador

Centro Hospitalar de Vila Nova de Gaia / Espinho, Vila Nova De Gaia, Portugal

Introduction

Cerebral Venous Thrombosis (CVT) is rare (less than 1% of strokes) and is often underdiagnosed. It is more common in young adults and women, with an incidence of 7 cases/million. Acquired or hereditary thrombophilias, oral contraceptives, pregnancy, puerperium and neoplasias are highlighted as risk factors. The clinical presentation is variable and dependent on the occluded vessel. The diagnosis is based on brain CT and MRI with venographic study. We present the case of CVT in a young man with an inherited thrombophilia and discussion of therapeutic options.

Case description

A 42-year-old man, with obstructive sleep apnea and obesity, was brought to the ER after an inaugural tonic-clonic crisis, associated with headache and vomiting within the last 4 days. At admission he presented GCS 12 and motor aphasia. Cranial CT revealed left temporal parenchymal hematoma associated with hyperdensity of the lateral sinus. In the veno-CT, there was no filling of the lateral sinus and left jugular vein, compatible with CVT, and hypocoagulation was started. He evolved unfavorably, with depressed level of consciousness and motor deficits. A new CT confirmed the hematoma was conditioning compression of the brainstem and incipient hydrocephalus. Decompressive craniectomy was performed and he was admitted in the ICU where he kept therapy to control intracranial pressure (13 days). The etiological study identified Factor II mutation 20210A in heterozygosity and 4G variant at position -675 of the plasminogen activator inhibitor-1 (PAI-1) gene in homozygosity. After 40 days, the patient is oriented, with slight mixed aphasia, with no campymmetric deficit or oculomotor limitation, right central facial paresis and grade 4 right hemiparesis.

Discussion

Mutations in the Factor II and PAI-1 genes are associated with an increased risk of venous thrombosis. The cases describing both mutations are rare and may explain the etiology of the mentioned case. There are several therapeutic options in CVT such as hypocoagulation, reperfusion techniques (intravenous thrombolysis or mechanical thrombectomy) and decompressive craniectomy. Given the low incidence of CVT, the available clinical evidence is scarce. Mortality doubles in patients with associated hemorrhage and management of the risks/benefits of hypocoagulation can be hard. There are still no evidence whether the patient would have benefited from endovascular reperfusion therapy. Randomized trials are essential for better guidance and therapeutic standardization.

DURAL ARTERIOVENOUS FISTULA MIMICKING A ISCHEMIC STROKE

Ivan Cadena, Sara Nicolau, Soraia Texeira, Joana Canadas, Manuela Grego

Hospital de Santarem, Santarém, Portugal

Clinical summary

A 74-year-old male with hypertension and dyslipidemia, was admitted due to the progressive appearance of transitory disorientation deficits that worsened in the last 24 hours with ataxia and aphasia of expression. At the physical exam disartic language, facial asymmetry and hypoesthesia in the right upper extremity. CT-angiography head and neck revealed the existence of tortuous vessels in the left internal temporal region, which raised the suspicion of dural vascular malformation. Cerebral Angiography showed a complex multipedicular dural fistula

centered in the left lateral sinus / sigmoid, which is imprisoned with marked retrograde cortical and transcerebral venous flow. Embolization with Oxyx® obtained in the final closing of the fistula, without interurrences on an NIHSS1 scale.

Figure #2244. Multipedicular complex dural fistula centered on the lateral / left sigmoid sinus.

#2249 - Abstract

A RETROSPECTIVE ANALYSIS OF ACUTE STROKE PATIENTS IN A GENERAL MEDICAL WARD

Rita Valente, Estefânia Turpin, Filipa Cardoso, André Rebelo Matos, Tiago Pacheco, Margarida Sá Pereira, Isabel Marcão
Central Lisbon University Hospital - S.José - Medicina ¹4, Lisbon, Portugal

Background

The acute cerebrovascular stroke is a major cause of hospital admissions, having multiple risk factors and several possible outcomes, from lack of neurological injuries to fatal events.

Methods

Retrospective analysis of clinical records from patients admitted in a general medical ward with diagnosis of acute stroke between January and December 2018.

Results

Among 922 patients, 123 acute strokes were identified: 98 ischaemic (18 transient ischaemic attacks and 80 ischaemic

strokes) and 25 hemorrhagic events. Both subgroups had similar mean age at onset (approximately 76 years old) and there was no substantial gender difference. The ischaemic subgroup presented a higher prevalence of cerebrovascular risk factors: 80% of patients had at least 2 risk factors vs 56% in the acute hemorrhagic stroke (AHS) subgroup. Regardless of the injury type, arterial hypertension and dyslipidemia were the most common (prevalence of 80% and 40%). Only two patients who suffered an AHS were taking an anticoagulant (warfarin), both due to a previous diagnosis of atrial fibrillation (AF). Considering the 98 patients with an ischaemic event: 37% had AF, 29% previously diagnosed, 50% (n=14) of these already medicated with an anticoagulant - 36% (n=5) warfarin and 64% (n=9) direct oral anticoagulant (DOAC); 7 patients eventually switched to another drug and, overall, 9 started anticoagulation (8 DOAC). Most underwent additional cardiovascular examination: 63% transcranial and/or carotid doppler ultrasound, 51% transthoracic echocardiogram and 29% 24h-Holter monitoring. Furthermore, 28% were submitted to endovascular procedures: fibrinolysis (n=15), thrombolysis (n=9) or both (n=1). Regarding the outcome after an ischaemic accident: 51% had none or minor neurological sequelae, while 13% became totally dependent and 7% died. This contrasts with AHS, which caused no impairment in only 24% and were fatal in 44% of situations. Altogether, 35% of patients were referred to a public rehabilitation center or another hospital.

Conclusion

Despite the existence of specialised stroke care units, cerebrovascular events are still a leading diagnosis in general medical wards and its approach is constantly evolving. Well-recognised risk factors, as AF, have several treatment possibilities and should be regularly assessed. A considerable amount of patients develop neurological injuries that might compromise their autonomy and/or have recovery potential, illustrating the crucial importance of a proper rehabilitation center network.

EMERGENCY AND ACUTE CARE MEDICINE

#138 - Abstract

TRANSFERS FROM SUBURBAN HOSPITALS: DO WE REDO TOO MUCH EXAMS? A RETROSPECTIVE STUDY

Jérôme Bertrand¹, Christophe Fehlmann¹, Olivier Groscurin^{1,2}, François Sarasin¹, Omar Kherad^{3,4}

¹ Emergency division, Department of Acute Medicine, Geneva University Hospitals, Geneva, Switzerland

² Division of internal and general medicine, Department of Medicine, Geneva University Hospitals, Geneva, Switzerland

³ Division of Internal Medicine, Hôpital de La Tour, Meyrin, Switzerland

⁴ Department of Medecine, University of Geneva, Geneva, Switzerland

Background

Patients' transfer from primary to tertiary care emergency departments (ED) is frequent, mainly because medical resources, technology and/or specialist consultations are lacking. Receiving hospital often repeat laboratory and/or radiographic tests despite receiving data from the sending structure. The aim of this study was to quantify the number of patients transferred to a tertiary care ED, and to estimate the frequency and inappropriateness of repeated procedures.

Methods

We conducted a retrospective chart review of all patients transferred from one primary care ED to a tertiary care ED from January 2016 to December 2016. We considered as redundant a procedure repeated during the 8 hours following the transfer despite the availability of the results. Two authors independently assess whether redundancy was appropriate or not. The inter-observer agreement was measured with a Kappa-coefficient. Factors predicting repetition of procedures were identified through a logistic regression analysis.

Results

During the year 2016, 432 patients were transferred from the primary emergency center to the tertiary center. Two-hundred and fifty-one procedures were repeated: 179 patients had a repeated laboratory tests, 34 a repeated radiological procedure and 19 both. The only risk factors for a repeated blood test was an advanced age (>65 years old) (aOR=1.8, 95%CI 1.2-2.7), and for a radiological procedure, a surgical (versus a medical) problem (aOR=1.9, 95%CI 1.0-3.7). Repeated procedures were judged

as partially or totally inappropriate for 197 (99.5%) laboratory tests (Kappa=0.57) and for 39 (73.6%) radiological procedures (Kappa=0.82).

Conclusion

Over half of the patients transferred from another emergency department have a repeated procedure. In most of the case (94%), these repeated procedures were considered as inappropriate.

#164 - Case Report

AN UNUSUAL BUT EMERGENT CAUSE OF CHEST PAIN

Cristina Martins, João Pina Cabral, Pedro Ribeiro, Armando Carvalho

Centro Hospitalar e Universitário de Coimbra - Hospital Geral, Coimbra, Portugal

Introduction

Chest pain is responsible for 5.5 to 5.8 million visits to emergency rooms (ER) each year. It has many possible causes: cardiac, respiratory, muscular-skeletal, esophageal/gastrointestinal, neurological, psychological, making it difficult to reach a definite diagnosis, when particular clinical settings are present. Chest pain related to esophageal disorders may be particularly difficult to diagnose and to distinguish from a cardiac origin pain.

Case description

A 67 years old man, with hypertension, dyslipidemia and obesity, presents to the ER complaining of anterior chest pain, irradiating to the back, with 2 hours of evolution, accompanied with nausea and vomiting (with no blood). On admission he was febrile, with a BP of 144/78 mmHg, a HR of 108 bpm and a SpO₂ of 90%, breathing air. He was conscient and oriented, with an innocent physical exam, except for a diminished respiratory sound in the inferior left pulmonary region. His blood gas analyses showed a type I respiratory failure (pO₂ 57.2 mmHg; pCO₂ 36.4 mmHg) and a rise in lactate level (3.24 mmol/L) with no acidemia. ECG was normal, except for a sinus tachycardia. Fluids, oxygen and analgesia were administered, with no improvement. Blood analysis revealed a discrete leukocytosis, a normal C-reactive protein, and normal levels of troponin and d-dimer. The chest X-ray, though, showed signs of pneumomediastinum (in the

posterior incidence: a tubular artery sign; in the lateral incidence: a continuous diaphragm sign), later confirmed with a chest CT, that related a pneumomediastinum, particularly important in its posterior region, next to the posterior-lateral section of the distal esophagus, suggesting an esophageal rupture. It also identified a left sided pleural effusion, with air within, suggestive of a hydropneumothorax. A Boerhaave Syndrome was assumed as the most probable cause of this pneumomediastinum and, therefore, of this chest pain. The case was discussed with general surgery, and the patient was submitted to a near total esophagectomy, and then admitted into the Intensive Care Unit.

Discussion

Pneumomediastinum is defined as free air or gas contained within the mediastinum. Although unusual (particularly in the setting of a spontaneous esophageal rupture - Boerhaave Syndrome), it may be an emergent cause of chest pain, so clinicians should always be aware of its possibility, specially since its diagnosis may be suspected after careful examination of a chest x-ray, as happened in our case.

AIRWAY MANAGEMENT IN AN ACUTE CASE OF ANGIOEDEMA

Adriana Bandeira, Joana Gonçalves, Luís Pereira
Centro Hospitalar de Leiria, Leiria, Portugal

Clinical summary

71 year old patient presenting in the ER with a rapid onset of dyspnoea and refractory angioedema of the face and neck, requiring immediate intubation with videolaryngoscopy support and ventilation.

CT scan less after intubation showed marked symmetrical edema involving the entire anterior facial and cervical region, as well as the perivisceral deep planes extending to both below the superficial aponeurosis of the neck and the posterior cervical compartment, suggesting a more generalized, systemic cause. The more probable cause was an allergic reaction as the episode occurred after eating octopus for the first time, and steroids and antihistamine treatment was started. Within 72 hours there was a clinically significant improvement leading to ventilatory weaning and extubation.

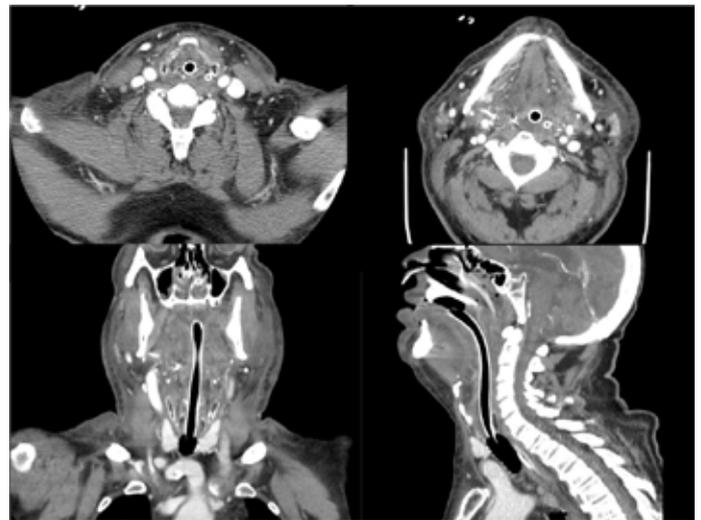

Figure #173. Head and neck CT scan showing patient with severe angioedema and a 6cm endotracheal tube. Axial, sagittal and coronal planes.

#206 - Abstract

THE INTENSITY OF PULMONARY EMBOLISM IN AN ICU - CLASSIFICATION AND MORTALITY

Sara Lopes Fernandes¹, Alexandre Fontoura², Nuno Sousa², Hélia Martins¹, Luísa Lopes²

¹ Leiria Hospital Center, Leiria, Portugal

² Local Health Unit of Guarda, Guarda, Portugal

Background

Pulmonary Embolism (PE) is an important cause of hospitalization and mortality, with an increasing incidence in Portugal. The clinical spectrum includes shock and cardiac arrest, requiring tight surveillance and control, including admission in an Intensive Care Unit (ICU).

Methods

Retrospective study of patients with PE admitted in a ICU, from January 2014 to November 2018. Evaluation and descriptive analysis of the classification and mortality of the PE.

Results

A total of 36 patients were admitted in the UCI with PE (66% bilateral or central), with a mean age of 66 ± 19 years and higher prevalence of men (58%). The main reason for admission was respiratory failure (58%), shock (11%) and cardiac arrest (8%). In the initial assessment, 9 patients had shock or hypotension (25%), 22 had positive cardiac biomarkers (61%) and echocardiogram showed dysfunction of the right ventricle (RV) in 18 cases (50%). The Severity Index of Pulmonary Embolism (PESI) was calculated, with an average of 136 ± 56 , most of them grade IV and V (75%). The short-term risk-of-death classification divided patients into low (6%), intermediate-low (33%), intermediate-high (36%) and high (25%) risk subjects. Comparing this groups, there was a significant

difference in the mean age ($p=0.005$), with a successive increase especially from the lowest to the highest risk group ($p=0.007$). Unlike the others, the high risk group had more female than male ($p=0.76$). The mean PESI score was significantly different ($p=0.000$), with increased values associated with increased risk. Total mortality was 19% ($n=7$), 6 of them in-hospital (17%), with 57% males and mean age of 82 years. Of those who died, 57% belonged to the high risk group, 29% to the intermediate-high and 14% to the intermediate-low risk group; 100% had PESI score V (mean 183 vs 127, $p=0.008$), 86% had positive cardiac biomarkers ($p = 0.069$) and 50% RV dysfunction.

Conclusion

PE is associated with a high morbidity and mortality rate. The results of this series show the importance of risk classification and stratification of patients with PE, as a form of early warning and a more timely and targeted approach.

#217 - Case Report

DRUG HYPERSENSITIVITY - THE IMPORTANCE OF DIAGNOSTIC SUSPICION

Marta Rafael Marques, Dolores Vazquez, Susana Marques Sousa, Vera Seara, Sónia Fernandes, Alexandre Mendonça

Centro Hospitalar Póvoa de Varzim/Vila do Conde, Vila Do Conde, Portugal

Introduction

The appearance of urticaria after a few hours of use of a new drug is easily recognized as possible drug hypersensitivity. However, many clinical presentations of drug hypersensitivity are more complex or occur in the context of disease and / or polytherapy.

Case description

An 84-year-old woman, hypertensive and dyslipidemic, came to the emergency room with generalized malaise, nausea and abdominal discomfort with 4 days of evolution, associated with a febrile peak (axillary temperature 38.5°C) and lipothymia on the previous day. She had been medicated for the previous 9 days with trimethoprim-sulfamethoxazole (TMP-SMX) 160/800 mg, orally, for uncomplicated acute cystitis. At admission, the patient was awake, glasgow coma scale 15, hypotensive (PA 87/45 mmHg), FC 87 bpm, without fever; she presented with generalized, symmetrical rash with maculopapular rosacea lesions, some discrete and small and others confluent, not pruritic, on the trunk, abdomen and more proximal extremities compatible with morbilliform exanthema and diffuse erythema on the back. Analysis revealed pancytopenia (normochromic normocytic anemia Hb 11.0 g/L, leucopenia 3790/L, absence of eosinophilia and thrombocytopenia 106,000/L), acute renal damage (Creatinine 2.3 mg/dL, Urea 81.1 mg/dL), hyponatremia, hepatic lesion (IGT 56 U/L, TGP 41 U/L, GGT 60 U/L, FA 114 U/L, normal bilirubin) and elevated inflammatory parameters (CRP 11.42 mg/dL, VS 26 mm/h). HBV, HCV, HIV, CMV and HBV were negative. Electrocardiogram and Chest X-ray were

normal. Because of suspicion of late hypersensitivity reaction to TMP-SMX with multiple organ dysfunction (cardiovascular, hematological, renal, hepatic and cutaneous), the antibiotic was discontinued and support measures were initiated. In the first 24 hours, there was also progression with erythema of the face and oral mucosa reaching, without erosions. However, after 72 hours, it evolved favorably with regression of rash and gradual normalization of the organic disfunctions.

Discussion

TMP-SMX is generally well tolerated in non-HIV infected patients, with adverse reactions occurring in about 6 to 8% of subjects. The most common side effects involve the gastrointestinal tract and the skin, with nephrotoxicity being uncommon. Potentially fatal effects, such as neutropenia, anaphylaxis and severe dermatological reactions, usually affect the elderly, so a high degree of clinical suspicion and early drug discontinuation are required.

#229 - Case Report

MIDDLE-AGED MALE PATIENT WITH RENAL INFRACTS DUE TO FIBROMUSCULAR DYSPLASIA PRESENTS WITH ACUTE ABDOMINAL PAIN

Dimitra Stathi, Konstantinos Kounouklas, Panagiotis Petrikos, Anna Mari, Eleni Karantoni, Nikolaos Symeonidis

General Airforce Hospital, Athens, Greece

Introduction

Acute abdominal pain due to renal infraction as result of fibromuscular dysplasia is rarely reported. The aim of our case report is to emphasize the importance of a broad differential diagnosis in patients presenting with acute abdomen.

Case description

A 47-year old male with no medical history or regular medical treatment was admitted due to acute upper abdominal pain. Physical examination revealed epigastric tenderness. Differential diagnosis included acute cholecystitis, choledocholithiasis, acute pancreatitis, acute pyelonephritis, ACS, gastric ulcer, mesenteric ischemia, renal infarcts and polyarteritis nodosa. Lab tests in the ER: SGOT: 63, SGPT: 79, LDH: 657, CRP: 75 (normal values <10), no other significant findings. An abdominal U/S followed by a CT scan without contrast was performed and revealed a gallbladder polyp and fatty liver. Patient was admitted for further investigation. Gastroscopy, MRCP and echocardiogram were scheduled. Mild erosive gastritis, pancreas divisum and a mild pericardial effusion were correspondingly revealed from the above tests. However, due to progressively increasing pain and worsening of lab tests, a thorax-abdomen CT with IV contrast was performed and showed renal parenchymal defects on both kidneys, right renal artery stenosis as well as bilateral arterial wall thickening. Diagnosis was confirmed by renal angiography, which besides renal infarcts also revealed multiple bilateral renal arteries and the "string-of-beads" feature, characteristic of fibromuscular dysplasia.

Discussion

The significance of our case depends on the rare appearance of fibromuscular dysplasia in a male patient presenting with acute abdominal pain and increased LDH due to renal infarcts. The diagnostic value of CT scan with IV contrast should also be noted. Clinicians should include the case of acute renal infarcts in their differential diagnosis when acute abdominal pain and increased LDH are present.

CAN A URINARY RETENTION CAUSE BOWEL OBSTRUCTION?

Ana Isabel Andrade Oliveira, Joana Morais, Olga Pires, Inês Burmester, Isabel Agonia, Maria João João Regadas, Paulo Gouveia

Hospital de Braga, Braga, Portugal

Clinical summary

Mechanical or functional conditions can cause bowel occlusion. A woman in her 90's was brought to the emergency with depression of consciousness and confusion. Her daughter reported urinary incontinence, lack of bowel transit and a urinary tract infection. On examination, she had abdominal distension, tympanism and high frequency of metallic abdominal sounds. The x-ray showed air-fluid levels, consistent with obstruction. An enema was done without effect. After that, a CT revealed urinary retention and dilatation of the excretory systems. A urinary catheter was placed draining 1500 cc of urine. With bladder decompression the intestinal transit restarted and her cognitive status improved. This case represents an atypical and exuberant cause of intestinal occlusion that could have gone unnoticed.

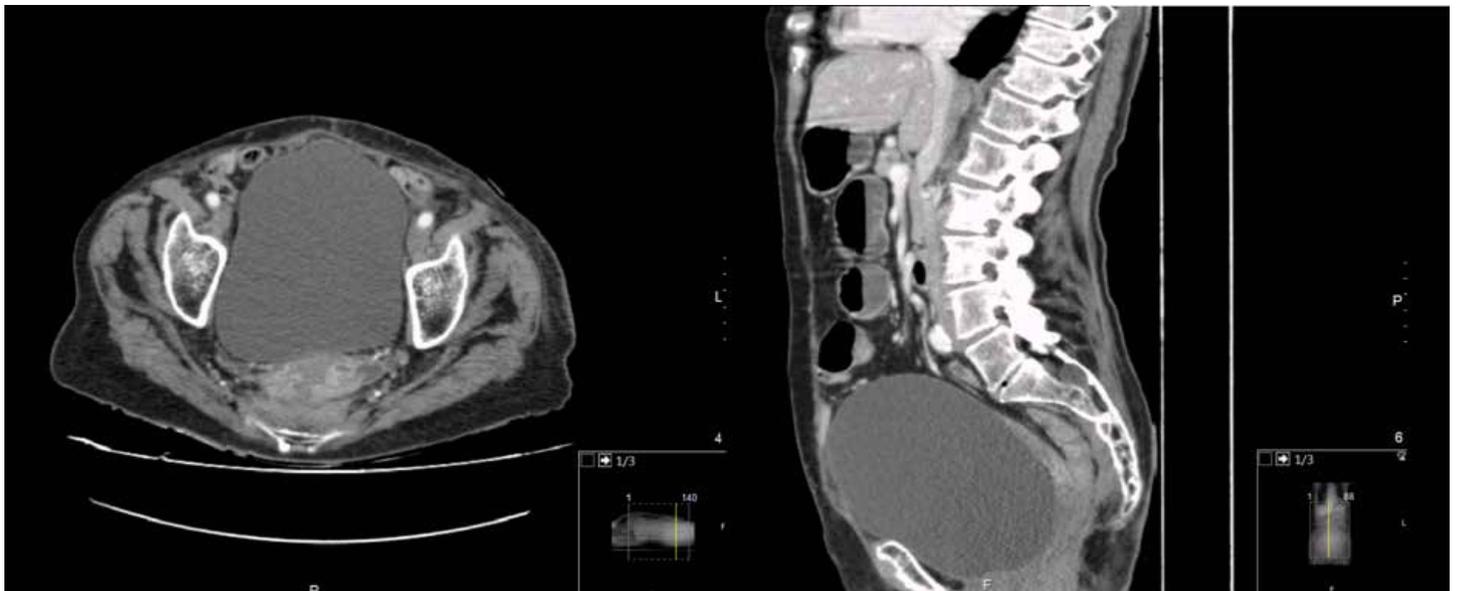

Figure #234.

RARE AND UNDERDIAGNOSED COMPLICATION OF LONG-STANDING DIABETES: A CASE REPORT OF DIABETIC MYONECROSIS

Cristina Gavala, Loura Khallouf, Erik Holzwanger
UMassMemorial Hospital, Worcester, United States

Introduction

Diabetic myonecrosis, also termed diabetic muscle infarct, is a rare and severe complication of longstanding, poorly controlled Diabetes Mellitus. Angervall and Stener first described this condition in 1965 and less than 200 cases have been reported in the literature since. This disorder typically presents as a nontraumatic acute onset of pain and swelling of the affected muscle most frequently in the lower extremities and involving

the muscles of the thigh. Diabetic myonecrosis usually occurs in patients with an established longstanding history of diabetes in the setting of other associated microangiopathic changes such as retinopathy, neuropathy, and nephropathy. The main treatment involved with this disorder involves strict blood sugar regulation. We present an exceedingly rare case of diabetic myonecrosis in a 54-year-old woman with poorly controlled type II Diabetes Mellitus (DMII).

Case description

A 54-year-old woman with history of longstanding DMII, heart failure with reduced ejection fraction (EF 25%), and hyperlipidemia, presented with a four-week history of atraumatic left medial thigh swelling and pain. She had two courses of broad spectrum antibiotics during this time without improvement. Erythrocyte sedimentation rate and c-reactive protein were mildly elevated,

and she had a normal creatine phosphokinase and anti-nuclear antibody. Hemoglobin A1c done was 10.9%. X-ray of the left femur displayed mild osteoarthritis and soft tissue swelling, however no evidence of fracture or dislocation. Left lower extremity duplex was negative for deep vein thrombosis. MRI of the left thigh showed an area of high T2 signal and nonenhancement within the vastus medialis that measured 9.1 cm craniocaudally, 5.5 cm transversely, 2.3 cm posteriorly along with edema within the vastus medialis muscle both below and above the area of nonenhancement. The MRI findings were consistent with myonecrosis of vastus medialis. In the absence of infectious signs and symptoms along with no improvement in symptoms on broad spectrum antibiotics, she was diagnosed with diabetic myonecrosis. Muscle biopsy is not necessary to establish a diagnosis in such cases.

Discussion

We present an exceedingly rare case of diabetic myonecrosis. Being able to recognize the clinical presentation of this complication early in its course, avoiding unnecessary/invasive testing such as muscle biopsy and initiating treatment for the goal of pain/tighter glycemic control and is essential in prevention of further complications.

#381 - Abstract

ANALYSIS OF RADIOLOGY EXAMS REQUESTED BY AN EMERGENCY DEPARTMENT: DO PHYSICIANS PROVIDE ADEQUATE CLINICAL INFORMATION?

Rute Martins^{1,2}, Pedro Raimundo³, Pedro Alves^{1,2}, Rodrigo Monteiro^{4,2}, Luís Duarte Silva^{4,2}, André Gomes^{1,2}, Graça Afonso^{1,2}

¹ University Hospital Center of Algarve, Faro, Portugal

² Algarve Biomedical Center, Faro, Portugal

³ University of Algarve, Faro, Portugal

⁴ University Hospital Center of Algarve, Portimão, Portugal

Background

Although imaging exams are essential for diagnosis in the emergency context, many unnecessary imaging exams are still requested. The clinical information available is critical to assess the appropriateness of the exams but also to improve their interpretation. Therefore, we aimed to analyze the computed tomographies and ultrasounds requested by the Emergency Department in a district hospital.

Methods

We retrospectively analyzed the computed tomographies and ultrasounds requested by the Emergency Department to the Radiology Department at the University Hospital Center of Algarve during a 20-day period. The selected variables were: requested imaging exam, clinical information provided by the clinician, exam appropriateness and outcome of the exam (relevant findings and findings related to the clinical context). Variables were compared using Pearson's Chi-squared tests.

Results

Out of the 1427 requests analyzed, only 219 (15.3%) were considered to have complete clinical information. Nonetheless, 1075 (75.3%) requests were considered appropriate. Relevant findings were present in about one-third (n=453; 31.7%) of the exams and most of these findings were related to the clinical context (n=410; 90.5%). The presence of relevant clinical findings in the exam were found to be significantly related with the exams classified as appropriate (P<0.001). Moreover, a statistically significant association was observed between the relevant findings and the findings related to clinical context (P<0.001).

Conclusion

The fact that most requests did not provide complete clinical information obscures the radiologist task to understand the clinical usefulness and interpretation of an exam, implicating that each exam requires longer time of analysis, with impairment for both the patients and clinicians involved. Improvement of the communication between doctors, in the form of clinical information, should allow the optimization of the resources available by precluding unnecessary exams, enhancing its prioritization, reducing the time spent per exam and improving its diagnostic accuracy.

#395 - Case Report

SODIUM HYPOCHLORITE ACCIDENT DURING AN ENDODONTIC PROCEDURE - CASE REPORT

Joana Aguiéiras Cabrera, Margarida Mota, Diogo Ferreira

Centro Hospitalar Vila Nova de Gaia / Espinho, Vila Nova De Gaia, Portugal

Introduction

Cleaning and disinfection are mandatory for the success of endodontic treatments. There isn't any irrigation solution that has all the desirable functions. However, NaOCl seems to be the most suitable, since it covers more requirements than any other – it has the unique capacity of dissolving the necrotic tissue and destroying microorganisms organized in biofilms and located in the dentin tubes. Despite these advantages, accidents are reported every year using NaOCl in high concentrations during endodontic treatments: when the solution comes in contact with the organic periodontal and periapical tissues it creates severe necrotic changes with a dangerous organic destruction lesions associated.

Case description

The authors present a clinical case of a 47-year-old female that arrived at the ER with clinical information from her dentist describing the formation of an exuberant edema on the upper lip during a treatment with NaOCl. She showed an increased edema of the upper lip, maxillary region bilaterally with growing equimosis in the described area. There were no stridor or ADRS signs and the mimics of the upper floor of the face was preserved. In the evaluation of the

oral cavity, there were no visible lesion of the mucosa. Blood tests showed an increase in the inflammatory parameters. Treatment with corticosteroid, antihistaminic and antibiotic was administered immediately, but the edemas and the equimosis continued to grow and reached the right periorbital during the first 12 hours. In the following days, the edema was strongly improved and in day 3 equimosis were only seen in the lower right eyelid.

Discussion

In spite of all the advantages, NaOCl is a cytotoxic agent that causes hemolysis and ulceration, inhibits the migration of neutrophils and causes lesions on endothelial cells and fibroblasts.

The literature confirms the occurrence of serious accidents caused by the injection of NaOCl in periapical tissue, resulting in: severe pain, edema in adjacent tissues, bleeding into the root canal, discontinuation of the skin and mucous membrane (ecchymosis), tissue necrosis, secondary infection with formation of abscess and persistent paresthesias. When the NaOCl solution exudes into the peri-radicular tissues, the effect may ranging from a burn to localized or extensive tissue necrosis. Treatment with anti-inflammatories and antibiotics and sometimes a surgical drainage may also be required, depending on the extent of edema and tissue necrosis.

#408 - Abstract

CAN SPEECH-ENABLED PHRASELATORS IMPROVE HEALTHCARE ACCESSIBILITY? A CASE STUDY COMPARING BABELDR WITH MEDIBABBLE FOR ANAMNESIS IN EMERGENCY SETTINGS

Valerie Boujon¹, Antony Janakiram², Johanna Gerlach³, Pierrette Bouillon³, Herve Spechbach²

¹ Translator at AMPLEXOR, Toulouse, France

² University Hospitals of Geneva, Geneva, Switzerland

³ Faculty of Traduction and Interpreting, Geneva, Switzerland

Background

Language barriers are an important problem for healthcare services for minority groups like refugees or sign language users. Interpreters are not always available in emergency settings. Alternatives such as online machine translation are unsatisfactory in terms of languages covered, data confidentiality and translation reliability. Some Phraselators were developed in collaboration with medical staff to produce reliable translations, but they remain unsophisticated. To improve on this, the Geneva University Hospitals and the Faculty of Translation and Interpreting have developed BabelDr, a speech-enabled phraselator. When the doctor asks a question, the system uses speech recognition to recognize what was said and automatically maps this recognition result to the closest pre-translated core sentence.

Methods

The goal of this experiment is to compare two phraselators: BabelDr and MediBabble. We focused on two main criteria:

functional suitability (does speech help to provide the correct result?) and usability (does speech make the system more usable?). We used a crossover design: both systems were used twice by ten medical students in order to find precise information about the patient, based on two different scenarios.

Results

Both phraselators made it possible to collect most of the required information from the patients in the dedicated time. In the two sessions, participants collected 195/200 correct elements with MediBabble and 198/200 with BabelDr. This shows that both phraselators allowed doctors to obtain the correct answers to the medical questions. The two systems are thus closely matched in terms of functional suitability.

In both sessions users took less time to collect information with BabelDr, with an average time difference of 11 seconds (95%CI 4.6 à 17.3, $p < 0.001$) per question.

The average number of mouse clicks is always lower for BabelDr than for MediBabble, with an average difference of 2.7 clicks (95%CI 1.8 à 3.7, $p < 0.001$) per question.

Participants had to fill in a questionnaire after each task, rating statements on a Likert scale. Different questionnaires were used for the first and second session. The first contained 10 questions focussing on ergonomics; the second contained 9 questions with a focus on learnability.

Globally, we observe that BabelDr has more positive answers than MediBabble.

Conclusion

We find that objectively and subjectively the availability of speech in BabelDr makes this system more suitable than a standard phraselator.

#420 - Medical Image

WHEN THE LIGHT BURNS

Maria Vilela

Hospital Santa Maria Maior, Barcelos, Portugal

Clinical summary

A 57-year-old man, with no relevant medical history, presented himself to the Emergency Department in mid August with a painful and pruriginous erythematous edema of both forearms that begun in the previous hour. He reports that he was pruning a fig tree, which he regular does during winter, but had never done during summer.

Several plants, including the fig tree, contain furocoumarin compounds (psoralens) that cause a particular form of dermatitis. Phytophotodermatitis is a condition caused by sequential exposure to photosensitizing substances present in plants followed by ultraviolet (UV) light.

After corticoid administration, the edema reduced and the patient was discharged.

Figure #420.

#485 - Abstract

USE AND ABUSE OF ABDOMINAL RADIOGRAPHY IN EMERGENCY UNIT

María De Los Angeles Galindo-Andúgar, Inmaculada Espinosa-Monroy, Paula Miján-Caño, Jesús Monllor-Méndez, Clara Díaz-Parreño Quintanar, Antonio Martín-Castillo, Míriam Sánchez-López, Cristina Casado-Delgado, Dolores Macarena Lara-Doblas, Marina Cartas-Verdugo

Hospital General La Mancha Centro, Alcázar de San Juan, Spain

Background

The updating and use of New Technologies allow us to improve the medical assistance. However, in overloaded departments as Emergency can head to an abuse of some diagnosis test like the abdominal radiography (ARX). Our purpose is to evaluate the right indication for the ARX in the Emergency Department.

Methods

Descriptive study made in our hospital. We reviewed the patients who came to Emergency department in January, 7th of 2019, choosing those patients with ARX made that day. The correct indication of the ARX was evaluated according to 'Making the best use of a Department of Clinical Radiology: Guidelines for Doctors' from the Royal College of Radiologists of London.

Results

They were included 29 cases from 191 patients who came to Emergency Unit. 17 were males (58%). Median age was 49 years-old (range between 8 and 87), with 2 children below 14 years-old. The main diagnosis was abdominal pain in 12, followed by renal colic (6), diarrhea (3), respiratory infection (3), weight loss (2), urinary infection(2) and intestinal bleeding (1).

8 patients were admitted (27%) and 21 were discharged. A chest radiography was requested in 17 patients (58%) in addition to the ARX. Regarding the 8 inpatients, both radiographies (chest and abdominal) were requested from Emergency department in 7 of them.

There were 11 cases in which the indications were requested for one of the guidelines (38%), which are the followings: ureteral stones (6), acute abdominal pain (2), bowel obstruction (1), perforated viscus (1) and acute renal failure (1). The findings of the ARX were normal or unspecific in most of the patients (18 cases, 62%), followed by faeces (8), dilated bowel loops (2) and ureteral stone (1).

Conclusion

The number of ARX requested in the Emergency Department is bigger than guidelines. The correlation with the radiologist is moderated. It would be recommended a better knowledge of the guideline and the dosage radiation.

#500 - Abstract

PILOT-STUDY OF THE POINT-OF-CARE TEST FOR EVALUATION OF THE HEART TYPE FATTY ACIDS BINDING PROTEIN AND CARDIAC TROPONIN I EFFICACY IN SUSPECTED ACS

Valentin A. Kokorin ¹, Ivan G. Godeev ¹, Mikhail N. Arefiev ², Anna A. Yakovtsova ³, Anna Ya. Goncharova ³

¹ Pirogov Russian National research medical university, Moscow, Russia

² Minicipal clinical hospital #15 named after O.M. Filatov, Moscow, Russia

³ Alliance of Competences, Obninsk, Russia

Background

The simultaneous evaluation of different biomarkers of the myocardial injury (a multimarker strategy) may allow to confirm or exclude the diagnosis of acute myocardial infarction (AMI) more quickly and precise than the serial measurement of cardiac troponins. We aimed to assess the diagnostic efficacy of the new point-of-care express-test for the qualitative simultaneous evaluation of the heart type fatty acid binding protein (H-FABP) and cardiac troponin I (cTn I) concentrations in patients with suspected acute coronary syndrome (ACS).

Methods

One hundred eighteen patients, who were admitted to the clinic with the referral diagnosis of ACS, and had typical chest pain with duration of at least 20 min in the interval between 1 and 24

h before admission were enrolled in the study. The qualitative evaluation of H-FABP and cTn I concentrations was performed upon admission by the immunochromatographic point-of-care test "CARD-INFO 1+1" («CARDIO-Plus», Russia) in addition to the standard diagnostic procedures, including the serial measurement of the high-sensitive Tn I (hsTn I). Diagnostic threshold to H-FABP is 7 ng/ml, to cTn I - 1,5 ng/ml.

Results

AMI was diagnosed in 78 patients (66.1%), unstable angina - in 30 (25,4%), other reasons of chest pain - in 10 (8,5%). The sensitivity of "CARD-INFO 1+1" express-test was 85.9% (95% CI 77.7-91.8%), specificity - 77.5% (95% CI 64.4-87.3%), diagnostic accuracy - 83.1% (95% CI 76.0-88.6%), positive prognostic value - 88.2% (95% CI 80.3-93.5%), negative prognostic value - 73.8% (95% CI 60.5-84.3%). The diagnostic efficiency of the express-test in patients with ACS with and without ST-segment elevation had no significant difference ($p>0.05$). The sensitivity of the "CARD-INFO 1+1" express-test reached the maximum in the period between 3 and 6 hours from the chest pain onset. The application of the "CARD-INFO 1+1" test in addition to the first measurement of hsTn I performed at admission allowed to identify 17.5% more cases of AMI compared with hsTn I evaluation alone.

Conclusion

The pilot-study of the express-test "CARD-INFO 1+1" clinical application demonstrated its high efficiency in the diagnosis of AMI. We require further studies to confirm these compromising results and to clarify the possible implementation of such multimarker point-of-care tests in the diagnostic algorithms of suspected ACS.

#506 - Abstract

ROLE OF RADIOGRAPHY IN EMERGENCY DEPARTMENT. NICE AND CHEAP, BUT ALSO GOOD?

María De Los Angeles Galindo Andúgar, Clara Díaz-Parreño Quintanar, Inmaculada Espinosa-Monroy, Paula Miján Caño, Jesús Monllor-Méndez, Carmen Alarcón-Viejo, Laura Oriente-Frutos, Carolyn Itala Prieto-Espinoza, Luis Alonso González-Sánchez, Ruth Espinosa-Aunión

Hospital General La Mancha Centro, Alcázar de San Juan, Spain

Background

The Spanish Public Health System is universal, and it provides free assistance (cheap). The radiologic tests are widespread, especially in Emergency Unit because of their rapidity and usefulness (nice). However, in overloaded departments as Emergency can head to an abuse of some diagnostic tests. The need for a fast solution can increase the number of requests and therefore the radiation dose received by the patients (no good). The objective is to estimate the number of radiologic test requested in the Emergency Department and if it was related to a trauma in patients with osteomuscular pain.

Methods

Descriptive study made in our hospital. We reviewed the patients who came to Emergency department in January, 7th of 2019, choosing a winter day within the influenza epidemic. Depend on the pathology, the patients were distributed inside the Emergency Unit in four different areas: Pediatrics, Medical/Surgical area, Specialty (includes Ophthalmology, Psychiatry, Orthopedic etc.) and Critic area (provided for advanced cardiopulmonary resuscitation). The clinical reports were reviewed from 'Mambrino XXI' (the clinical informatics system used in our hospital), and the radiology was obtained from 'Ykonos' (all the radiologic test are digitalized and included in this database since the year 2002). Analysis with PASW Statistics 18.

Results

A total of 191 patients were included, 86 males and 105 females, with median age of 51 years-old (range between 3 months and 100 years-old), with 8 oncologic patients and 2 road accident. The distribution was the following: Pediatrics 21 cases (11%), Medical/surgical area 89 (47%), Specialty 70 (37%) and Critic Care 2 (1%). Most of the patients were discharged from Emergency (154 cases, 80%), 32 were admitted at the hospital (17%) and 5 left the unit without assistance. All they stayed between 1-30 hours (median 4 hours). When we reviewed the last year, it was the first time in Emergency only for 89 patients (47%), with 2 patients with 10 and 12 visits.

Radiography was request in 120 cases (63%). The most usual were chest radiography (72), abdominal radiography (29), limbs (15) and spinal column (14). There were 49 patients with osteomuscular pain. If we exclude 7 patients without radiography in this visit, we found more request for patients with traumatic pain than those cases without trauma (24 vs 18) with no statistical significance ($p=0.4$).

Conclusion

Radiologic test were request in two thirds of patients. A previous trauma increases the risk.

#512 - Case Report

MESENTERIC ISCHEMIA - A DIAGNOSTIC CHALLENGE

Catarina Sofia Martins Nóbrega, Ana Margarida De Abreu Temtem, Jéssica Chaves, Catarina Miriam Capelo Freitas, Filipe Pernetá, Maria Da Luz Reis Brazão

Hospital Central do Funchal, Funchal, Portugal

Introduction

Mesenteric Ischemia (MI) is a tissue lesion of ischemic nature that reflect an unbalance between vascular perfusion and metabolic needs. It has a reduced prevalence, affecting mostly the eldest, but when it occurs, it brings about significant morbimortality, mostly related with a difficult timely diagnosis, given its unspecific symptoms. The treatment, in its acute presentation, warrants immediate surgery

the restore abdominal blood flow, and is more prevalent in the female gender and associated with the occlusion by embolus of the superior mesenteric artery. Most patients will require surgical removal of necrotic bowel segments. The main risk factors associated are atrial fibrillation, atrial flutter, cardiac valve disease, ischemic cardiac disease and other structural heart abnormalities.

Case description

A 79-year-old female, with personal history of dyslipidaemia and arterial hypertension, already medicated. Presents herself to the A&E because of vomit and occasional liquid bowel discharges without blood or mucus, with one week of duration. The patient also referred diffuse abdominal pain and fever. Its physical exam the patient was prostrated, feverish, with low BP, with a diffuse abdominal discomfort upon palpation, but without peritoneal reaction. Her blood chemistry evidenced elevation of the Acute Phase Parameters (APP) (CRP 272.23 mg/L), acute kidney failure and a urinalysis with leucocyturia and bacteriuria. She was initially admitted with a presumptive diagnosis of pyelonephritis with gastroenteritis and dehydration and begun Cefuroxime empirically. On the 5th day of admission, although with a stable blood pressure, the patient maintained daily fever spikes, with a slight downfall in the APP. A surgical consult was requested and a subsequent Abdomen CT scan revealed pneumatosis and pneumoperitoneum. A laparotomy with subtotal colectomy and terminal ileostomy was performed, due to multiple colonic perforations. The patient was admitted in the ICU unit for post-operative care but developed multiple organ failure, passing away a few hours after her admission.

Discussion

The previous case reminds us the necessity of a timely diagnosis in IM, difficult in face of unspecific semiology which warrants an increased clinical suspicion. Only a diligent approach with early surgical intervention can be expected to improve prognosis and reduce mortality.

A RARE CAUSE OF SUBCAPSULAR HEMATOMA

Catarina Sofia Martins Nóbrega, Carolina Aguiar, Ana Marta Mota, Sofia Escórcio, José Júlio Nóbrega
Hospital Central do Funchal, Funchal, Portugal

Clinical summary

A 57-year old male with a past history of elevated BP was admitted in the resuscitation room after cardiac arrest following acute myocardial infarction. Subsequently, an angioplasty of the proximal anterior descending coronary artery was immediately performed. On the 2nd day of admission, the patient developed sudden epigastric pain with a fall in haemoglobin from 14.0 g/dL to 9.0 g/dL and increased transaminases although with decreasing values of the cardiac markers. An abdominal CT scan exposed

a large hepatic subcapsular hematoma (red dashed line in the images). Its origin was associated with a costal arch fracture. The trauma, coupled with abciximab therapy and the double antiaggregation, caused this rare complication. He doesn't need invasive procedures, with the hematoma absorbing.

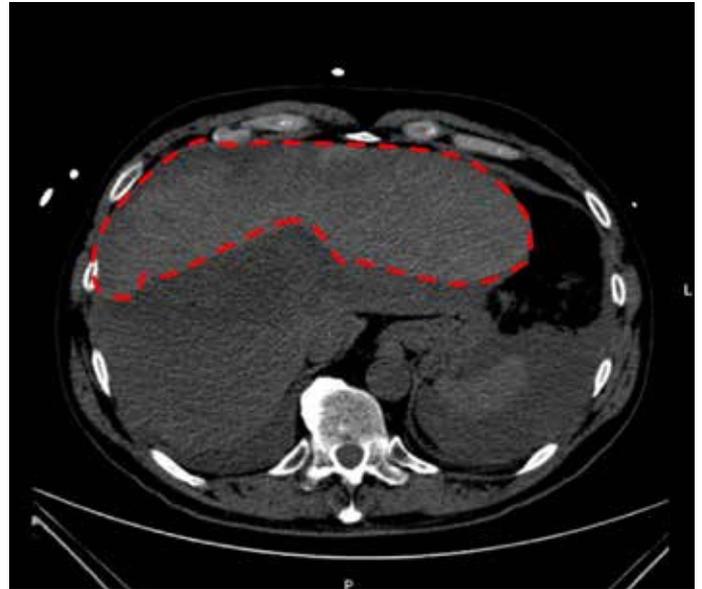

Figure #518. Abdominal CT scan with large hepatic subcapsular hematoma.

#528 - Abstract

PATIENTS WITH ACUTE CORONARY SYNDROME AND CONDUCTION DISTURBANCES IN REAL-LIFE CLINICAL PRACTICE

Yulia Venevtseva, Aleksandr Balko

Medical Institution of Tula State University, Tula, Russia

Background

Recent studies have shown that patients with bundle branch block (BBB) have worst outcome after an acute coronary syndrome (ACS), particularly with right BBB. Six comorbidities were predictive for risk stratification in elderly non-ST-segment elevation ACS patients: renal failure, anemia, diabetes, peripheral artery disease, cerebrovascular disease and chronic lung disease. The aim of the study was to determine clinical and functional characteristics in non-ST-segment elevation ACS patients with conduction disturbances.

Methods

From 188 consecutive patients admitted to the intensive care unit of cardiology department in Tula Emergency Hospital in autumn 2018 with nonfatal non-ST-segment elevation ACS, 50 patients (71.4±1.6 yrs) were selected: 19 patients (14 females (F) with left BBB, 18 (6 F) with right BBB and 13 (9 F) with I grade atrioventricular (AV) block.

Results

93% patients of all groups had history of hypertension; 42% of patients with left BBB, 27.8% of those with right BBB and 46.2% of AV-block - history of type II diabetes mellitus; 36.8; 27.8 and 38.5% of patients - renal disease. 33.3% of patients with right BBB had COPD.

Patients with left BBB were slightly older than those with right BBB and AV-block (74.2±2.4; 68.1±3.2 and 72.8±2.3 yrs: p=0.07). Body mass index in patients with right BBB was bigger than in patients with left BBB (31.4±1.3 vs 28.6 kg/m²; p=0.046). Patients with left BBB had more often pressing pain, patients with right BBB - chest pain and those with AV-block - burning pain. Permanent atrial fibrillation was more often seen in patients with right BBB (33.3%) whereas paroxysmal atrial fibrillation - in those with left BBB (36.8%).

Patients with left BBB demonstrated higher level of blood creatinine than patients with right BBB (132.8±14.0 vs 98.4±6.1 µmol/L; p=0.017) and lower thrombocytes count compared to patients having AV-block (155.9±12.3 vs 219.2±23.1 × 10⁹ /L). Patients with AV-block had more often digestive pathology (69% - cholecystitis, 31% - gastritis), lower hemoglobin level (119.8±15.4 g/l) and bigger left atrium size (44.4±4.4 mm). Lower left ventricular contractility (EF=56.4±2.9%) may be due to previous cardiac events: 38.5% of patients were suffered an AMI.

Conclusion

Patients with conduction abnormalities and clinical presentation of acute coronary syndrome have some clinical and functional features required more attention from the attending physician.

ST-ELEVATION MYOCARDIAL INFARCTION (MI) IN A MAN WITH TRANSIENT ISCHEMIC ATTACK (TIA)

Catarina Vilaça Pereira, Fernando Nogueira, José Cunha Marques, Diana Ferrão, Pedro Ribeirinho Soares, Jorge Almeida
Centro Hospitalar São João, Porto, Portugal

Introduction

The speciality of Internal Medicine is characterized by the challenge that the diagnostic approach constitutes, in a multi-systemic approach, as the pathologies that concern the specialty so require.

Case description

We present the case of a 67-year-old man, a history of hypertension, obesity, type 2 diabetes mellitus and active smoker. One day, he uses the Emergency Department (ED) for complaints of hypersudoresis, decreased sensation in the left upper limb, dysarthria and deviation of the labial commissure, lasting 2-3 minutes. In the ED without other complaints, namely chest pain, dyspnea, asthenia or syncope. Physical examination was hemodynamically stable and normal neurological examination.

The transient ischemic attack (TIA) hypothesis was applied and a study was requested in this context (cerebral computerized axial tomography (CT), electrocardiogram (ECG), analytical study and chest X-ray). In this follow-up, ECG is performed with evidence of sinus rhythm and ST segment elevation in the leads corresponding to the inferior wall, with q waves. The patient is transferred to the emergency room for monitoring and is evaluated by cardiology, performing an echocardiogram that demonstrates "inferior-posterior acinesia with cicatricial aspect and lateral apical acinesia, moderate left ventricular dysfunction and preserved right ventricular systolic function." The CT reveals "carotid vascular degenerative pathology, mild cortical atrophy, however without recent vascular lesions". Analytically necrose markers with troponin I high sensitivity in ascending profile (763,6 -> 1680.1 -> 37360.8 ng/L). Given the clinical stability (sustained non-existence of chest pain or anginal equivalents), hemodynamics and electrocardiographic changes do not allow to accurately estimate the evolution time, it is understood that there are no criteria for the performance of emergent catheterization, performed on the day after admission.

Discussion

The present clinical case intends to alert to the importance of an exhaustive clinical history and a complete physical examination. However, and even in the absence of suggestive clinical history and objective examination, it culminated in the diagnosis of infarction in an asymptomatic patient from the cardiac point of view from admission to the hospital and that, during the etiological study of a cerebral vascular event is raised the hypothesis of acute myocardial infarction (later confirmed by enzymatic elevation).

PNEUMOCYSTIS JIROVECII PNEUMONIA CASE IN A NON-HIV

Maria João Castro¹, Sara Raimundo², Márcia Souto², Andreia Rocha Costa², Anusca Paixão², Ricardo Amaral², Andreia Rei³, Ana Paula Dias², Francisco Esteves²

¹ ULSNE, Bragança, Portugal

² CHTMAD, Vila Real, Portugal

³ HESE, Évora, Portugal

Introduction

Pneumocystis Jirovecii Pneumonia (PJP) is a fungal infection that most commonly affects the immunocompromised and can be life-threatening. In general, patients at risk are those with any underlying disease states that alter host immunity such as those with cancer, the HIV, transplant recipients, or those taking immunosuppressive therapies and medications. Patients may show signs of fever, cough, dyspnea, and, in severe cases, respiratory failure.

Case description

We describe the case of a seventy-three, caucasian man with

history of Evan's Syndrome, taking a low dose of prednisolone (2.5 mg 3 times per week for 3 years). He was admitted at the Emergency department with fever, severe dyspnoea and bad general condition. He was febrile at 39.3°C, tachycardic at 95 bpm, tachypneic at 30 bpm and mean arterial pressure 55 mmHg. He had bilateral fine crackles on pulmonary examination. He presented with metabolic acidosis and severe hypoxemia, HIV test was negative. The chest radiograph revealed diffuse bilateral perihilar interstitial infiltrates. Computed tomography scan revealed "Extensive confluent densities in both lungs, demonstrating diffuse reticulodular pattern interstitial thickening."

Therefore, he was admitted in Intensive Care Unit (ICU) with de diagnostic of septic Shock owing to pneumonia and started on empiric antibiotic, endotracheal intubation was performed and vasopressor support was initiated after fluid challenge. Bronchoscopy was performed and bronchoalveolar lavage (BAL) revealed the presence of PJ. The antibiotherapy was changed to Trimethoprim-Sulfamethoxazole 1920 mg EV 6/6h per 14 days. The antibiotics were converted to oral dosing and he required decreasing amounts of oxygen. He spent a total of 10 days in the ICU and after gradual return to his baseline level of respiratory function; he was discharged on hospital day 18.

Discussion

This case reflects the importance of personal history in patient evaluation. It is crucial to identify immunosuppressed individuals at risk for developing PJP because several studies have shown that the morbidity and mortality in non-HIV patients is significantly worse than in patients with HIV. In this case PJP was suspected at the second day in the ICU because his clinical presentation and image pattern. Fortunately PJ was isolated earlier which allowed to initiate the adequate therapy. This case serves as an important reminder about how to approach similar patients.

#705 - Abstract

A "BRAIN COMPUTER INTERFACE" ON EEG SIGNAL FOR IMPROVING THE EMERGENCY DIAGNOSTIC PROCEDURE OF ACUTE ISCHEMIC STROKE.

Nicolò Casano¹, Giuseppe Placidi², Matteo Polsinelli², Carmine Marin³, Clara Balsano¹

¹ School of Emergency and Urgency Medicine, Department of Clinical Medicine, Life, Health & Environmental Sciences-MESVA, University of L'Aquila, L'Aquila, Italy

² University of L'Aquila, Computer Science laboratory, Department of Clinical Medicine, Life, Health & Environmental Sciences-MESVA, L'Aquila, Italy

³ University of L'Aquila, Stroke Unit, San Salvatore Hospital, L'Aquila, Italy

Background

Acute ischemic stroke is a time dependent disease, since the likelihood of a positive outcome of reperfusion therapies relies upon a timely intervention. Unfortunately, only a few patients are

eligible to be treated due to delays in the management of patients. In order to reduce the time door to needle or time door to decision, many efforts were done to develop new strategies in the pre-hospital management of acute ischemic stroke patients. Even if EEG, being associated with the cerebral blood flow, could be a reliable diagnostic tool in the differential diagnosis of ischemic, so far, there are few evidences on its application in emergency. Our purpose is to evaluate the effectiveness and reliability of EEG in early diagnosis of acute ischemic stroke. To this aim we started to validate the measurement of a "Brain Computer Interface" EEG in acute ischemic stroke patients, hospitalized in Stroke Unit.

Methods

We evaluated 10 ischemic stroke patients admitted to the Stroke Unit of San Salvatore Hospital in L'Aquila. The EEG measurements were performed with a Brain Computer Interface, Enobio 8 5G, a wireless electrophysiology sensor system for EEG recording.

Results

The EEG measurements were performed in the Stroke Unit, within 10 hours from symptoms, onset and after accomplishing the therapeutic procedures. The track recordings collected gave promising results on the possible use of this device to improve and to ease the diagnostic procedure of acute ischemic stroke.

Conclusion

In our opinion this device could be a valiant tool to support healthcare personnel in make the decision to activate the stroke code. Other studies need to be done to validate the EEG measurements during the transport of patients in the medical ambulance.

#714 - Abstract

"VIA VERDE CORONÁRIA" – A FAST APPROACH PROTOCOL FOR CHEST PAIN PATIENTS: WHAT HAVE WE LEARNED IN THE LAST 6 MONTHS?

Joana C F Lima¹, João Aguiar², Margarida Paixão Ferreira¹, Rita Calixto¹, Vera Cesário¹, José Vaz¹

¹ Hospital José Joaquim Fernandes, Beja, Portugal

² Instituto de Investigação do Medicamento (iMED.Ulisboa), Faculdade de Farmácia, Universidade de Lisboa, Lisboa, Portugal

Background

Coronary disease is one of the leading causes of death in Portugal and myocardial infarction accounts for 80% of all cardiovascular deaths. "Via Verde Coronária" (VVC), a fast approach protocol was developed few years ago to decrease the time between the first medical contact and the effective treatment. Our aim was to characterize the main diagnoses detected in VVC patients.

Methods

A cross-sectional study was undertaken in a Beja's hospital in the last 6 months. Upon admission, patients (aged 18 or older) were

included in the VVC if they presented an oppressive precordial pain that may irradiate to the left arm or neck, and may be associated with sweating, nausea and/or epigastric pain. Data was extracted from medical charts. Data analysis was performed using uni- and bivariate statistics (IBM SPSS v.20.0).

Results

A total of 181 patients were included (44% (n=79) female; mean age of 63.4±14.4 years old). The majority of diagnoses were from the circulatory system (64%, n=115), followed by musculoskeletal (19%, n=35), mental and behavioural disorders (12%, n=21), and other systems (6%, n=10). Anxiety and musculoskeletal pain were the non-cardiac causes most frequently identified. Uncontrolled hypertension was the leading cardiac cause apart from acute myocardial infarction (AMI), which accounts for 25% of the sample (73% NSTEMI vs 27% STEMI). There were no differences in time of symptom onset of patients with and without AMI (p=0.815). Obesity (aOR=3.64; 95%CI 1.43-9.27), smoking (aOR=1.82; 95%CI 0.77-4.30), hypertension (aOR=1.65; 95%CI 0.65-4.19), and type 2 diabetes mellitus (aOR=1.50; 95%CI 0.62-3.62) were possible risk factors for AMI, when compared with non-AMI; however, apart from obesity, there was no statistical significance on the other associations. In the AMI group, there may be no differences between the number of risk factors in patients with NSTEMI and STEMI (1.66±0.98 vs 1.69±1.02 risk factors per patient, respectively). The mean difference between maximum and at admission troponin I was 11.19±16.43 ng/ml. According to the Killip-Kimball classification, the majority of NSTEMI and STEMI were class I (88%, n=29; 92%, n=11, respectively). Only one of the two patients with class IV have died.

Conclusion

Data suggest that only 25% of all VVC cases were AMI. This finding corroborate that chest pain may not be sensitive enough to firstly include patients in VVC at admission. New screening technologies could be used to help triage patients with chest pain.

SUPERIOR VENA CAVA SYNDROME

Cátia Pereira, Joana Paixão, Sandra Santos, Joana Costa, Amílcar Silva

Centro Hospitalar Universitário de Coimbra, Coimbra, Portugal

Clinical summary

The superior vena cava syndrome (SVC) is characterized by a group of signs and symptoms caused by obstruction of the blood flow of SVC. Obstruction may be caused by extrinsic compression associated with malignancy. Treatment includes endoluminal stents, surgery, chemotherapy or radiation therapy. The image shows a 58-year-old woman who was admitted with facial and cervical oedema, flushing and thoracic collateral circulation with 3 weeks of evolution. History of Graves' disease. Smoker. Chest X-ray with one lesion superimposed on the projection of the clavicle. Computed tomography of the chest with a nodule of

41x22 mm in the right upper lobe. Evaluated by the interventional radiology that performed dilation of the filiform stenosis. Cytology compatible with pulmonary carcinoma metastasis.

Figure #756. Obstruction of blood flow through the superior vena cava.

SEVERE PAIN AFTER NSAID INGESTION – AN UNCOMMON PRESENTATION OF ANAPHYLAXIS.

Yuhei Mogi, Ivor Cammack

Teine Keijinkai Hospital, Sapporo, Japan

Introduction

Anaphylaxis commonly causes hypotension, rash, dyspnea and gastrointestinal symptoms. Crampy abdominal pain is common, but pain elsewhere is rare. We describe a patient who presented with lower back and bilateral leg pain 10 minutes after taking an over-the-counter NSAID.

Case description

A 62-year-old Japanese male presented to ER with back and leg pain and mild dyspnea. His symptoms began when he went to toilet, 10 minutes after ingesting Beneslon, a combination containing aspirin and hydrotalcite, an antacid.

Several years ago, he developed anaphylaxis to CT contrast dye which presented as severe generalized pain and dyspnea. He was otherwise in good health.

On examination, his blood pressure was 105/77 mmHg, heart rate 52 bpm, respiratory rate 28/min, SpO₂ 98% (Room Air), temperature 36.6°. There was no rash or perioral swelling. Cardiorespiratory exam was normal.

We diagnosed anaphylaxis based on the sudden onset of hypotension to 70% of his usual blood pressure and respiratory tract symptoms soon after ingestion of a new medication. He was treated with 0.3 mg intramuscular adrenaline, rapid intravenous fluid resuscitation, 5 mg chlorpheniramine maleate. His symptoms including the pain resolved within 10 minutes.

Discussion

In the literature, lower back pain in anaphylaxis has been reported as uterine cramping in women, but we couldn't find any published reports of this symptom in a male population.

During anaphylactic reactions, histamine release contracts smooth muscle.

Lower back pain is caused by contraction of ovary, which has been reported as a symptom of anaphylaxis in woman. Contraction of bladder and urethral smooth muscle are also known to cause lower back pain. Therefore, the pain in this case may be due to contraction of bladder smooth muscle.

This case highlights that lower back pain can be a symptom of anaphylaxis.

#798 - Abstract

ACUTE PANCREATITIS IN AN INTERMEDIATE CARE UNIT

Margarida Rodrigues Fonseca, Mariana Constante, Rita Ivo, Pedro Ribeiro Dos Santos, João Lopes Delgado, Isabel Madruga
Centro Hospitalar de Lisboa Ocidental, Lisboa, Portugal

Background

Acute pancreatitis (AP) is a potentially life-threatening disease with a wide spectrum of severity. Though most cases of AP are mild, the challenge remains in identifying and managing the severe cases and the associated complications. The present review aims to characterize all patients with AP admitted to an Intermediate Care Unit (IntCU).

Methods

Retrospective analysis of data concerning patients admitted to IntCU with the diagnosis of Acute Pancreatitis in 2017 and 2018 – demographic characteristics and clinical severity.

Results

Thirteen patients were admitted (5 in 2018 and 8 in 2017). One patient was excluded due to administrative reasons. Six were male and the median age was 57 years (24–81 years). Most patients (67%) were admitted from the Emergency Room. Two patients (17%) were transferred to the Intensive Care Unit. The median duration of stay was 5.5 days (0–13 days). Gallstones were identified in five patients. Nine patients had CT evaluation which revealed pancreatic necrosis in two. The initial APACHE II score was 9 (0–21) and the initial SAPS 2 score was 19 (6–46). The Ranson score at diagnosis was 1.6 (0–3) and the cumulative was 2.5 (0–4). The patients with APACHE II score higher than 10 (33%) had more acute renal injury and higher lipase at admission. Two of these patients needed vasopressor support due to haemodynamic instability.

Conclusion

Risk stratification plays a key role in identifying the best suitable candidates for IntCU admission in order to provide the best

management of complications. Acute renal injury and higher lipase at admission seem to be related with APACHE II scores higher than 10, and therefore with predicted mortality of more than 10%.

#918 - Case Report

MYOCARDIAL INFARCTION: THE CULPRIT IS NOT ALWAYS A CORONARY ARTERY

Ana Neto¹, Daniel Seabra¹, Diana Pissarra², Inês Oliveira¹, Mário Jorge Amorim², Aurora Andrade¹, Paula Pinto¹

¹ Tâmega e Sousa Hospital Center, Penafiel, Portugal

² São João Hospital Center, Porto, Portugal

Introduction

Embolic myocardial infarction (MI) is an uncommon complication of infective endocarditis (IE); diagnosing this complication requires high suspicion.

Case description

72-year-old obese male, with hypertension, dyslipidaemia and moderate aortic stenosis, presented at the emergency room with dyspnoea at rest after acute-onset chest pain during the night. He had weight loss history, night sweats and progressive shortness of breath in the past 3 weeks. On examination, he had respiratory distress and desaturation (90% with FiO₂ 60%), tachycardic but normotensive, no fever; bilateral pulmonary rales and no cardiac murmurs. Electrocardiogram (ECG) showed R wave poor progression in anterior leads, evolving with anterior QS waves and mild ST-T elevation. Laboratory data: mild anaemia, leucocytosis, mild C-reactive protein rise and elevated troponin I. Bedside echocardiography showed severe depression of left ventricular function with interventricular septum and anterolateral wall hypokinesia, moderate aortic stenosis, moderate to severe aortic regurgitation and an apparently flail valve with an hyperechogenic mass attached.

He was intubated in order to perform emergent cardiac catheterization that showed no significant coronary artery disease and a severe aortic regurgitation with no aortic dissection. Subsequent transoesophageal echocardiography confirmed severe regurgitation and a mobile image suggestive of vegetation (larger diameter ~3 cm), apparently attached to the 3 cusps of the aortic valve, conditioning dynamic obstruction of LV outflow tract. Thickening of the mitroaortic curtain suggestive of periaortic abscess was stated. He was transferred to cardiothoracic surgery referral centre and submitted to aortic valve replacement and abscess exclusion with pericardial patch. All sets of blood cultures and bacteriological examination of the valve were negative. Initial post-operative period was uneventful. Unfavourable clinical course with cardiac tamponade 10 days after with surgical reintervention, multiorgan dysfunction and death.

Discussion

IE can be associated with embolic phenomena carrying a high risk of morbimortality. Intracoronary septic embolization resulting in

MI is an uncommon complication of IE. Although no angiographic evidence of coronary emboli in our case, the probability of a MI secondary to coronary embolization is supported by the clinical presentation of chest pain, ECG findings and a significant rise in troponin. Management of MI in this setting remains controversial.

BILATERAL PNEUMOTHORAX AND PAZOPANIB

Marta Dalila Martins, André Paupério, Lindora Pires, Sofia Garcês Soares, Inês Ferreira, Mari Mesquita

Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal

Clinical summary

A 77 year old man diagnosed with synovial sarcoma with pulmonary metastasis, presented to the emergency department with worsening dyspnea in the prior week. Examination revealed respiratory distress, high blood pressure (BP: 219/119 mmHg) and hypoxia (1). Pulmonary auscultation with prolonged expiratory time and scattered rhonchi and wheezing. Chest x-ray showed a bilateral pneumothorax (panel A), confirmed with computed tomography (panel B). The last exam displayed a pleural effusion on the left side (panel B). Two thoracic drains were placed with subsequent improvement of the dyspnea. The patient was being treated with pazopanib, which is described to be associated with pneumothorax in a small percentage of patients.

Figure #929.

BILATERAL OBSTRUCTIVE UROLITHIASIS - AN UNUSUAL AND CHALLENGING DIAGNOSIS IN THE ACUTE SETTING

Inês Albuquerque, Jorge Almeida

Centro Hospitalar de São João, Porto, Portugal

Clinical summary

A 57-year-old woman presented to the emergency room

complaining of hematuria and dysuria for four days. Two days earlier bilateral lumbar pain radiating to the lower abdominal quadrants and anuria settled. She was febrile, hypotensive and with a compensated metabolic acidosis. After correct placement of a urinary catheter, there was no urine output. Initial work-up showed acute kidney injury, leukocytosis and elevated C-reactive protein. Pancreatic enzymes were normal. We requested a contrast computed tomography of the abdomen, which confirmed the clinical suspicion of bilateral obstructive urolithiasis with massive hydronephrosis and markedly distorted kidneys. Emergency kidney stone removal surgery was performed.

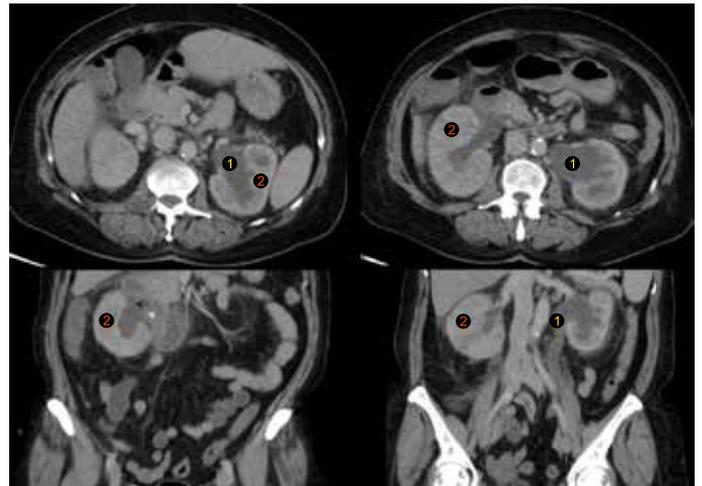

Figure #930. Contrasted computed tomography of the abdomen. Axial and coronal images showing (1) hydronephrosis and (2) distorted kidneys.

#932 - Case Report

AN INTERESTING CASE OF NON - CARDIOGENIC PULMONARY EDEMA DUE TO DELIBERATE CALCIUM CHANNEL BLOCKER OVERDOSE

Sofia Avgeri, Evaggelia Sergi, Aggeliki Tsifi, Stela Stefanova, Apostolos Voulgaridis, Maria Katsiari

Konstantopouleion - Patision General Hospital Of Nea Ionia, Athens, Greece

Introduction

Calcium channel blockers (CCBs) are widely used anti-hypertensive and anti-arrhythmic pharmaceutical agents, divided in two categories: dihydropyridines (such as amlodipine, nifedipine and felodipine) and non-dihydropyridines (verapamil and diltiazem). Overdose of these drugs can cause severe cardiovascular collapse and the potential complications include hyperglycemia, bowel ischemia and non-cardiogenic pulmonary edema.

Case description

We, hereby, present the case of a 58-year-old woman with a history of thyroid disease and obesity, who deliberately consumed 28 tablets (sustained release) of nifedipine 20 mg and 20 tablets

(sustained release) of verapamil 240 mg with suicidal intent. When she arrived in the emergency department she had a 9/15 in the Glasgow Coma Scale, hemodynamic instability, hypoxemia and hyperglycemia. She received gastric decontamination through a Levin tube and activated carbon was administered. She was also supported with oxygen, vasoconstrictive agents, insulin, iv Calcium gluconate and iv crystalloid fluids. Due to the consequent deterioration, presenting with lactic acidosis and respiratory failure, she was intubated and transferred to our Intensive Care Unit (ICU). Her X-rays revealed images compatible with Acute Respiratory Distress Syndrome (ARDS) and she was treated with high Positive End Expiratory Pressure (PEEP) mechanical ventilation. During this hospitalization, she suffered from fever due to central line infection which was treated with antibiotic agents. After being hemodynamically stabilized, iv furosemide was administered in order to maintain negative fluid balance. She gradually improved and she was extubated and monitored during spontaneous breathing. She was released from ICU after 15 days and she returned stable to the initial hospital ward.

Discussion

The mechanism of non-cardiogenic pulmonary edema in patients with CCB overdose is not exactly clarified. It is possible that selective precapillary vasodilatation leads to pulmonary capillary transudation causing an increase in transcapillary hydrostatic pressure and interstitial edema. Hyperglycemia – possibly due to decreased insulin release from the pancreatic cell, but also decreased insulin sensitivity and glucose uptake from the tissues, must also be treated. Cardiovascular complications – such as hypotension and reflex tachycardia – must be restored so as to maintain adequate circulation and breathing and oxygenation are of critical significance to be supported.

#955 - Case Report

DROWNING: PROMPT HIGH FLOW OXYGEN, PEEP AND HYPOTHERMIA - FOR A BETTER OUTCOME

Dulce Rita Correia, Carolina Alves Rodrigues, Catarina M Salgado, Manuel Morais, António Pais-De-Lacerda, Marco Ribeiro Narciso CHULN, Lisboa, Portugal

Introduction

Drowning is a serious public health problem with more than 500,000 deaths/year worldwide. Moreover around one-third of the survivors have severe neurological sequelae. Optimal pre-hospital and hospital care with rapid correction of hypoxemia and acidosis is determinant for a better outcome.

Case description

A 70-years-old housewife, with hypertension, dyslipidaemia and depression attempted suicide by drowning. The on-site emergency team (unconscious victim found in the irrigation tank) verified asystole in ECG monitoring, and started CPR

manoeuvres (adrenalin 1mg IV Q 3min X2, 200J shock for ventricular fibrillation), and performed orotracheal intubation. At hospital A&E admission (1h later) with Glasgow Coma Score (GCS) 3, non-dilated pupils but without corneal reflexes, she was hypertensive (158/115 mmHg) with tachycardia (123 pm), hypothermic (34.1°C) and hypoxemic - SpO₂ 93% (high flow mask FiO₂ = 80% with 15L O₂ p/M), with severe lactic acidosis (101 mmol/L). New onset atrial fibrillation developed. Chest x-ray revealed bilateral diffuse interstitial infiltrates, and brain CT-scan showed discrete decreased cortical gray matter attenuation with a loss of normal gray-white differentiation, bilateral basal ganglia attenuation and diffuse oedema with effacement of the CSF-containing spaces. With the resolution of acidosis, GCS increased to 6 with eye opening to pain, and present corneal reflexes. She was then admitted to the Intensive Care Unit (ICU) and remained mechanically ventilated (controlled mode) for 24h with Fi O₂ 80% and positive end-expiratory pressure (PEEP)=12cm H₂O. Targeted temperature between 34°C and 36°C was maintained for the first 3 days. Fiberoptic bronchoscopy revealed mucosal oedema; microbiological investigation was negative. Multiple bilateral, asymmetric patchy small nodular and reticulo-nodular opacities involving predominantly the lung bases, with bilateral pleural effusions were treated empirically for 7 days with Amoxicillin/clavulanic acid. Progressive neurological improvement (GCS 6->12) enabled her to be weaned from mechanical ventilation on day2 of ICU, and to be transferred to hospital ward (day3). She was discharged at day 15, without any neurological sequel, GCS 15.

Discussion

Rapid pre-hospital cares, and the prompt and effective correction of hypoxemia and acidosis, maintaining hypothermia for at least the initial 24 hours, are all essential measures to achieve a good prognosis in drowning.

#970 - Abstract

ARE D-DIMER DOSING BEING WELL PERFORMED FOR VENOUS THROMBOEMBOLISM DIAGNOSIS IN OUR EMERGENCY DEPARTMENT?

Bárbara Soeiro, Helena Greenfield, Carolina Guedes, Sílvia Sousa Hospital Pedro Hispano, ULSM, Matosinhos, Portugal

Background

Venous thromboembolism (VTE) refers to Deep vein thrombosis (DVT) and Pulmonary embolism (PE). Currently, there are 2 validated scores for pre-test probability of PE: Wells score and revised Geneva score, and 1 for DVT: two-level wells score.

D-dimer test has sensitivity of over 95% and high negative predictive value for the diagnosis of VTE. On the other hand, the specificity has lower values, and falsely positive results can be observed in cases of active infection, neoplasms and necrosis.

Our goal was to analyse every Emergency Department episode

in which d-dimer dosing was performed. The variables analysed were: presence or absence of clinical symptoms suggestive of VTE, the suitability of d-dimer request according to pre-test probability scores, performance of CT angiography if d-dimer elevation and number of confirmed VTE.

Methods

We performed a retrospectively analysis of all cases of patients over 18 years of age in whom D-Dimers test was performed in our Emergency Department from the 1st of July to the 31st of December of 2017.

Results

589 episodes were included in our analysis (565 patients). There was a light predominance of female gender, representing 61% (n=361). The median age was 62±19 years-old, minimum of 19 and maximum of 98.

The commonest presenting symptoms were dyspnea (29%, n=168), chest pain (28%, n=162), unilateral lower limb pain (14%, n=83) and syncope (13%, n=78). In 28% (n=165) no suggestive symptoms or signs were identified. The pre-test probability was calculated for each episode: for Wells Score, low level in 75% (n=441), intermediate level in 24% (n=144) and high level in 1% (n=4) with 6, 20 and 1 cases of confirmed VTE, respectively; for Revised Geneva Score, low level in 61% (n=361), intermediate level in 36% (n=214) and high level in 2% (n=3), with 4, 20 and 3 cases of confirmed VTE, respectively. For Two-Level Wells score, likely in 11% (n=62) and unlikely in 89% (n=527), with 12 and 3 cases of confirmed DVT.

D-dimers were elevated in 55,5% of all episodes (n=327). In only 27,8% (n=91) of these angio-TC was performed. VTE was confirmed in 4,6% (n=27) of all episodes, 2% (n=12) of PE and 2% (n=12) of DVT and overlap in 3 cases.

Conclusion

This analysis shows a substantial d-dimer dosing in patients without clinical likelihood and low-level pre-test probability. Consequently, a significant number of false positives were obtained. We intend to establish a VTE diagnosis protocol in our Emergency Department and reevaluate these results.

ACUTE EOSINOPHILIC PNEUMONIA REQUIRING EXTRACORPOREAL MEMBRANE OXYGENATION

Verónica Botelho Guiomar, Carla Basílio, Nuno Príncipe, Roberto Jr Roncon-Albuquerque, Teresa Honrado
Centro Hospitalar e Universitário de São João, Porto, Portugal

Introduction

Acute eosinophilic pneumonia is a rare cause of hypoxemic respiratory failure that if not rapidly recognized can progress to refractory respiratory failure. The first case published of acute eosinophilic

pneumonia requiring Extracorporeal Membrane Oxygenation was in 2010 and there were only six cases described in the literature.

Case description

Case 1

An 18-years-old female was admitted in the emergency. Nine days before, she started with productive cough, fever and odynophagia that persisted despite 8 days of clarithromycin. On admission, she was febrile, tachypneic, with diffuse crackles on respiratory auscultation and hypoxemic respiratory failure. Blood tests showed elevated white cell count and chest X-Ray showed bilateral consolidation in inferior lobes. A diagnosis of community-acquired pneumonia was made and it was started an antibiotic. She was admitted in the Intensive Care Unit as she didn't present any signs of good evolution, extracorporeal membrane oxygenation was performed. We documented peripheral eosinophilia and bronchoalveolar lavage revealed eosinophilic alveolitis. The patient started glucocorticoids and she was successfully decannulated and extubated at day-13. Case II: a 55-years-old female was admitted in the emergency. Fifteen days before hospital admission, she started with productive cough, fever and dyspnoea after exposure to wood and plastic burnings. On admission, she was febrile, tachypneic, diffuse crackles and wheezing on respiratory auscultation and hypoxemic respiratory failure. Blood tests showed elevated white cell count and C-reactive protein. Chest X-ray showed bilateral consolidation. A diagnosis of community-acquired pneumonia was made and the patient started an antibiotic. In the following days, the respiratory failure worsened and the patient was transferred to Intensive Care Unit and in day-4 of admission Extracorporeal Membrane Oxygenation was started and a TAC-guided lung biopsy was made. The biopsy revealed signs of acute fibrinous and organizational pneumonia and eosinophilic infiltration, so the patient started glucocorticoids. She was successfully decannulated and extubated at day-15.

Discussion

The diagnosis of acute eosinophilic pneumonia depends on a high index of clinical suspicion and characteristic findings in bronchoalveolar lavage. Patients usually respond well to glucocorticoids but some require extracorporeal membrane oxygenation to have clinical improvement.

#995 - Abstract

METFORMIN-ASSOCIATED LACTIC ACIDOSIS: ANALYSIS OF 19 YEARS IN AN INTENSIVE CARE UNIT

Ana Pedroso¹, Inês Ferreira¹, Rita Santos¹, Vasco Costa², Carolina Paulino², Bernardino Valério², Luís Coelho², Vítor Mendes², Camila Tapadinhas², Pedro Póvoa²

¹ Internal Medicine Department, Hospital de São Francisco Xavier (CHLO), Lisboa, Portugal

² Polyvalent Intensive Care Unit, Hospital de São Francisco Xavier (CHLO), Lisboa, Portugal

Background

Metformin is the most commonly prescribed oral antihyperglycemic and the first line therapy for newly diagnosed type 2 diabetes. It is contraindicated in patients with renal or hepatic insufficiency, in very elderly patients, and in patients with conditions of circulatory dysfunction such as congestive heart failure, due to increased risk of lactic acidosis. Metformin-associated lactic acidosis (MALA) is an extremely rare condition (≤ 10 events per 100,000 patient-years of exposure) and are associated with mortality rates of 30-50%.

Methods

Retrospective analysis of the patients admitted with MALA in an Intensive Care Unit from 2000 to 2018.

Results

During this period 32 patients were admitted with MALA (age 73.8, 72% feminine, APACHE 30.6, SAPSII 61.8 and mortality in UCI 25%). The admission symptoms were gastrointestinal symptoms $n=23$ (71.9%), neurologic $n=7$ (21.9%) and respiratory $n=2$ (6.3%). Metformin doses were unknown in 6 patients, but 2109mg in average (median 2000mg) and 18 patients (56.3%) medicated also with diuretics and/or anti-hypertension drugs. On admission, every patient presented with acute kidney failure, needing continuous renal replacement technic in 93.8%. 68.8% presented in shock and needing mechanic ventilation 59.4%. The median creatinine at admission was 6.36 mg/dL [4.40-8.03], lactate 13.9 mmol/L [9.70-18.0], pH 6.980 [6.872-7.100] and bicarbonate 5.00 mmol/L [3.50-8.40].

Conclusion

Although metformin is largely used, attending this complication is rare, MALA is often non-recognized or late diagnosed. Patients and families should be aware of alarm symptoms (vomiting and nausea) and precipitant factors that should lead to metformin suspension and quick searching for medical evaluation. Doctors should be more conscious about contraindications and higher doses usage, because this complication is rare, but often fatal, without specific treatment.

AN EXTREME ELECTROCARDIOGRAPHIC SINE WAVE PATTERN

Francisca Abecasis, Rita Homem, Mafalda Sequeira, Henrique Santos, Inês Pintassilgo

Hospital Garcia de Orta, Almada, Portugal

Clinical summary

A 57-year old woman with hypertension, chronic heart failure and end-stage renal disease on hemodialysis was admitted after progressive onset of weakness and altered consciousness. Her last dialysis session had been three days before. On examination she revealed slurred speech, generalized weakness and

tachypnea. The electrocardiogram (EKG) showed largely widened QRS complexes merging with T waves in a sine wave pattern (A). Potassium (K^+) measured on a blood gas sampling was 9.2mmol/L, with compensated metabolic acidosis.

Calcium gluconate and K^+ -wasting measures were emergently initiated. After 20 minutes, the only EKG changes were peaked T waves and ST-segment depression (B). Blood gas analysis now showed a K^+ of 7.4mmol/L. Emergent dialysis was started with clinical improvement.

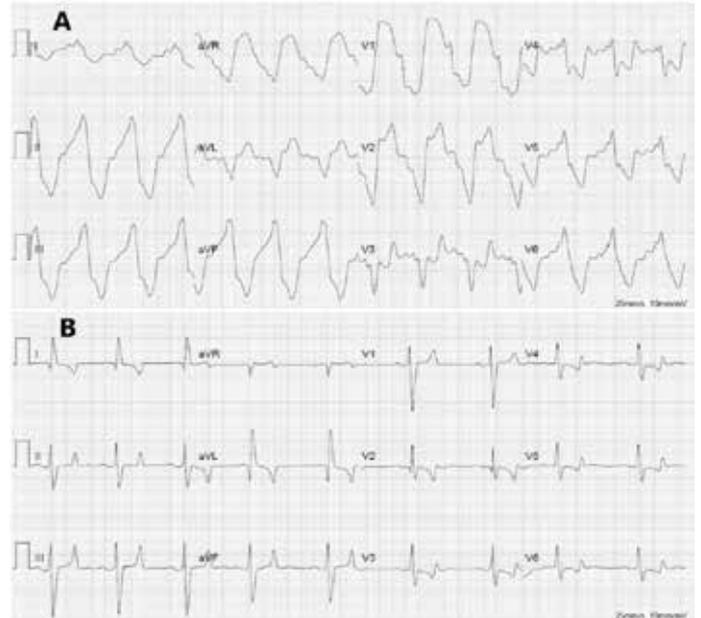

Figure #1003.

EXTRAPLEURAL HEMATOMA: A RARE IMAGIOLOGIC FINDING

Carolina Nunes Coelho, Iuliana Cusnir, Diana Vital

Hospital de Santarém, Lisboa, Portugal

Clinical summary

A 74 year old man was admitted in Emergency Department after a fall with thoracic trauma. He was medicated with rivaroxaban. At admission he was clinically stable, normal arterial pressure, normocardic, peripheral saturation 93%, no pain. The chest radiograph showed a opacity in the superior part of right lung (Figure 1). Computed tomography revealed a extrapleural hematoma with 9x6x18 centimetres associated with fractured 4th to 7th costal arches. He was hospitalized, performed a thoracic drainage and then had a cirurgic approach.

Extrapleural hematomas are uncommon, and often associated with blunt chest trauma and rib fractures. Patients with anticoagulation medication has additional bleeding risk. The correct evaluation of initial chest radiograph is mandatory for early recognition.

Figure #1010. Chest radiograph with extrapleural hematoma.

HYPOTHERMY AT THE INTERFACE BETWEEN SPECIALTIES

Nicoleta Dima¹, Elena Rezus¹, Roxana Ganceanu-Rusu¹, Elena-Daniela Onofras², Andreea Clim², Codruta Minerva Badescu¹, Minela Aida Maranduca¹, Ciprian Rezus¹

¹“Grigore T. Popa” University of Medicine and Pharmacy, Iasi, Romania

²“Sf. Spiridon” Clinical Emergency Hospital, Iasi, Romania

Background

Hypothermia is a thermoregulation imbalance characterized by alteration of the thermogenetic and thermolithic processes, with the appearance of a negative caloric balance, with the decrease of the body temperature. Many patients develop acute lower limb ischemia requiring amputation, with important functional and social consequences.

Methods

We conducted a prospective study on 100 patients admitted to hypothermia at the IIIrd Medical Clinic of the “Sf. Spiridon” Clinical Emergency Hospital, Iasi, between 1 January 2016 and 31 December 2018. The analyzed parameters included demographic data, presence of cardiovascular risk factors, clinical symptoms, associated co-morbidities and the impact of medical treatment on disease progression. For batch monitoring, we performed: bioimoral tests, electrocardiogram, ankle-brachial index (ABI) measurement, transthoracic echocardiography and vascular Doppler ultrasound.

Results

In the study group, the predominance of urban, male patients, aged 52-92 years, averaged 71.45±10.15 years. Smoking was

the main cardiovascular risk factor. Associated comorbidities were high blood pressure, diabetes mellitus, dyslipidemia and alcohol consumption. Low adherence to treatment is a negative prognostic factor.

Conclusion

Serious hypothermia negatively influences the vital prognosis by the determined systemic pathophysiological phenomena. The most serious systemic complication of hypothermia is multiple organ failure syndrome. The major objective is to improve the quality of life of the patient by remission or alleviation of the algic syndrome, as well as preserving the viability of the affected member. Patient monitoring is extremely important and involves a multidisciplinary team.

#1031 - Abstract

EPIDEMIOLOGY OF INFECTIONS IN CRITICAL CARE

Pascual Valdez, Melina El Halli Obeid, Carla Huaman, Vanesa Segovia, Jonatan Bornia, Vanesa Vecchio, Soledad Galasso, Paula Ramos, Cintia Simón, María Del Rosario Bruno, Diego Yahni, Leonardo Vasta

Vélez Sarsfield Hospital. Government of the Autonomous City of Buenos Aires. Argentina

Background

Objectives: To determine the number of infectious events, establish mortality and factors associated with it.

Methods

Methods: Prospective, observational, longitudinal, analytical design. We analyzed patients from the ICU of the Velez Sarsfield Hospital in the months of February to July 2015. Sample: consecutive.

Results

Results: 52 cases, 58% males, medium: 61.50±16.50 years, stay 14.00±8.00 days, Apache II: 12.00±4.50, comorbidities: 2.00±1.00. Central route (CVC): 75%, median placements: 2.00±1.00/patient, permanence: 17.00±12.00 days. Bladder catheter (SV): 82.69%, median permanence: 15.50±11.50 days. Mechanical ventilation (VM): 46.15%, median permanence: 17.50±12.50 days. Deceased: 30.76%, almost all linked to infections. Total infectious events: 86, per patient: 1.65. Cultures positivity: 44%-66%. Antibiotic adjustment was required in the first event: 46.66% (31.10% for failure, the rest for desquamation). Most frequent focus: lung (38.82%), second unknown (21.17%). Most common germs: Acinetobacter (21.94%), KPC (18.44%) and MRSA (10.67%). Most used drugs in decreasing order: vancomycin (19.10%), colistin (12.73%), piperacillin tazobactam (10.82%). Predictors of mortality in multivariate analysis: older (p 0.002), need adjustment of Atb? (p 0.06). Events linked to devices: 60.91 infections every 1000 days. Infection rate every 1000 patients day: 8.43 (CVC),

32.80 (VM) and 19.68 (SV). Infection rate for 1000 days of use: 9.34 (CVC), 56.36 (VM) and 21.78 (SV).

Conclusion

Population of moderate severity and few comorbidities, with 1.65 infectious events per patient, mainly respiratory. Mortality 31%, associated with age and tendency to a greater number of infectious events

#1048 - Case Report

TRANSIENT GLOBAL AMNESIA IN EMERGENCY ROOM: CASE REPORT

Mario Angelo Cenedesi Junior^{1,2}

¹ Sao Paulo University, Ribeirao Preto, Brazil

² Monte Alto Municipal Emergency, Monte Alto, Brazil

Introduction

Transient global amnesia (TGA) is a reversible condition characterized by acute and limited malfunction of episodic declarative memory, with no change in motor, sensory and perceptive function or lowering of consciousness level. Episodes of TGA are the reason for urgent visits, and the diagnoses can be as varied as possible, from strokes to dissociative disorders.

Case description

A 69-year-old woman was taken to the hospital by a family member with memory loss 30 minutes ago during breakfast. She could not remember what she was doing, what day it was-but she remembered the name of her husband and her children, her full name, her birthday, but she could not calculate her age. At physical examination, cooperative, without sensory-motor alterations, but he did not remember recent facts. Deny fever, allergies and traumas. He presented Transient Ischemic Accident episode three years ago, without sequels. Hypertensive and with hypothyroidism, without change of medication in the last months. He did not know where he was (even with the staff repeating), and could not record the doctor's name. Skull tomography performed without changes, as well as electrocardiogram and routine laboratory exams. Patient presented sudden recovery of memory 07h after the onset of the picture, was released (not knowing how she arrived at the hospital). Two days later, he performed brain resonance, which showed no morphological changes or evidence of acute ischemic injury. No residual symptoms or signs were noticed. Patient resumed his social and work activities without loss.

Discussion

The incidence of AGT among the population is 5.2 to 10 per 100,000 people per year, increasing over 50 years. It is a sudden and transient disorder of anterograde memory that usually lasts from four to 6h, and can last for up to 24h, with no alteration of consciousness level, sensory-motor examination, personality or other cognitive alterations. Acts such as writing, directing and looking at hours are preserved, as well as relating to other people

(the patient, despite repetitive questioning, remained cooperative and heeded the examiner's commands). The diagnosis is clinical, and it is necessary to perform imaging tests to rule out other pathologies. There is no consensus in the medical literature regarding the pathophysiology of TGA (the most accepted explanation was secondary to arterial ischemia and history of migraine). The differential diagnosis should include, in addition to transient ischemic attack, intoxication and others.

AN UNUSUAL CASE OF ABDOMINAL AORTIC ANEURYSM RUPTURE

Jose Claro Rodriguez¹, Jose Ramon Seco Vasco¹, Juan Francisco Lopez Manchado²

¹ SCCU Sevilla Sur. Servicio Andaluz De Salud, Sevilla, Spain

² Har Moron De La Frontera. Asbg., Moron De La Frontera, Spain

Clinical summary

69 years old male, affected by multiple pathologies, beginning with a mild low back dull ache that stopped with oral intake of acetaminophen. On the next day, patient showed a confusing abdominal condition, with transient episodes of diarrhea and general discomfort, distended abdomen with mild rigidity, dullness, and downward blood pressure. This abdominal CT proved an infrarenal aneurysm, and early bleeding in retroperitoneum. Emergency endovascular surgery followed, with satisfactory results and prognosis.

#1116 - Case Report

A CASE REPORT ON CAVERNOUS SINUS INFECTIOUS THROMBOPHLEBITIS IN A PATIENT WITH LOCALLY ADVANCED OROPHARYNGEAL CANCER.

Lara Cantero Del Olmo, Marta Del Palacio Tamarit, María José Díez Medrano, Blanca Rodríguez Alonso, Sandra Bello León, María Pavón Moreno

Fundación Jiménez Díaz, Madrid, Spain

Introduction

Septic thrombophlebitis of the cavernous sinus is a rare disease with high mortality rates. Before the availability of antimicrobial agents, mortality was near 100%, but since the onset of the antibiotic era, it has markedly decreased to approximately 20% to 30%.

Case description

A 74-year-old female patient presented to the emergency room with fever and asthenia that had progressed over the last four days, together with redness and swelling of the left eye. Her past medical records were remarkable for a T4aN2cM0 oropharyngeal epidermoid carcinoma that had been treated with palliative chemotherapy with paclitaxel and carboplatin.

On physical examination she had redness and oedema of the left eye, as well as conjunctival hyperemia, with bilateral asymmetrical paresis of extraocular muscles: partial ptosis of the right eye and complete ptosis of the left eye and obvious weakness of right superior rectus and lateral rectus muscle, together with a left "frozen eye", with weakness affecting all muscles.

Blood work showed leucocytosis, with neutrophilia and a high C-reactive protein level of 44 mg/dl (normal limits between 0-0.5 mg/dl).

A non-contrast brain CT scan showed enlargement of the left ophthalmic vein with periocular inflammatory changes as well as a partial filling defect in the left cavernous sinus.

A diagnosis of infectious thrombophlebitis affecting both cavernous sinuses as well as left orbital cellulitis was made.

Empiric antibiotic therapy with vancomycin 1 gr q 12hr, cefepime 1 gr q 8hr, ampicillin 1 gr q 6hr and metronidazole 500 mg q 6hr was started. Enoxaparin was prescribed as well at a dose of 60 mg q 12hr.

The patient was admitted to the Oncology Department.

Hypokalaemia was detected as a secondary effect of chemotherapy, and tubulopathy was diagnosed.

After receiving positive blood cultures for *Streptococcus anginosus*, antimicrobial treatment was adjusted, removing ampicillin from the treatment.

The main complication that arose during hospitalization was dysphagia, with the patient rejecting the option of a nasogastric tube. Finally, she was moved to a palliative care hospital.

Discussion

Nowadays, it is rare to observe the full clinical presentation of cavernous sinus thrombosis.

Oropharyngeal cancer patients are more vulnerable to complicated local infections, particularly after receiving local radiotherapy or cytotoxic chemotherapy.

Ophthalmic symptoms in the setting of fever and headache should always raise suspicion of cavernous sinus involvement.

CARRYING THE ANSWER

Marta Fonseca, Mário Ferreira, Zélia Neves, João Machado

Hospital Prof. Doutor Fernando Fonseca, Amadora, Portugal

Clinical summary

50-year-old man, with previous hypertension history without medication, comes to emergency room with acute chest pain. While waiting for observation, the patient had a generalized tonic-clonic seizure. In the resuscitation room he was hypertensive and agitated. No tachycardia was observed. Symptoms were controlled with midazolam and isosorbide dinitrate. The patient suffered a vomit expelling plastic fragments.

Initial laboratory findings showed a total creatinine kinase of 6869 U/L, negative troponin, leucocytosis, urinary cocaine dosing with a maximum of 26,000 mg/dL. The abdomen and pelvic computerized tomography revealed signs of multiple packages along all digestive track.

The patient was submitted to a laparotomy surgery with the removal of 73 cocaine packages.

Figure #1121. Abdominal TC scan.

#1192 - Case Report

SUPERIOR VENA CAVA SYNDROME (SVCS): THE IMPORTANCE OF PHYSICAL EXAMINATION

Adriana Girão^{1,2}, Rui Pina^{1,2}, Isabel Fonseca^{3,2}

¹ Centro Hospitalar e Universitário de Coimbra, Serviço de Medicina Interna, Coimbra, Portugal

² Clínica Universitária de Medicina Interna, Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal

³ Centro Hospitalar e Universitário de Coimbra, Serviço de Urgência A, Coimbra, Portugal

Introduction

Superior vena cava syndrome has a distinct clinical presentation, can be life threatening and is a rare oncologic emergency. A thorough history and physical examination are critical, focusing on the signs and symptoms of SVCS. Practitioners should specifically assess for dyspnea, upper extremity swelling, nonproductive cough, facial swelling and collateral veins on the neck or upper chest. Family members may note these signs to be more prevalent in the early morning.

Case description

A 65-year-old male was admitted in the emergency room (ER) with a month evolution of dyspnea with slight limitation of physical activity, swelling of the face, mostly around the eyes and in the morning and, non pruriginous purpuric lesions in the face and thorax with progressive worsening. He was previously medicated by his general practitioner with dexamethasone and desloratadin, without any improvement. His past medical history included a bladder carcinoma submitted to a transurethral resection and an 80-pack-year smoking history. As for the physical exam, he presented with edema of the face and neck with central cyanosis, evidence of collateral circulation – thoracic telangiectasis, jugular ingurgitation and digital clubbing. Bloodwork, gasometric analysis and EKG were normal. The X-ray revealed a right para-hilar hypotransparency and due to the raised suspicion of superior vena cava syndrome, a computerized tomography angiography was performed confirming the presence of SVCS by an occlusive mass with at least 7x5x8 cm, suggestive of tumoral invasion (small cell carcinoma of the lung). Interventional radiology decided on stenting the lesion and the patient was admitted to the ward for complementary study. A transthoracic biopsy was performed revealing a neuroendocrine small cell carcinoma and the patient started chemotherapy with Cisplatin and Etoposide. Despite the early diagnosis the patient died 3 months after diagnosis.

Discussion

SVCS is caused by cancer in 95% of the time being the other 5% mostly related to thrombosis from insertion of venous catheters or pacemaker wires. SVCS caused by cancer is a poor prognostic sign that is associated with high mortality.

#1241 - Case Report

DRESS SYNDROME: A RARE CASE BY VANCOMYCIN

Andreia Cinara Branco Diegues, Rita Silva, Elisa Tomé, Eugénia Madureira
ULSNE, Bragança, Portugal

Introduction

Drug rash with eosinophilia and systemic symptoms (DRESS) syndrome is a severe and idiosyncratic drug reaction characterised

by rash, fever, lymphadenopathy and internal organ involvement. The pathogenesis is not fully understood and many drugs have been associated with this disease, like antibiotics but in a rare cases. There are a high risk of morbidity and mortality.

Case description

A 75-year-old female was admitted to the orthopaedic department for revision of the prosthesis because of an infection. She had history of Alzheimer's disease and a right total hip prosthesis because of coxarthrosis. She was submitted to surgical debridement and antibiotic therapy with vancomycin and rifampicin, with good clinical evolution at the firsts days. However, 3 weeks later started with maculopapular morbilliform rash affecting the face, trunk and lower limbs and purpuric lesions on the limbs, which progressed to become exfoliative and was intensely pruritic and painful, associated with fever (38.5°C) and without lymphadenopathy or hepatosplenomegaly. Laboratory test results showed eosinophilia (7.7%), renal dysfunction (creatinine 2.1 mg/dL) and increase of transaminases (aspartate aminotransferase 130U/L, alanine aminotransferase 175U/L). Blood cultures, searching for CMV, EBV, hepatitis B, hepatitis C and HIV were negatives. Admitted Dress syndrome secondary to antibiotic therapy with vancomicina. Suspended vancomicina and initiation treatment with Co-trimoxazole, maintaining rifampicin. It was associated prednisolone and hydroxyzine. After 5 days, with clinical and analytical improvement. She was discharged with Co-trimoxazole and rifampicin for 3 months and corticoid therapy for 1 month. At the end of the first month, on the revaluation consult, with a normalisation of renal and liver function and without rash at the inspection.

Discussion

DRESS syndrome is of particular concern in patients with long courses of antibiotics. The findings at the history of our patient (skin eruption with eosinophilia in complete blood cell count and the involvement of the liver and kidney, that can be affected commonly) support the diagnosis. The rapid diagnosis was very important, allowing a prompt withdrawal of the antibiotic, which is the pillar to treat any drug hypersensitivity reaction. Also the supportive therapy with steroid and anti-histaminic allowed to reduce the symptoms.

#1259 - Case Report

WUNDERLICH SYNDROME AS A RARE CAUSE OF ABDOMINAL PAIN IN THE EMERGENCY ROOM

José Pedro Leite, João Pina Cabral, Diana Leite Gonçalves, António Pedro Pissarra, Joana Coelho, Fátima Silva
Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Wunderlich syndrome (WS) is a rare condition in which spontaneous renal hemorrhage occurs into the subcapsular

and perirenal spaces. It can manifest with a life-threatening presentation of fulminant hypovolemic shock. We report the case of a woman with sudden onset of intense abdominal pain and shock whose final diagnosis was a WS of idiopathic cause.

Case description

A 59-year-old woman with prior history of resistant arterial hypertension, submitted to renal sympathectomy 8 years before, presented to the emergency room with a sudden onset of severe abdominal pain in the upper quadrants and left flank with associated symptoms that included nausea, vomiting and diaphoresis. Besides hypertension, she had no other relevant history, including trauma, anticoagulant or antiplatelet medication. At initial examination she was pale and sweaty, leaning forward in a sitting position. She had cold extremities, thin pulse, a blood pressure of 65/45 mmHg and a heart rate of 115 bpm. Hemodynamic stabilization was achieved with crystalloid fluid resuscitation. After that, she maintained severe left upper quadrant pain with ipsilateral costovertebral angle tenderness. Laboratory tests showed a hemoglobin of 11.9 g/dL (later 8.5 g/dL) and leukocytosis but normal creatinine, troponin, amylase and lipase. An abdominal computed tomography (CT) was performed revealing an anterior perirenal hematoma of 13x6 cm in the anterior face of the left kidney, compatible with WS. A subsequent angiography revealed no evidence of active bleeding and the patient was managed conservatively, being discharged asymptomatic after 5 days. At 3 month follow up, abdominal CT still showed an organized hematoma of 5cm contiguous to the left kidney anterior border. She had also a nonfunctioning left adrenal incidentaloma of 8x6cm and is awaiting elective adrenalectomy.

Discussion

WS is a rare entity with around 300 cases described in the literature. Classic presentation includes sudden or insidious onset flank pain, palpable flank mass and hypovolemic shock. Hematuria can be present. Neoplasms are the most common etiology, mainly angiomyolipoma and renal cell carcinoma. Vascular diseases like polyarteritis nodosa may also be the cause. WS management is mainly conservative, although endovascular or surgical interventions may be required in cases of massive hemorrhage or persistent hemodynamic instability. This case report is a good illustration of the main features of this syndrome.

#1285 - Abstract

EPIDEMIOLOGICAL ANALYSIS OF HYPEROSMOLAR HYPERGLYCAEMIC STATE (HHS): POPULATION-BASED INCIDENCE AND CLINICAL OUTCOMES

Francesco Medici^{1,2}, Ritwika Mallik¹, Shivani Gor¹

¹ Homerton University Hospital NHS Foundation Trust, London, United Kingdom

² Queen Mary, University of London, London, United Kingdom

Background

Epidemiological studies on Hyperosmolar Hyperglycaemic State (HHS) are scanty and the incidence of HHS is unknown. In addition, the evidence-base of current published guidelines is very limited. The objectives of our study were to ascertain the incidence of HHS in a European urban population and evaluate the clinical outcomes.

Methods

Retrospective survey focusing on hospital admissions with Hyperosmolar Hyperglycaemic State (HHS). Setting: Homerton University Hospital in London UK is the main provider of secondary care for City & Hackney Clinical Commissioning Group, with a total catchment population of 286,000. Measures: rate of misdiagnosis or miscoding, incidence, demographics, percentage of intravenous insulin therapy, complications and outcomes. Data source for identification of index cases: Electronic Patient Records (EPR) with systematic search for the HHS definitions used for clinical coding. Data source for analysis: paper notes and EPR (whichever applicable). Data set: patients' names, hospital numbers, dates of birth, gender, dates of admission, clinical outcomes, complications, insulin therapy. Survey period: five years from 1 July 2012 to 30 June 2017.

Results

The number of index cases identified was 127. Scrutiny of the clinical records identified 54 misdiagnosis (simple hyperglycaemia without hyper-osmolality, diabetic ketoacidosis or hyperglycaemia with ketosis) and 33 coding errors, leading to 40 confirmed cases of HHS. The incidence rate of HHS was 2.7/100,000/year, with a hospital caseload of 8.0 /year. The mean age was 67.8 years (SD 12.9). Twenty-four (60%) were males and 16 (40%) females. We observed 5 (12.8%) deaths, but the HHS-attributable deaths were only 2 (5%). Sixteen (40%) patients required transfer to the Intensive Care Unit. Twelve (30%) of HHS cases were on insulin therapy before the admission. In total 39 (97.5%) patients required intravenous insulin therapy. Only 2 (5%) experienced transient hypoglycaemia and none developed cerebral oedema or osmotic demyelination.

Conclusion

Our study provides the first available data about the population-based incidence of HHS and new data regarding outcomes. The observed mortality rate appears much lower than previously reported in the literature. Our data suggest that intravenous insulin therapy is safe and effective in the vast majority of cases of HHS, contrary to some current published recommendations. Our findings could be helpful to inform service planning and to modernise local and national guidelines.

#1294 - Abstract

GERIATRIC EMERGENCY UNIT: AN INNOVATIVE MODEL OF SENIOR CARE

Veronique Trombert, Katharine Di Silvestro, Fassier Thomas, Dina Zekry

Geneva University Hospitals, Thonex, Switzerland

Background

Elderly patients are more likely to consult in emergency services. In addition, after a visit to an emergency department, they are at high risk of adverse outcomes such as early readmission and functional decline. In the emergency department of Geneva University Hospital, 25% of the patients are older than 75 years old. Generally, elderly patients spend more time than younger in an emergency unit. This environment adds a supplementary stress increasing the risk of complications. Moreover, in Geneva, the following day, they must be routed to the geriatric hospital, 7 km distance, when a hospitalization is needed.

Methods

For all these reasons, a new model of care was proposed inside the Geneva Geriatric Hospital (292 beds: 180 acute care and 112 rehabilitation).

Results

This geriatric emergency unit (18 beds) was created on November 2016 for seniors older than 75 years old presenting no vital urgency. The interdisciplinary team was trained to geriatric syndromes and the environment was adapted for this population. In addition the lack of waiting time allows a less stressful stay for these patients.

After 2 years of experience, we will present results regarding the typology of patients, degree of urgency, hospitalization and readmission rates, length of stay, rate of discharge, mortality, diagnosis and compare the performance of this unit to the general hospital.

Conclusion

This new model improves the care of old patients in the emergency room.

#1295 - Case Report

PERICARDIOCENTESIS: A PALLIATIVE PROCEDURE?

Rodolfo Viríssimo Gomes, João Pacheco Pereira, Manuel De Sousa, António Messias

Hospital Beatriz Ângelo, Loures, Portugal

Introduction

Lung cancer is the most commonly related with pericardial involvement. Neoplastic cardiac tamponade usually has a subacute course, and may have floating symptoms.

Case description

A 78-years-old caucasian female with type-2 diabetes mellitus and systemic hypertension went to the Emergency Room (ER) because of a 2-week long progressive dyspnea with dry cough, with simultaneous 10.7% loss of total body weight. Ethiological studies revealed a stage 4 small-cell lung carcinoma with pleural, hepatic, bone and cerebral metastasis, having been discharged with scheduled holocaranial RT and follow-up.

She came back to the ER the next day due to worsening dyspnea and signs of poor peripheral perfusion. ABG showed global respiratory insufficiency with compensated mild respiratory acidosis; blood tests had no significant changes. Thoracic ultrasound had no signs of pleural effusion, but transthoracic echocardiogram revealed signs of right ventricular diastolic collapse with anterior pericardial effusion (max diameter 33.6 mm) and 35% transmitral flow variation. So, she was admitted at the ICU for clinical stabilization.

She maintained progressive worsening of respiratory distress despite optimized medical therapy and non-invasive ventilation, so due to refractoriness to medical therapy after new respiratory exacerbation, delirium and Beck triad presence, cardiac ultrasound was repeated confirming cardiac tamponade. The patient was then submitted to echo-guided pericardiocentesis with drainage placement with total output of ~250 cc of slightly cloudy citrus yellow liquid, with almost immediate reversal of the symptoms and echographic reevaluation with vestigial effusion only; cytology was compatible with carcinoma cells.

Discussion

Neoplastic pericardial disease treatment depends on symptoms severity, primary neoplasia and its curative potential, and average life expectancy of each individual patient. Although it is an invasive and risky technique, in highly symptomatic patients with hemodynamic compromise, pericardial fluid removal is the only attitude that will allow symptom relief.

In this case, despite being a patient with plurimetastised lung neoplasia with a very poor short-term vital prognosis, pericardiocentesis was performed as a successful palliative attitude, what allowed to establish and fulfill personal and therapeutic plans.

#1296 - Abstract

EXTREME HEAT IN PORTUGAL: PATIENT OUTCOMES IN AN EMERGENCY DEPARTMENT

Daniela Marto, Salvador Morais Sarmiento, Ana Brito, Hugo Inácio, Miguel Sousa Leite, Sofia Mahomed Mateus, Andreia Amaral, Dina Rodriguez Pita, Paulo Barreto, Catarina Salvado

Centro Hospitalar Universitário de Lisboa Central, Lisbon, Portugal

Background

The deaths and comorbidities related to heat are potentially preventable, and with the current climate changes, this type of

extreme temperatures will become more frequent. We intend to evaluate the impact of extreme heat in our emergency department, including morbidity, mortality and emergency response capability.

Methods

Retrospective cohort study including all patients with medical conditions treated in a tertiary hospital emergency department, during a six days long heat wave (2nd to 6th August 2018) – exposed –, compared to a homologous non-heat wave period in 2017 - non-exposed. Outcome measures were: time in emergency department, inpatient ward admission, total hospital mortality.

Results

We registered a total of 3983 admissions at our emergency department on both periods, in which 2092 were patients with medical conditions: 1115 on those exposed to heat and 977 on non-exposed patients.

The exposed patients were slightly older (mean age of 56.4 years on those exposed to heat, and 52.7 years on those not exposed), and in both cases 55% were women.

Also, the exposed patients stayed a longer period in emergency department: median of 5.79 hours on exposed patients (interquartile range: 3.36-10.29) vs. 4.25 hours on non-exposed patients (interquartile range: 2.73-6.44) - $p < 0.001$.

In addition to that, the exposed patients tended to be more often admitted to inpatient ward (16.8% vs 13.4%) - risk ratio of 1.25 [confidence interval 95%: 1.02-1.54] - and had a greater likelihood of death, being admitted to reanimation room or intensive care units (4.3% vs 1.8%) - risk ratio of 2.34 [confidence interval 95%: 1.37-3.99].

Conclusion

During a period of extreme heat patients stayed longer in emergency department, with more admissions to inpatient ward, and higher mortality. These data support the importance of contingency plans in this situation.

#1347 - Abstract

UNDERGRADUATE ULTRASOUND CURRICULUM: INTRODUCING BASICS OF US IN AN ITALIAN UNIVERSITY AFFILIATED HOSPITAL

Ivan Silvestri, Daniela Torzillo, Francesco Casella, Marta Del Medico, Alessia Lo Surdo, Chiara Scaccabarozzi, Sara Di Gregorio, Chiara Cogliati

Department of Internal Medicine, L. Sacco Hospital, ASST-FBF-Sacco, University of Milan, Italy

Background

Point of care ultrasound (POCUS) has become a key step in clinical practice. This study concerns the introduction of a US curriculum in the third year of medical school and the evaluation of students' satisfaction and teaching efficacy.

Methods

Four 2.5 hours frontal lessons were planned: basics of physics, artefacts, cardiac, abdominal, vascular and thoracic US semeiotics were addressed. Then, students groups (6+tutor) underwent a 2,5 hours hands-on session practising by using each other as models and finally answered an anonymous satisfaction survey. During the second semester an elective US hands-on course (20 hours) was offered to 20 students/year (5 students+tutor groups). 4 tutored alternating with 4 self-practising sessions were held. In self-practising sessions students were asked to reproduce pre-defined scans and to load them on Google Plus for remote tutors review. An evaluation test (score 1-4, not sufficient, sufficient, good, optimal) aimed to evaluate competence in visualization of: lung sliding; lung curtain sign; parasternal long axis heart view; inferior vena cava (IVC) diameter and collapsability; suprahepatic veins; abdominal aorta; bladder volume estimation. Finally, a call for 'tutor training' was launched to increase faculty by creating a peer-tutoring system.

Results

185 students in 2 years completed the questionnaire. 98% thought that US was useful to recall anatomical and physiological correlates and 84% declared that US should be incorporated in Anatomy and Physiology course too. For 96% US introduction was useful for the comprehension of physical examination and 94% were interested in attending a hands-on course. 35 students completed the elective course. At least a sufficient grade (2-4) was obtained for: gliding scan 97%; lung curtain sign 97%; parasternal 94%; IVC 94%; suprahepatic veins 100%; aorta 100%; bladder 100%.

Finally, seven students joined the 'tutors program' and were involved in the hands-on sessions faculty for the on-going courses.

Conclusion

Introduction of US during physical examination teaching was really appreciated by students. Results from elective course test demonstrate that US basics competency can be obtained by third year students by alternating tutored and self-practising sessions. Finally, as previously shown, peer tutoring can be an effective way to increase faculty, one of the main limitation in US programs adoption. Efficacy of peer-tutoring teaching will be assessed in the continuation of the study.

#1361 - Case Report

IT WAS SUPPOSED TO BE AN ALLERGIC REACTION

Francisco Chambel Belém, Eduardo Carvalho, Maria Do Céu Evangelista, João Silva, Artur Costa, Juliana Sá, Margarida Ascensão, Leopoldina Vicente

Centro Hospitalar Universitário Cova da Beira, Covilhã, Portugal

Introduction

A pneumothorax is defined by the presence of air or gas in the pleural cavity. It can be caused by a blunt or penetrating

chest injury, medical procedures, underlying lung disease or spontaneously. Symptoms usually include sudden chest pain and shortness of breath.

If the released air gets into the tissues under the skin, we can stand before a subcutaneous emphysema. The most common and visible sign and symptom is swelling around the neck accompanied with pain in the chest. Other signs include cervical pain, difficulty in swallowing, breathlessness or wheezing.

Case description

We present a case of an 87-year-old male patient that went to the Emergency Department after waking up with facial and palpebral exuberant edema along with hoarseness immediately after starting Metamizol prescribed by the primary care doctor the day before due to chest pain caused by a fall from own height.

The patient presented edema from the face to neck region, slightly flushed, eyes exuberantly swollen, especially the upper eyelids. He has normal breathing, without neurological symptomatology and a slight hematoma in the right costal grate, due to the fall.

Thinking of an allergic reaction to metamizol, was immediately medicated with corticosteroids, antihistamine and adrenaline but without expected effectiveness in reduce symptoms.

Two hours later in the observation room, the patient becomes disoriented and agitated and developed subacute dyspnea.

In the X-ray of the thorax, we observed subcutaneous emphysema, an apparent fracture of the 4th right costal arch, with signs of pneumothorax on the right side.

We performed a thoracostomy with 30F thoracic drainage in the 5th right intercostal space.

The patient remained in the inpatient service for 5 days, with a drainage system, at rest and under analgesia, with good clinical evolution, need of supplemental oxygen at 2L/h and progressive improvement of disorientation and agitation.

At discharge, the patient had no pneumothorax on the x-ray, without subcutaneous emphysema, slight bruising on the right side of the costal grid, and normal breathing.

Discussion

Emergency requires thought processes that incorporate risk stratification, assessment of urgency and need for immediate treatment.

This case shows a changing clinical scenario in which a patient appears to have an obvious diagnosis but it turns into another completely different situation.

In the emergency medicine, behavioral flexibility is essential as doctors need to be able to adapt to a changing situation.

#1371 - Case Report

DECOMPRESSION SICKNESS AT LOW WATER DEPTH

Kristoffer K. Brockhattingen

The Department of Geriatrics, Odense University Hospital, Region of Southern Denmark, Odense C, Denmark

Introduction

Decompression sickness (DCS) is a rare but potentially fatal condition. In Denmark the occurrence is approximately 15 cases a year.

This case report describes that one cannot solely rely on water depth as an absolute parameter when it comes to DCS.

DCS is divided into two forms: a mild and a severe. Mild DCS can be constant, varying in intensity or with negative progression, with a change over the course of several hours.

Severe DCS manifests onset with potentially fatal neurological and/or cardio pulmonal manifestations due to gas embolisms.

Case description

A 38-year-old male arrived at the emergency department after having done an hour-long dive at 3 meters depth the previous day. He was cleaning the underside of a boat, as he underwent a rapid and sudden ascend due to a broken inflatable diving vest. When arriving at the surface he felt a tingling sensation in the right arm. The patient described a tingling/stabbing sensation in the thorax, diffuse muscle and joint pain, starting with a tingling/stabbing sensation in the right arm, intense pain in the loin and a tingling sensation in the back. There was no preceding fever, cough or flu like symptoms.

The patient was adipose with no history medical history. The neurological examination revealed subjective sensory paraesthesia in all four extremities and the back. The vital parameters were all normal, including blood gas analysis.

Due to suspicion of DCS oxygen therapy was started and the ward at the Department of Anaesthesiology at Rigshospitalet, Copenhagen, was contacted. It was recommended to continue oxygen therapy for a few hours and confer again. Subsequently most of the symptoms went into remission. However, the pain in the loin and the subjective sensory paraesthesia in the back persisted.

The patient was transferred to hyperbaric therapy at Rigshospitalet where after the symptoms went to total remission confirming the DCS diagnosis. The patient was given a four week long diving ban and was referred to control at the outpatient clinic six months later.

Discussion

The literature describes a significant connection between the formation of gas bubbles and body mass index, fat deposits, age and diving exposure, wherefore the mentioned state of nutrition of the patient and the diving time mentioned in the history is presumed to have been a factor in this case.

The treatment of DCS is oxygen with hyperbaric therapy as primary treatment and additional diagnostics must not delay this treatment.

DIFFERENTIAL DIAGNOSIS OF HEMATEMESIS- THINKING ABOUT OTHER ETIOLOGIES

Carolina Carrilho Palma, Inês Costa Santos, Ricardo Pereira, Joana Patrício, João Tavares, Ana Catarina Emídio, Joana Carreira, Beatriz Navarro, Hugo Casimiro, Mário Parreira, Ermelinda Pedroso
Centro Hospitalar de Setúbal, Hospital de São Bernardo, Internal Medicine Department, Setúbal, Portugal

Clinical summary

Upper gastrointestinal bleeding highly contributes to morbidity and mortality constituting a medical emergency. It can present as

hematemesis, melena or hematochezia. Stomach and duodenal ulcers are the most common causes however, other diagnosis must be considered. 75 year old male, history of abdominal aortic aneurysm (under surveillance for 3 years), presented to the emergency room with acute, massive hematemesis. Nasogastric intubation immediately drained 300 cc of blood. Arterial pressure was 95/55 mmHg, lab work showed haemoglobin 9.30 g/dL (previously was 11.2 g/dL). CT angiography showed that the aneurysm had ruptured and an aortoenteric fistula had formed. This case reminds of the importance of the clinical history in a differential diagnosis, ensuring the best outcome for the patient.

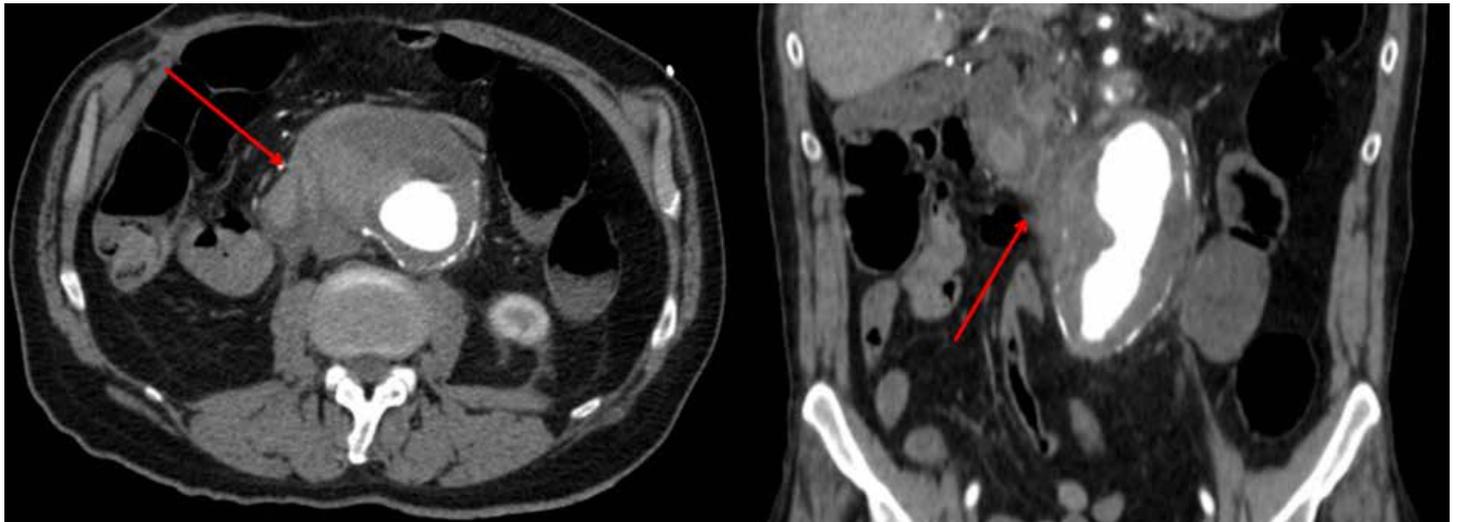

Figure #1376. CT angiography showing a ruptured abdominal aortic aneurysm together with an aortoenteric fistula.

CARDIAC ARREST IN THE ONCOLOGIC PATIENT: NEW CAUSES, NEW CHALLENGES

Ana Hipólito Reis, Daniela Coelho, Ernestina Gomes, Rui Araújo
Serviço de Medicina Intensiva, Hospital Pedro Hispano - Matosinhos Local Health Unit, Matosinhos, Portugal

Introduction

Successful outcome of an out-of-hospital cardiac arrest implies an interplay of the community, prehospital and intensive care medical teams. This interaction is crucial to ensure good care of critical patients, in order to deliver them again to the community.

Case description

A 57-year-old men with depression and a recently diagnosed colon carcinoma was referred to the local health centre to remove his chemotherapy infusion pump. He had had previous pelvic radiotherapy and colon surgery and had started the FOLFOX scheme 48 hours earlier, as well as haloperidol for his psychiatric disorder. While waiting for the procedure, he collapsed – cardiac arrest was promptly recognised, CPR with AED initiated and early defibrillation delivered with ROSC at 8 minutes. Prehospital

medical team assisted and transferred the patient to the hospital where reversible causes of cardiac arrest were excluded and post-resuscitation care was delivered. Interrogation of the AED identified a period of ventricular fibrillation and successful defibrillation. While in the intensive care unit, another episode of torsade de points degenerating in ventricular fibrillation was reverted. These episodes were filiated in cardiac dysrhythmia – primary or eventually secondary to FOLFOX and haloperidol, as described in the literature. The patient evolved well and was discharged without cardiac or neurological sequels, with a ICD and recommendation to not use these drugs again.

Discussion

Cardiovascular toxicity of many old and of new cancer therapies is one of the many dimensions of the growing field of cardio-oncology. Knowledge of potential toxicities is crucial for the approach of the ill cancer patient.

This case also reinforces the importance of the survival chain for the outcome of a cardiorespiratory arrest situation. Training of the medical community, structured AED program and the common and systematized emergency organization at the various sites of the healthcare network were determinants of success.

#1484 - Case Report

FATAL SEPTIC SHOCK DUE TO Fournier GANGRENE

Isabel De La Cal Caballero, Ana Patricia Gomes, Ricardo Gomes, Pedro Lito, José Proença, Leopoldina Vicente
Centro Hospitalar Universitario Cova da Beira, Covilhã, Portugal

Introduction

Fournier gangrene, is a rare (only 0.02% of hospital admissions) polymicrobial necrotising fasciitis of the perineal, perianal, or genital areas.

This rapidly progressive synergistic infection can lead to multiple organ failure and death within hours of onset. Broad-spectrum antimicrobials, aggressive surgical debridement and septic shock resuscitation are the mainstay of treatment.

Case description

A 51-year-old tetraparetic man was admitted to emergency ward several hours after a wheelchair accident. The patient had a history of alcohol abuse and heart failure.

Upon physical examination, patient was oliguric and hypotensive (78/52 mmHg) with tachycardia (122/min), fever (38.1°C) and tachypnea. His scrotum was swollen and erythematous. There were multiple black gangrenous patches mainly on the right posterior side of the scrotum. He had concomitantly elevated white blood cell count, neutrophils, C-reactive protein (CRP) and respiratory alkalose and hyperlactacidemia as well.

It was hypothesized septic shock due to Fournier's Gangrene and was commenced initial resuscitation with crystalloid fluid, vasopressor infusion (norepinephrine) and broad-spectrum antimicrobials (meropenem and clindamycin); this was followed urgently by surgical exploration and debridement.

Discussion

Fournier Gangrene is an infrequent pathology, but its high mortality (7-40%) forces to perform an early diagnosis to avoid its progression and complications.

As shown in this case, its high mortality rate it becomes a surgical emergency. It must also be associated with a postoperative on an intensive care unit by a multidisciplinary team.

#1510 - Case Report

SUCCESSFUL RECOVERY OF AN INTENTIONAL BARBITURATE POISONING - A CASE REPORT

Alexandra Esteves, Francisco Silva, Joana Abreu, Rogério Corga Da Silva, Tiago Veiga, Soraia Oliveira, Andriy Bal, Pedro Moura, José Caldeiro
Unidade Local de Saúde do Alto Minho, Viana Do Castelo, Portugal

Introduction

Pentobarbital was historically used for its anticonvulsant and hypnotic properties, later abandoned due to behavioural disorders and its physical dependence potential. Short-acting barbiturates

like pentobarbital have a narrow therapeutic margin, as shock and anoxia occur faster, and coma is more severe. Currently, it can be found both in medical and veterinary practice for anaesthesia and euthanasia, often cited by entities defending "painless death".

Case description

A 25-year-old veterinarian with a known history of depression, borderline personality disorder and previous self-mutilating episodes was found unresponsive in her clinic. Upon pre-hospital emergency care arrival, she was hypotensive, tachycardic, with a Glasgow Coma Scale of 3. A blood glucose level of 30 mg/dL was recorded. She had in her left forearm an intramuscular needle with a 20 cc syringe containing about 12 cc of a blue solution and near her was a bottle of pentobarbital for veterinary use (300 mg/mL) with 33 mL missing. Suspected self-administered dose was between 2.4 and 7.5 grams, well within lethal range. Glucose, naloxone and flumazenil and intravenous fluids were administered and she was intubated. On arrival to the Emergency Department there was an improvement on heart rate, blood pressure and glycemia, with no neurologic status change. Urine sample screened positive for barbiturates; serum acetaminophen, phenytoin and valproate concentrations were undetectable and blood biochemistry, brain computed tomography and electrocardiogram showed no significant changes. She was admitted to the Intensive Care Unit and remained in a comatose state for the first 48h. Vasopressor support was needed in the first 24 hours. Electroencephalogram performed during the drug washout period showed focal epileptic form, though no seizures were reported. On the 4th day, she had full recovery of awareness, with successful ventilatory weaning. Though psychiatric evaluation recommended admission on the Psychiatry ward, she was later discharged against medical advice without sequelae.

Discussion

Suicide and non-fatal suicidal behaviour in healthcare related professions are a growing concern. In patients presenting with shock, respiratory and central nervous system depression with an absence of brainstem reflexes the possibility of barbiturate intoxication should be considered, especially in patients with direct or indirect access. As no antidote is known, early supportive therapy grants the best chance of survival.

#1535 - Case Report

THE DIFFICULT CHALLENGE OF FLUID AND ACID-BASE BALANCE MANAGEMENT IN A COMPLICATED CASE OF ACUTE KIDNEY INJURY, SEPSIS AND GUT SUBOCCLUSION:ROLE OF US

Serena Melandri

Policlinico Umberto I - Sapienza University of Rome, Rome, Italy

Introduction

Fluids management is crucial in the care of critically ill patients. Hypovolemia results in decreased tissue perfusion and may lead to

MOF. Otherwise in an effort to reverse pre-renal oliguria, it is not uncommon, particularly when chronic kidney disease precedes sepsis, to exceed with resuscitation, leading to a dangerous overload. The focused Critical Care US has been adopted widely in the critical care hemodynamic monitoring because it allows a rapid volume-status assessment. Inferior Vena Cava diameter, its collapsibility and presence of B-lines in the lung are the “hot points” in the suspicion of a fluid overload.

Case description

A 73 years old man was admitted to Surgery Division for a toilette of a gouty lesion. In the ER he presented with acute on chronic renal insufficiency (creatinine 7.4 g/dl), due to a massive use of NSAIDs, and oliguria. Few days after surgery he developed severe constipation and biliary vomit. A CT-scan showed a pelvic faecaloma with bowel distension. He became anuric and pulmonary function got worsen, so he was transferred to Internal Medicine ward. At admission he was alert; BP 110/60, HR 78, SpO₂ 95% (FiO₂ 31%), tachypneic. Lab test showed hypocalcemia (5.8 mg/dl) and arterial blood gas (ABG) a mixed metabolic acidosis (pH 7,22; PCO₂ 33 mmHg; PO₂ 68; Lac 5 mmol/L, HCO₃⁻ 12). Calcium correction with 10 vials of calcium gluconate in 0.9% NaCl solution at 45 ml/h was started together with HCO₃⁻ bolus (50 mEq) followed by infusion of 100 mEq in 0.9% NaCl (20 ml/h); diuresis was forced by furosemide (10 mg/h). Despite a mild abdominal improvement due to evacuative enemas and correction of calcemia, the patient became hypotensive: BP 85/60 It's sensory got worse. In the suspicion of a septic shock (qSOFA 3) after blood, urine samples and empirical antibiotic, we used bedside US to assess volume status: IVC was normal but collapsed less than 50%; lung-US showed a mild “wet pattern”. We started an initial bolus of RL 500 ml and then a cautious “hydration”(80 ml/h). Vasopressor therapy with norepinephrine (0.2 mcg/kg/min) became necessary, together with a short cycle of NIV-Bi-Pap because of worsen ABG pH 7,10;PCO₂ 46; PO₂ 57; Lac 4 mmol/L; HCO₃⁻ 14. In 24 hours BP stabilized, metabolic acidosis reversed, CRP and procalcitonin were reduced and NIV interrupted. The ABG showed: pH 7.42; PCO₂ 33; PO₂ 87; Lac 2,8; HCO₃⁻ 21

Discussion

This case shows how a smart mix of clinical and US evaluation allows the right choice in fluid management of anuric septic patient

#1537 - Case Report

TETANY IN THE EMERGENCY ROOM – A SUDDEN MANIFESTATION OF HYPOCALCEMIA

Maria Margarida Pereira, Ana Vera Cruz, Marta Cerol, Petra Pego
Hospital Distrital de Santarém, Santarém, Portugal

Introduction

Hypocalcemia is a potentially fatal and often underdiagnosed electrolyte derangement. When it starts suddenly causes severe

and fast-onset symptoms such as seizures, cardiac arrhythmia, tetany or refractory hypotension, thus hospital admission and aggressive therapy are necessary. Despite this, the symptoms quickly regress with the normalization of calcemia values.

Case description

A 56-year-old female patient came to the emergency room with complaints of pain and generalized muscle stiffness starting an hour ago that made it impossible to walk, perioral paresthesias and of the hands and feet, nausea and an episode of vomiting. Her past medical history included arterial hypertension, noninsulin-treated type 2 diabetes mellitus, appendicectomy, depressive disorder and cholecystectomy about one month ago. Of note, physical examination revealed the presence of tachycardia and tachypnea, profuse sweating, tetany with carpal spasm with extension of interphalangeal joints and adduction and flexion of the metacarpophalangeal joints and a positive Trousseau's sign. Blood samples were immediately collected for arterial blood gas analysis that revealed hypocalcemia (0.81 mmol/L) and the 12-lead ECG showed prolongation of the QT interval. The patient was given a calcium gluconate bolus followed by continuous perfusion with dramatic improvement of the mobility of the lower limbs and progressive recovery of the articular amplitudes of the fingers. The blood test also showed hypomagnesemia, hypophosphatemia, hypokalaemia and rhabdomyolysis parameters; no hypoalbuminemia, hepatic or renal impairment was detected. She was admitted to the intermediate care unit for rigorous surveillance and monitoring and was then discharged to an internal medicine outpatient clinic. The cause of electrolyte disorder is still being investigated.

Discussion

This case represents a classic presentation of sudden onset hypocalcaemia with mild symptoms of tetany that include circumoral numbness, muscle cramps, paresthesias of hands and feet and generalized muscle cramps. In severe cases, patients may present with laryngospasm, seizures or myocardial dysfunction. Early diagnosis with rapid institution of therapy is fundamental for the prognosis; electrocardiographic monitoring during ionic replacement is recommended because of the risk of cardiac arrhythmia. The causes of hypocalcemia are varied, the most common being vitamin D deficiency. The etiological study is essential to avoid recurrences and institute targeted therapy.

#1587 - Abstract

PROGNOSTIC VALUE OF CELL DEATH BIOMARKERS IN CARDIAC ARREST SURVIVORS

Beata Csiszar^{1,2}, Almos Nemeth¹, Zsolt Marton¹, Janos Riba¹, Peter Csecsei³, Tihamer Molnar⁴, Laszlo Deres^{1,2}, Kalman Toth^{1,2}, Peter Kenyeres^{1,2}

¹ 1st Department of Medicine, University of Pecs Medical school, Pecs, Hungary

² Szentagothai Research Centre, University of Pecs, Pecs, Hungary

³ Department of Neurology, University of Pecs, Pecs, Hungary

⁴ Department of Anaesthesiology and Intensive Care, University of Pecs, Pecs, Hungary

Background

Ischemia-reperfusion injury during and after resuscitation from cardiac arrest results in increased systemic cell death. Cytokeratin-18 (CK-18) is released into the blood during cell death, its caspase cleaved form (ccCK-18) is specific to apoptosis. This study evaluates their prognostic value for mortality, neurological outcome and their association with conventionally used clinical parameters after successful cardiopulmonary resuscitation (CPR).

Methods

Plasma samples of 40 resuscitated patients were collected 6, 24, and 72 hours after successful CPR to determine the CK-18, ccCK-18 concentrations by ELISA. The circumstances of the cardiac arrest and CPR, laboratory and physical parameters were recorded. Mortality within 30 days was considered end-point.

Results

The 6-hour troponin-T, GOT, GPT, INR, lactate levels and WBC count were significantly elevated among the 26 non-survivors. Significant negative correlations were found between the survived days and 6-hour GOT, GPT, troponin-T, INR values ($r=-0.551$, -0.443 ; -0.446 ; -0.462 ; $p<0.05$). Resuscitated patients had highly elevated CK-18, ccCK-18 levels and decreased ccCK-18/CK-18 ratio compared to healthy subjects, septic and postoperative patients (CK-18: 3842 vs. 242; 559; 1644 ng/L; ccCK-18/CK-18 ratio: 0.14 vs. 0.58; 0.22; 0.24)^[1]. Neither the values of CK-18 and ccCK-18 nor their kinetics showed difference between survivors and non-survivors and they did not show association with the length of the resuscitation, the initial rhythm, the neurological outcome or the number of the damaged organ systems either. CK-18 showed a declining kinetics in patients with good renal function in contrast to patients with renal failure. Significant negative correlation was observed between the 6-hour CK-18 and hemoglobin concentrations ($r=-0.400$, $p<0.01$).

Conclusion

This study was the first to investigate CK-18 and ccCK-18 levels among resuscitated patients. Surprisingly, the marker levels did not have prognostic value for mortality or neurological outcome in a general resuscitated population. The increased levels of

troponin-T, GOT, GPT, INR and WBC count in non-survivors indicate severe organ damage as expected.

Support: Supported by the ÚNKP-18-3-I New National Excellence Program of the Ministry of Human Capacities"

THE ROLE OF RIGHT VENTRICLE-ARTERIAL COUPLING IN ACUTE PULMONARY EMBOLISM WITH RIGHT VENTRICLE DYSFUNCTION: A RETROSPECTIVE COHORT STUDY

Lorenzo Falsetti¹, Alberto Marra², Mattia Sampaolesi¹, Francesca Ricconi¹, Marta Buzzo¹, Lorenzo Nobili¹, Vincenzo Zaccone¹, Annalisa Marchetti¹, Maria Novella Piersantelli¹, Tamira Gentili¹, Cinzia Nitti¹, Aldo Salvi¹

¹ Internal and Subintensive Medicine, Ospedali Riuniti, Ancona, Italy

² Center for Pulmonary Hypertension, Thoraxklinik at Heidelberg University Hospital, Heidelberg, Germany

Background

According to current guidelines, the presence of right ventricle dysfunction (RVD) in patients with pulmonary embolism (PE) is a turning point for clinical decision making. Right ventricle-arterial coupling (RVAC) is defined as the capability of the right ventricle to compensate the rise of pulmonary pressures by increasing its contractility. RVAC can easily and quickly be assessed with echocardiography through the ratio between the tricuspid anteroposterior systolic elevation (TAPSE) and the pulmonary arterial systolic pressure (PASp) (TAPSE/PASp). Aim of the current study was to investigate right ventricle-arterial coupling in patients admitted for PE.

Methods

Consecutive patients admitted in a large tertiary center for PE were retrospectively analyzed, enrolling all subjects with RVD. For each patient we obtained, at the admission: age, sex, body surface area, heart rate, systolic pressure, respiratory frequency and the main echocardiographic findings. We treated the TAPSE/PASp ratio both as continuous and dichotomous variable, adopting a cutoff of 0.32, derived from current literature on pulmonary arterial hypertension. BOVA score was treated as a dichotomous variable, subdividing patients in low-intermediate risk (BOVA \leq 4, stages I-II) and high risk (BOVA $>$ 4, stage III). Continuous variables were related with linear regression analysis and compared with t-test and ANOVA.

Results

we finally obtained a sample of 109 consecutive subjects. Patients

in BOVA stage III showed, when compared with the other subjects: a significant reduction of TAPSE, TAPSE/PASp, significantly lower telediastolic and telesystolic volumes in left ventricle and a significant reduction of stroke volume and VTILVOT. Patients with a TAPSE/PASp ratio ≤ 0.32 showed: a higher RV/LV ratio, a higher prevalence of paradoxical septum movement, a significant reduction of TAPSE, a significantly reduced telediastolic and telesystolic volumes and a significant reduction of stroke volume and VTILVOT.

Conclusion

Patients with PE and RVD with a low TAPSE/PASp ratio show significantly worse echocardiographic parameters, suggesting that an alteration of RVAC could have strong implications in the ventricular interdependency and could be suggestive of a worse haemodynamic status. Patients in stage BOVA III show a worse RVAC and, consequently, worse LV performances thus representing the group at highest risk of hemodynamic instabilisation.

#1675 - Case Report

POINT-OF-CARE ULTRASOUND IN ACUTE DYSPNEA – IT MAKES A DIFFERENCE

João Alexandre Tavares¹, José Mariz², Jorge Teixeira²

¹ Centro Hospitalar de Setúbal, Setúbal, Portugal

² Hospital de Braga, Braga, Portugal

Introduction

Pulmonary embolism (PE) is defined as an obstruction of the pulmonary artery or one of its branches, usually by a thrombus originated elsewhere in the vascular system. PE is a very serious form of venous embolism, being fatal sometimes. Despite being frequent, the diagnosis of PE is not always easy because signs and symptoms are usually non-specific and can range from asymptomatic to shock and cardiac arrest. The approach to the patient with suspected PE should be made on the basis of clinical probability in order to avoid unnecessary testing but also to ensure an early start of adequate treatment.

Case description

We describe a case of a 50-year-old woman with a history of hypertension, who came to the Emergency Department complaining of dyspnea that worsened with minimal physical effort (had to stop after 10 meters) for the past 2 days. Patient had no fever, cough, sputum, thoracic pain or pain in the legs. Had no history of recent immobilization, trips or surgery. On physical exam she was restless, tachypneic with 90% peripheral O₂ saturation without supplement oxygen. Lung sounds were maintained bilaterally. Patient had hemodynamic stability and no changes in the lower limbs. EKG had no changes. Arterial blood gases showed type I respiratory failure with hypocapnia (pH 7.48, pO₂ 57, pCO₂ 29, HCO₃ 21, Lactate 1.2, SaO₂ 89%). Blood was drawn and while waiting for X-ray, Point-of-care Ultrasound

(POCUS) was performed: preserved function of left ventricle, dilated right cavities with a right ventricle larger than the left; dilated inferior vena cava with decreased respiratory variability (<50%); Lungs with bilateral A-pattern without pleural effusion; compression of the venous system of the right lower limb was maintained; on the left lower limb hyperechoic material was seen inside the common femoral and popliteal veins and compression was not possible. Assuming a PE the patient was started on 1 mg/Kg of enoxaparin every 12 hours. Later the CT scan showed a massive bilateral PE and the inferior limb doppler scan confirmed an ileo-femoro-popliteal thrombus. Patient was admitted in the Intermediate Care Unit and 48 hours later transferred to the Internal Medicine ward for further studying.

Discussion

POCUS is becoming a reality in everyday clinical practice, with reports of its use since 1989 by Lichtenstein and co-workers. It has shown to improve diagnostic ability, allowing a swifter and assertive diagnosis and an early start of definitive treatment, just like the case presented.

#1706 - Case Report

CARDIAC TAMPONADE AFTER THROMBOLYSIS FOR ACUTE ISCHEMIC STROKE – A CASE WITH AN EXCELLENT OUTCOME

Ana Vera Cruz, Maria Margarida Pereira, Marta Cerol, José Ramalho, Gonçalo Ferrão, Juliana Mortágua, José Pedro Andrade
Hospital de Santarém, Santarém, Portugal

Introduction

Intravenous administration of IV recombinant tissue plasminogen activator (rt-PA) has been very effective in reducing the neurological deficit in patients with acute ischemic stroke (AIS). Serious adverse events are not uncommon, being hemorrhage the major complication.

We describe a case in which a patient with indistinct cardiac symptoms prior to thrombolysis in who haemopericardium and hemodynamically significant cardiac tamponade occurred after treatment with rt-PA.

Case description

A 59-year-old woman with history of epilepsy, dyslipidemia and hypothyroidism presented to the emergency department with dysarthria, left labial commissure deviation and right hemiparesis with 2:30 h of evolution. Her National Institutes of Health Stroke Scale (NIHSS) was 11.

There was no history of other symptomatology prior to the neurologic deficit. On examination blood pressure was 166/78 mm Hg, pulse was 140 beats per minute and the electrocardiogram with atrial fibrillation. The computed tomography (CT) of the brain showed a hyperdense left middle cerebral artery and intravenous thrombolysis with rt-PA (0.9 mg/kg) was started 2:50 hours after symptom onset.

The patient fell into a coma 30 minutes after starting thrombolysis. Repeat CT brain showed no hemorrhage.

Shortly afterward, she developed hypotension maintaining atrial fibrillation with rapid ventricular rate. Point-of-care ultrasonography found large amount of echodense material in the pericardium compatible with hemopericardium causing cardiac tamponade. Pericardiocentesis was promptly performed, draining 600 ml of serohematic fluid and followed by the resolution of the shock. The patient recovered the conscious state within a few minutes, presenting with NIHSS of 2.

Discussion

Acute ischemic stroke patients may have undetected cardiac disease that may pose a risk for hemopericardium and life-threatening tamponade after treatment with rt-PA.

Despite uncommon cardiac tamponade must be suspected in a patient presenting with shock after thrombolysis because for a successful outcome every minute counts.

GASTRIC ISCHEMIA IN SEPTIC SHOCK: A CASE REPORT

Nuno Pereira, Nuno Fernandes, Enrique Romero, Vasco Marques, Miguel Rodrigues, Rita Marçal

Hospital Particular do Algarve - Gambelas, Faro, Portugal

Introduction

Gastric ischemia is a rare condition, mainly because of the rich collaterals around the stomach. The etiologies for gastric ischemia include local vascular causes, systemic hypoperfusion and mechanical obstruction. On imaging studies air can be detected in the splanchnic circulation. It carries a bad prognosis, being associated with significant mortality.

Case description

The authors relate the case of a previously healthy 38 year old woman, medicated only with an anticonceptual pill and with iodine allergy. She visited the E&A Department of our hospital with complaints of right back pain and fever. Her bloodwork was unremarkable except for elevation of C reactive protein, and urine analysis was positive for leucocytes. A CT exam showed right hydronephrosis conditioned by a 6 mm calculi in the ureterovesical junction. She was admitted to the hospital, urinary and blood cultures were withdrawn, antibiotic was started, and she underwent a urinary tract catheterization. The procedure was uneventful, except for transitory hypotension, responsive to fluids. On the night of admission, she developed a sudden clinical picture of diffuse abdominal pain, refractory hypotension with need for vasopressors and transient loss of consciousness. A CT exam showed extensive air embolism: gas bubbles inside intra-thoracic veins; pneumatosis of the gastric wall with gas bubbles inside the splanchnic circulation; properly positioned right urinary catheter without any local complications. The patient was submitted to

bowel rest and nasogastric intubation, and high flow oxygen and broad-spectrum antibiotics were initiated. An upper endoscopy revealed a circumscribed area of congestive mucosa suggestive of ischemic phenomena. A head and whole-body CT exam showed reabsorption of almost all of the gas bubbles previously related. An *Escherichia coli* grew on blood and urinary cultures, sensitive to the antibiotic administered. The patient's clinical condition progressively improved and she was able to start feeding orally with good tolerance, being discharged ten days after admission.

Discussion

We emphasize this clinical case because of its rarity and the diagnostic challenge posed by its peculiar presentation. Here we postulate that the critical event for the gastric ischemia and the subsequent gaseous manifestations was the systemic hypoperfusion related to the urinary sepsis. Fortunately, the clinical evolution was favorable with the support measures instituted and the patient didn't need surgical treatment.

LUDWIG'S ANGINA - AN EMERGENCY NOT TO FORGET

Isabel Ferreira, Sara Xavier Pires, Fábio Videira Santos, Lúcia Gonçalves, Gabriela Gonçalves, Cristina Pereira, Heloisa Castro
Centro Hospitalar Universitário do Porto, Porto, Portugal

Clinical summary

A 32 year-old female, previously healthy, was diagnosed with a dental abscess on the left inferior 3rd molar, initially treated with amoxicillin/clavulanate. She developed a painful left facial oedema and 2 days later, the inflammatory signs extended to the anterior cervical region with involvement of the upper airway, trismus and respiratory distress. Cervical CT-scan showed a diffuse thickening with phlegmon and emphysema of the soft tissues from the oral cavity to the anterior mediastinum with left internal jugular vein thrombosis and bulging of the walls of the upper airway at the base of the tongue.

Fibreoptic nasotracheal intubation and surgical drainage of the abscesses were performed, IV antibiotics started and she was admitted to the ICU.

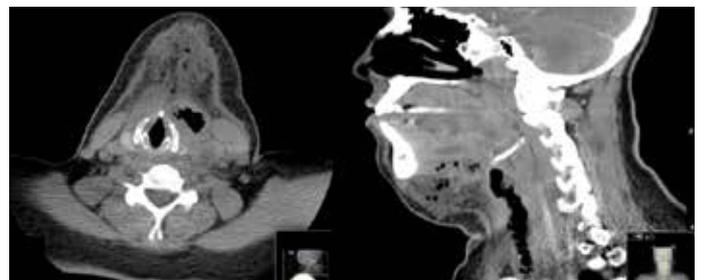

Figure #1718. Cervical CT scan with phlegmon and emphysema.

#1745 - Case Report

DISTRIBUTIVE SHOCK IS NOT ALWAYS A SEPTIC SHOCK – A CLINICAL CASE

João Alexandre Tavares, João Carvalho, Patrícia Carneiro, Catarina Emídio, Carolina Palma, Ricardo Pereira, Inês Costa Santos, Mário Parreira, Ermelinda Pedroso
Centro Hospitalar de Setúbal, Setúbal, Portugal

Introduction

Lyell Syndrome (LS) is a potentially fatal dermatologic disorder characterized by a widespread erythema, necrosis and bullous detachment of the epidermis and mucous membranes. Is usually a drug allergy, but can also be associated with infection, cancer and even vaccination. It has a mortality ranging from 25 to over 90% and is usually associated with sepsis, dehydration and multiple organ failure.

Case description

We describe a 47-year-old woman with no relevant history initially treated with acetaminophen and etoricoxib for tibiotarsus pain without arthritis. After 24 hours patient started to develop a pruriginous rash mainly in her back, and was treated with deflazacort and levocetirizine. The rash continue to worsen and she developed facial swelling and lethargy, being transported to the Emergency Department. At arrival she was confused, hypotensive, tachycardic and with cold extremities; had a disseminated rash of the entire body, mainly in the upper body not sparing palms and soles. Arterial blood gases showed: pH 7.45, pCO₂ 25, pO₂ 60, HCO₃ 17 and lactate 2. Labs showed increased markers of inflammation with multiple organ dysfunction. After fluid challenge patient was started on vasopressors in increasing doses. Blood was drawn for cultures and she was started on ceftriaxone and doxycycline (lived outside the city, had a cat and a typical rash). Echocardiogram showed hyperdynamic heart. She was admitted to the ICU with a Shock of undetermined etiology – septic vs other distributive type. Over the next 24 hours there was a worsening of the facial edema rash with multiple coalescent skin blisters and bullous detachment of the epidermis over 70% of her body, with positive Nikolsky sign. Lyell Syndrome was admitted. Skin biopsy later confirmed the diagnosis. She was transferred to a Burn Unit where she remained for several weeks, with various infectious complications. Patient had multiple skin grafts and intensive physical therapy, but remains with sequelae. She was referred to an allergy specialist.

Discussion

LS initial presentation as a distributive shock is very rare and not described in the literature. With a SCORTEN of 5 or more the mortality is around 90% but the patient ended up surviving. In emergency medicine is important to remember that there are other etiologies for distributive shock besides septic, specially when the cause is not immediately clear. Despite its cause, the basic principles of treatment are the same and should be known to every emergency physician.

#1747 - Case Report

A BIZARRE CASE OF REVERSIBLE HEART BLOCK - THEVETIA PERUVIANA INDUCED CARDIOTOXICITY

Anand Venugopal, Basavaprabhu Achappa
Kasturba Medical College, Mangalore, India

Introduction

Thevetia peruviana (yellow oleander) is a shrub found in the tropical and subtropical regions of the world belonging to the family Apocyanaceae. Consumption of the seeds are a very common method of suicide in South India and Sri Lanka. The toxic effects of the plant is similar to digitalis poisoning due to the presence of cardiac glycosides. The toxic effects usually begins within 24 hours of consumption which may lead to fatality if not identified in time and treated promptly.

Case description

57-year-old male complained of vomiting after accidental consumption of a seed. Seed was identified as 'Karaveera' (local name of yellow oleander seed) which was kept for plantation. On examination, he was conscious, oriented, pulse 74 beats/min, blood pressure 110/80 mmHg with systemic examination and ECG showing normal sinus rhythm. Gastric lavage was performed and admitted in the ICU for monitoring. Sodium, potassium magnesium and rest of the blood work up was normal, but after 10hrs of admission he developed giddiness with bradycardia (heart rate 40 beats/min) and hypotension (blood pressure 90/40 mmHg). Normal saline and atropine 0.6 mg IV was administered following which his BP improved but bradycardia persisted. Repeat ECG showed bradycardia with 2nd degree atrioventricular block – Mobitz type 2. This continued for next 3 hours in view of which electrophysiologist reference was obtained and patient was taken up for temporary pacemaker insertion (TPI). ECG returned to normal sinus rhythm and patient's condition improved.

Discussion

Yellow oleander (Thevetia peruviana) ornamental shrub grown widely in tropical and subtropical parts of the world. Leaves, flowers, seeds and fruits of plant are poisonous and are used as homicidal agents. Plant contains toxins thevetin A, thevetin B, nerifolin, thevetoxin, peruvoside and ruvoside. According to Eddleston et al. as little as two seeds lead to cardiac rhythmic abnormalities leading to fatality. Clinical symptoms of poisoning include nausea, vomiting, diarrhoea, giddiness and abdominal pain which often leads to cardiac arrhythmias. Since all parts of plant contains cardiac glycosides, toxicity mimics digitalis toxic toxicity. According to Eddleston et al. significant cardiotoxicity developed even 72 hours. Bradyarrhythmias are most common cause of mortality in yellow oleander poisoning which are treated with atropine, isoprenaline and temporary cardiac pacing. Learning point from this case is right identification of toxin and prompt treatment to prevent mortality.

#1755 - Abstract

EMERGENCY DEPARTMENT USE BY A GROUP OF PATIENT UNDER 55 YEARS OLD

Hugo Inácio, Ana Brito, Daniela Marto, Salvador Morais Sarmento, Miguel Sousa Leite, Sofia Mahomed Mateus, Dina Rodriguez Pita, Andreia Amaral, Paulo Barreto, Catarina Salvado

Centro Hospitalar Universitário de Lisboa Central, Lisbon, Portugal

Background

Currently, most inpatients with medical conditions are elderly and most of the Emergency Department (ED) studies address this population. However, little is known about the younger patients ED use. The aim of this study was to evaluate demographic characteristics of younger patients, their pattern in ED use, chief complaints (CC) and severity.

Methods

A retrospective observational study was performed, including all patients with medical conditions who visited the ED of a tertiary care hospital over a 12-month period. An exploratory data analysis showed that the median age divided the patients into 2 comparison groups: Group 1, 18-55, and Group 2 >55 years-old. We considered as CC the chosen flowchart using the Manchester Triage System (MTS). Patients were considered severe if they met at least one of the following criteria: admission to the resuscitation room and/or admission in an intensive care unit (ICU) and/or ED death.

Results

We observed 71469 patients (56% female), with an average age of 55 ± 22 (SD) years old. Group 1 (n=36,408 patients), mean age of 36 ± 11 and Group 2, (n=35061), mean age of 54 ± 11 .

Priority assigned by the MTS: 45% of patients was yellow or higher in Group 1 and 61% in group2; 56% of patients was green or lower in Group 1 and 39% in group2 ($p < .001$).

For the 10 most frequent CC, groups differ only in the frequency order. The most frequent CC in both groups was general disability (16% Group 1, 27% Group 2) followed by chest pain (10%) in group1; and dyspnea (17%) in Group 2; dyspnea was only the eighth most frequent in Group 1 (6%). Limb problems were the fourth most frequent CC in both.

Group 1 remained for 6 ± 8 hours in the ED and Group 2 for 10 ± 21 hours ($p < .001$).

Overall, 3% of the patients were considered severe in group1, and 12% in Group 2 ($p < .001$).

In total, 5% of group1 patients and 25% of group 2 were hospitalized ($p < .001$); and 0.03% of Group 1 patients and 0.08% of Group 2 were admitted in the ICU. Still, of the total patients admitted to the ICU, 25% were from group1.

Conclusion

The most frequent CC were similar in both groups, differing only in the frequency order. Group 1 seemed to be less severe than Group 2, remained almost half the time in the ED and was 5 times less likely

to be hospitalized. Nevertheless, it is crucial to note that while these results show that younger patients are less severe, 5% of inpatients and 25% ICU patients, admitted from the ED, were <55.

AORTIC DISSECTION – A RACE AGAINST TIME

Ana Valada Marques, Miguel Falcão, Tânia Gaspar, Isabel Maldonado, Rosa Amorim

Centro Hospitalar do Oeste, Caldas Da Rainha, Portugal

Clinical summary

70 years old male, past history of type 2 diabetes, dyslipidemia, ischemic heart disease, admitted at the emergency room (ER) after sudden onset of severe chest pain and consciousness deterioration. Glasgow coma scale 7 (O1, V1, M5), horizontal nystagmus, symmetrical muscular strength. Blood pressure (BP) 121/98 mmHg, normocardial, peripheral oxygen 97%. Peripheral pulses absent. Normal electrocardiogram. BP dropped to 55/31 mmHg, no fluid challenge response, started vasopressor support and airway protection. Computed tomography angiography images showed an aortic dissection beginning at ascending aorta and ending after the emergence of left subclavian artery, extended to the left common carotid artery with rupture and hemopericardium. Patient was referred for surgical intervention.

#1847 - Abstract

SUICIDE ATTEMPTS BY CHEMICAL INGESTION - A RETROSPECTIVE STUDY

Joao Gamito Lopes, Lucas Diaz, Jose Sousa E Costa

Hospital do Litoral Alentejano, Santiago Do Cacém, Portugal

Background

Suicide attempts and deliberate self-harm is a critical psychological issue worldwide with data suggesting an increasing trend.

Internists, as emergency doctors, are responsible for the acute management of the complications that result from these attempts. Each chemical type has its particularities and doctors need to be aware of those most frequently observed to best adequate their immediate response. The authors proposed to characterize the suicide attempts by chemical ingestion.

Methods

Cohort retrospective study over 4.5 years. Inclusion criteria was the need to hospitalization after a suicide attempt by chemical ingestion. Other methods of suicide attempt were excluded. Descriptive analysis on demographic variables, relevant medical history, ingested chemical characteristics, and outcome was done.

Results

101 hospitalizations episodes were included, corresponding to 96 patients. Women predominance (61,4%). Age varied between 18 and 91 years old, with a mean 55,7 years (SD: 19,1) and median of 55 years (IQR: 31). 32,7% were already on a Psychiatrist. Benzodiazepine was the most prevalent chemical used (33,7%), followed by organophosphate (16,8%) and antipsychotic drug (15,8%). More than a third of the patients used more than one type of drug, and 19,8% ingested three or more different types of drugs. 7,9% died. No seasonality was found.

Conclusion

The authors address the need to invest in physician's education on managing these drug complications. However, providing adequate follow-up care and address the problem as preventable should be a major concern.

#1901 - Case Report

WHEN A SIMPLE "FLU" HIDES SOMETHING ELSE: MEETINGS BETWEEN INTERNAL MEDICINE AND HAEMATOLOGY

Sandra D. Santos, David Lopes Sousa, Joana Paixão, Lídia Gomes, Ana Catarina Lucas

Serviço de Medicina Interna, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

The triad cough, dyspnoea and fever can correlate with a myriad of differential diagnoses, among the most obvious the respiratory infections. However, these symptoms can mean more serious illness.

Case description

A 47-year-old woman, with no significant personal background and no usual medication, presented with a 3-day history of productive cough, dyspnoea and pleuritic pain, without fever. The patient denied any B symptoms and complained of recurrent skin infections in recent weeks. The week before, she had been medicated with amoxicillin/clavulanic acid for inguinal furunculosis.

She was hemodynamically (HD) stable, afebrile, and cardiopulmonary auscultation had no major changes. The chest X-ray showed diffuse bilateral cotton-like infiltrates, she had type 1 respiratory failure, and laboratory studies revealed severe acute pancytopenia [White blood cells = 3.56 k/μL (4-10 k/μL), Neutrophil = 1.9, with 6% immature cells), haemoglobin = 8.6 g/dL (12-16 g/dL) and platelets 17 k/μL (150-400 k/μL)]. The peripheral blood smear showed marked dysplasia of the myeloid line and erythrocyte morphology with moderate anisopoikilocytosis. An extended serological study was negative for syphilis, HBV, HCV, HIV, Chlamydia trachomatis, C. pneumoniae, Coxiella spp, S. pneumoniae and Legionella spp and revealed immunity for CMV, HSV-1, EBV and PpV-19. Blood, urine and sputum cultures were also negative. A thoracic CT-scan showed extensive areas of heterogeneous parenchymal densification in both lungs, especially in the upper lobes, with air bronchogram, which were admitted being of infectious nature. In addition, hilar adenomegalies were present, the largest on the right with 11 mm short axis. At this point, the patient was admitted to the Haematology ward and started on broad spectrum antibiotics. As soon as possible, a myelogram was performed, confirming the diagnostic suspicion of acute myeloid leukaemia, and chemotherapy was started.

Discussion

The authors present the case of a patient with a common presentation of acute cough, fever and dyspnoea leading to a diagnosis of acute myeloid leukaemia.

This case report demonstrates the importance of considering less obvious diagnoses even in cases that seem simple and highlights the importance of a good articulation between hospital specialties in the early resolution and early initiation of urgent treatments, namely chemotherapy.

#1931 - Case Report

ABDOMINAL HEMATOMA DUE TO ANTICOAGULANT THERAPY – A SERIES OF CASES

Cristina Moreira Marques, Márcia Ribeiro, Carolina Veiga, Carina Costa Silva, João Mota, Ana Ogando, Carlos Oliveira

Hospital Santa Maria Maior, Barcelos, Portugal

Introduction

Abdominal wall hematomas are uncommon, difficult to diagnose and are often associated with systemic anticoagulation. Studies report an incidence of 1.5 to 2% in hospitalized patients and overall, is more common in female than males. This series of uncommon cases reports 8 hospitalized patients that suffer from haemorrhagic shock due to abdominal wall haematoma in a period of 6 months in an internal medicine service, which were in therapy with LMWH. This paper intends to review all the factors that can have triggered this life-threatening, uncommon and abnormal situation in this hospital.

Case description

This series of 8 cases happened between October of 2018 and March of 2019, under LMWH during their stay in the hospital. All the patients were women with ages between 53 and 82. Four of our cases needed adjustment of the dosage of LMWH (age, kidney function, weight, previous treatments). From those under therapy with warfarin, two of them had therapeutic levels of INR, at the time of the start of the first administration of LMWH. One of the patients was under NOAC therapy, and at admission had coagulopathy. All the 8 patients suffer from haemorrhagic shock due to abdominal wall haematoma, which occurred 5 to 14 days after their hospitalization. The first case was approached surgically. Conservative treatment was decided in all the 7 of the other patients because of the high risk of a surgical approach; with the necessary support. Seven of patients recover completely, being discharged after 3 to 4 weeks from the hospital, with partial reabsorption of the haematoma. Death occurred in one of the cases. To all the patients the scores of CHA₂DS₂-VASc and HASBLED were calculated, having all scored higher than 5 and lower than 3, respectively.

Discussion

LMWH can cause bleeding complications and sometimes leads to major life-threatening complications. Even though 3 of the report cases could have been due to iatrogenic procedures; 5 of them happened in patients without any other triggers. It is important to be aware of all the factors that can influence anticoagulation (oral and systemic) therapy, the administration of these therapies and the relation with the drug itself. This series of cases pretends to alert to these serious and many times undiagnosed situations, the importance of early recognition and treatment and the extreme importance of the continuous revision of the anticoagulation's protocols in use.

#1954 - Abstract

EFFECT OF AGE IN THE INCREASED RISK OF MORTALITY OF SEPTIC PATIENT

André Simões¹, Sofia Durão², João Gonçalves Pereira¹

¹ Serviço de Medicina Intensiva - Hospital de Vila Franca de Xira, Lisboa, Portugal

² Serviço de Hematologia e Transplantação de Medula Óssea - Centro Hospitalar Lisboa Norte, Lisboa, Portugal

Background

Several studies have shown a close relationship between infection and mortality in critically ill patients. It is not known whether this effect is dependent of age.

Methods

Retrospective, observational, unicentric study to assess the impact of age and clinical severity on mortality of patients admitted to an Intensive Care Unit (ICU) with infection.

All patients admitted to the ICU between July 2016 and June 2017 were included. Patients were segregated in 6 different

groups, according to the presence of infection on admission to the ICU and according to their age (divided in 3 terciles).

We evaluated the mortality at hospital discharge and after 6 months.

Results

A total of 737 patients were included, (58.3% male, mean age of 66.6±16.3 years).

Infection on admission was noted in 216 patients. Its prevalence was similar in the 3 age groups (p=0.97). Respiratory was the most prevalent focus of infection (32.9%).

Infected patients had higher SAPS II (44.3±19.3 vs. 39.6±18.1, p=0.006) and hospital mortality (27.8% vs 20.4%, OR 1.5 [1.04-2.17]; p=0.033).

However, after 6 months, mortality was already similar in both groups (39.4% vs 34.9%, p = 0.274). Around 25% of the older patient's group, discharged alive from the hospital, died during the subsequent 6 months.

Conclusion

Patients with infection on admission to the ICU have higher mortality, largely explained by their higher severity at admission. This difference is transversal to all age groups and decrease significantly in the first 6 months after discharge.

#1987 - Case Report

TRASTUZUMAB, A LIFESAVER WITH A REMARKABLY AUGMENTED RISK FOR CARDIOVASCULAR EVENTS

Adriano Pacheco Mendes, André Gonçalves Mendes, Ruben Raimundo, Joana Cochicho, Sara Viana, Rita Parente, José Lessa, Ana Neves, Maxim Suleac, Isabel Lavadinho, Isabel Soles
Unidade Local de Saúde do Norte Alentejano, Portalegre, Portugal

Introduction

Trastuzumab is a life-extending therapy for breast cancer patients overexpressing the human epidermal growth factor receptor 2 (HER2+), but has known cardiotoxic risk and an increased risk for cardiovascular events.

Case description

We report a case of a 60-year-old woman, who was being treated with trastuzumab for breast infiltrating ductal carcinoma (HER2+), that has been admitted in the emergency department after a car crash coming off road. According to her medical history, she completed 6th cycles of chemotherapy for breast carcinoma and hypertension had been recently diagnosed. Although treatment with an ACE inhibitor plus calcium channel blockers, the blood pressure was poorly controlled. On physical examination she presented with left hemiplegia, an altered level of consciousness and elevated blood pressure. The CT scan revealed a right intracerebral hemorrhage with 7 cm of larger diameter and with a mass effect 4 mm to the left. After 10 days, with a good recovery

status and an optimization of antihypertensive therapy, she got discharged from hospital.

Discussion

More women are living with and surviving breast cancer because of improvements in breast cancer care. Despite the fact that trastuzumab has significantly improved outcomes for women with HER2-positive tumours, breast cancer patients are regarded as a population of high cardiovascular risk, risk that might be remarkably augmented under trastuzumab chemotherapy due to its known, but not that common, adverse effect such as hypertension. Since hypertension is a potent modifiable risk factor during breast cancer treatment, a stricter control of hypertension in these patients is desirable in order to avoid events such as hypertensive emergencies and their complications.

#2044 - Case Report

A CASE OF TAKOTSUBO SYNDROME IN THE IMMEDIATE POSTOPERATIVE PERIOD

Luciana Faria¹, Adriana Alves², Ana Mesquita²

¹ Centro Hospitalar Póvoa de Varzim/Vila do Conde, Vila Do Conde, Portugal

² Unidade Local de Saúde de Matosinhos, Matosinhos, Portugal

Introduction

Takotsubo syndrome (TS) is an increasingly recognized entity, but rarely described as an immediate complication after elective surgery.

Case description

A 59-year-old woman, active smoker, with hypercholesterolemia, depression with anxious distress and right hemithyroidectomy at age 44. Medicated with levothyroxine, escitalopram and alprazolam. Electively admitted for left hemithyroidectomy by follicular carcinoma. Preoperative study with ASA II, euthyroid and normal electrocardiogram (ECG). The surgery was performed under general anesthesia and no peri or intraoperative complications were reported. In the immediate postoperative period, after extubation, hypoxemic respiratory failure was identified, with desaturation up to 85%, without airway obstruction and not responsive to increase FiO₂. Noninvasive ventilation was started. ECG showed inversion of the T waves in DI, DII, DIII, aVF, V2 to V6 and prolongation of the QTc interval. Analysis with elevation of troponin I (maximum 1303 ng/L) and BNP (453.6 pg/mL). Thoracic angiography by computed tomography showed only bilateral opacities in the lower lobes and excluded pulmonary embolism. Echocardiogram (Day 1) showed a compromise of the left ventricle systolic function (Ejection Fraction = 30%), hyperkinesis of the basal segments with mid-apical segmental akinesia. Cardiac catheterization (Day 1) excluded significant coronary artery disease (40% stenosis at the beginning of the distal segment of the AD) and ventriculography documented severe depression of left ventricular systolic function

and segmental contractility suggestive of TS. Cardiac magnetic resonance imaging (MRI) (Day 8), showed “non-dilated ventricular cavities with normal biventricular systolic function, not apical bulging of the left ventricle, without evident areas of edema, fibrosis or myocardial necrosis and small pericardial effusion.” Considering the initial ECG, biomarkers (BNP), echocardiogram with absence of coronary disease, with subsequent normal study (MRI) the diagnosis of TS was made. The patient had discharge (Day 11), asymptomatic, with ECG with normal QTc but remaining inversions of Twaves and, medicated with aspirin, atorvastatin, levothyroxine, alprazolam, escitalopram.

Discussion

Since the surgery and extubation are considered a stressful events, this entity should be thinking as a differential diagnosis of acute respiratory failure/complication after a elective surgery.

#2059 - Abstract

SEPTIC SHOCK AS THE MAIN CAUSE OF ICU MORTALITY - 6 MONTHS IN REVIEW

Eduardo Cernadas¹, João Corrêa¹, Dália Estevão¹, Irene Aragão²

¹ Centro Hospitalar Cova da Beira, Covilhã, Portugal

² Centro Hospitalar do Porto, Porto, Portugal

Background

Shock is a life-threatening condition of circulatory failure. The effects of shock are initially reversible, but rapidly become irreversible, resulting in multiorgan failure (MOF) and death. Septic shock is a potentially fatal medical condition that occurs when sepsis, which is organ injury or damage in response to infection, leads to dangerously low blood pressure and abnormalities in cellular metabolism. The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3) defines septic shock as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone.

Methods

Analysis and review of the main causes of mortality in an Intensive Care Unit (ICU) of a Central Hospital, between July 2018 and December 2018.

Results

The authors reviewed 6 months of clinical activity at an Intensive Care Unit, with a total of 230 patients (54% males; 46% females). The average time of internment at the unit was 6.7 days. Regarding mortality in the time object of the study, 46 (20%) have deceased being the shock (n=21), the main cause. From an etiologic point of view, the vast majority of these patients have died from Septic shock (n=14) being the respiratory and genito-urinary tract the main focus. Reference must be made to at least 7 patients, who died from distributive shock in the context of acute severe polytrauma and other causes of shock (like hemorrhagic or obstructive).

Conclusion

Septic shock is associated with significant mortality and is the leading non cardiac cause of death in intensive care units (ICUs). The results are in agreement with the clinical sense and international guidelines that efforts must be made to detect and treat shock as soon as possible, as septic shock still remains one of the main causes of mortality in ICU.

THE GREAT DECEIVER

David Prescott, Ana Isabel Brochado, Margarida Pimentel Nunes, Inês Branco Carvalho, Isabel Montenegro Araújo, Beatriz Donato, Rita Sérgio, José Luís Ferraro, Vasco Evangelista, António Martins Baptista, José Lomelino Araújo

Hospital Beatriz Ângelo, Loures, Portugal

Clinical summary

We present the case of a sixty-one year old that calls the emergency services because of sudden lumbar pain, nausea, hyperhidrosis and referred hypotension. He mentioned an average systolic blood pressure greater than 200 mmHg the previous days, which he assumed was normal. On-site observation was unremarkable except for obtundation of consciousness and muffled heart sounds. His BP was 110/78 mmHg. ECG had no changes suggestive of ischemia. He was quickly transported to hospital where bedside echoscopy showed cardiac tamponade. The following Angio-CT images show a Stanford type A aortic dissection from the coronary arteries all the way to the left iliac artery. Extravasation of contrast material to the pericardial sac can be seen.

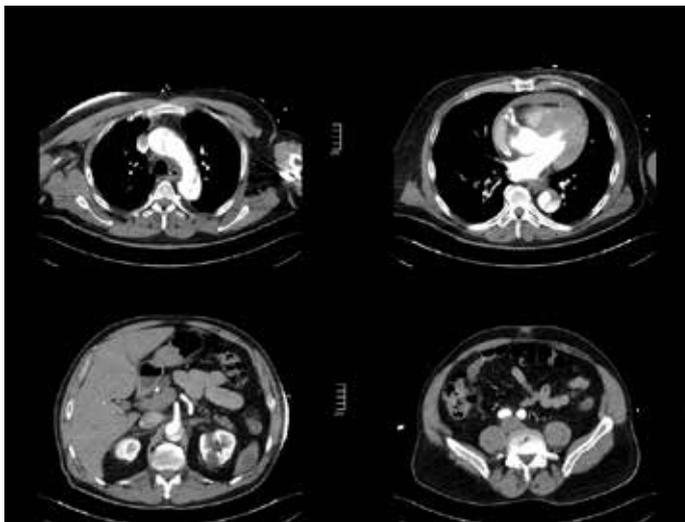

Figure #2080. Top Left: Aortic arch and Descending aorta dissection. Top Right: Contrast leak to pericardial sac and Thoracic Aorta dissection. Bottom Left: Abdominal Aorta dissection. Bottom Right: Common iliac arteries and Left common iliac artery dissection.

#2091 - Case Report

LUDWIG'S ANGINA – AN EMERGENCY

Cristina Silva, Sara Freitas, Jorge Cotter

Hospital da Senhora da Oliveira, Guimarães, Portugal

Introduction

Ludwig's Angina is a form of rapidly progressive cellulitis, which involves the sublingual and submandibular space. It can arise from an infection of the oral cavity or upper respiratory tract. Clinically, the patient may present with dysphagia, odynophagia, "hot potato" voice and fever. The most feared complication is airway obstruction, which is potentially fatal.

Case description

An 84 years old male was brought to the Emergency Department because of fever, mucopurulent sputum and right neck swelling of recent onset. He had prior medical history of hypertension, type 2 diabetes, atrial fibrillation, cerebrovascular disease, dementia and left sialadenitis. On physical examination, it was observed swelling in the right submandibular region, abundant secretions in the oral cavity, salivary stasis and elevation of the mouth's floor. The patient went into respiratory arrest, which was reverted by aspiration of secretions of the oropharynx. Computed tomography of the neck revealed "enlargement of the right submandibular gland with heterogeneous contrast uptake, compatible with sialadenitis". It also showed "reticulate densification of the ipsilateral superficial and deep fat plans of the neck, compatible with cellulitis/ phlegmon, extending to the floor of the oral cavity", inducing "flattening of the vallecula and right piriform sinus" as well as "thickening of the aryepiglottic fold, right ventricular band and vocal cord and infrahyoid muscles". These abnormalities were causing "moderate airway reduction in the oropharynx plan". It was requested an evaluation by Otolaryngology and it was decided to perform an emergent tracheostomy along with drainage of the purulent collections.

Discussion

Ludwig's Angina is an increasingly less frequent entity, in part because of the improvement of oral health. Nevertheless, because of the risk of airway obstruction, it may have a fulminating course and a fatal outcome. At an early stage, it can be treated with intravenous antibiotics but, in advanced stages, tracheostomy and surgical drainage can be necessary. This case intends to stress the importance of early diagnosis and immediate treatment of this condition.

#2117 - Abstract

OBSTETRIC ADMISSION TO INTENSIVE CARE UNIT – A FIVE YEAR REVIEW

Sofia Xavier Pires^{1,2}, Helena Gonçalves¹, Anusca Paixão¹, Sónia Canadas¹, Henrique Santos¹, Ricardo Amaral¹, Nelson Barros¹, Francisco Esteves¹

¹ Centro Hospitalar de Trás-os-Montes e Alto Douro, Vila Real, Portugal

² Hospital Senhora da Oliveira, Guimarães, Portugal

Background

Maternal mortality has declined since the 1960s as a consequence of improved health programs and is currently estimated at 7 per 100,000 births in 2015 (PorData). Obstetric pathology is a rare admission cause in Intensive Care, however, early admission improves prognosis of severe obstetric pathology. The objective of this study was to evaluate all medical records concerning pregnant and postpartum women who were admitted to ICU care, describing the characteristics of the mothers, their previous comorbidities, and identifying risk factors for maternal and neonatal mortality.

Methods

A descriptive retrospective study was carried out. All female patients admitted to the Intensive Care Service from 1 January of 2012 to 31 December of 2016 were included. Data was collected by clinical records reading. Data analysis was performed using descriptive statistics, and data was treated using SPSS software.

Results

Eight obstetric patients were admitted to the Intensive Care Unit during the study period, corresponding to 0.24% of all admissions. The mean age of the patients was 28 years. The most frequent cause for admission were complications related to hypertension, namely HELLP Syndrome in 38% of patients (n=3) and pre-eclampsia in 25% (n=2) of all admissions. The majority of complications occurred in the third trimester, with only one admission occurring in a second trimester pregnancy. In fifty per cent of cases an emergent cesarean was performed. The mean SOFA score at admission was 3 (minimum 2, maximum 5). On average, patients had 3 organ dysfunctions, with hepatic, respiratory and hematologic dysfunctions being the most frequent. The mean APACHE II on admission was 16.1, corresponding to an estimated mortality of 47.3%. The co-morbidity most frequently present was obesity in 63% of patients (n=8), followed by chronic hypertension in 38% (n=3) of all patients. The mean hospitalization time was 2.2 days. The maternal mortality rate was zero, and a fetal death was reported.

Conclusion

Admission in ICU care is rare due to obstetric complications with hypertensive complications leading the most frequent cause for admission.

#2118 - Abstract

NON-INTENSIVE CARE UNIT ACQUIRED PNEUMONIA: DATA FROM A TERTIARY CENTER

Andreia Margarida Margarida De Matos¹, André Filipe Goulart², Eduardo Santos³, Catarina Monteiro¹, Paulo Martins¹

¹ Coimbra Hospital and Univesity Center, Coimbra, Portugal

² Hospital de Santo Espírito Da Ilha Terceira, Açores, Portugal

³ Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

Background

Hospital-acquired pneumonia (HAP) is a frequent cause of nosocomial infections, with great morbidity and mortality worldwide but most of the available data is in mechanically ventilated patients. Non-ICU acquired pneumonia (NIAP) has been described as a distinct clinical entity with few data as suggested in 2016 Marta Di Pasquale et al article review. The aim is to describe epidemiology and risk factors of NIAP in a tertiary center.

Methods

retrospective study of patients with NIAP admitted to a 29-bed tertiary care ICU from 2015 to 2017.

Results

From a total of 2904 patients admitted to ICU, 84 patients (4.0%) were admitted for NIAP: 76% men, with a mean age of 67,4±14,7 (26 to 90 years), APACHE-II 19.6, SAPS-II 49.7, SOFA-score at admission 9.9, and SOFA-score at discharge 3.2, 96.4% with mechanical ventilation (average 10 days). Fifty-five per cent had ≥3 comorbidities: 29% with recent malignant neoplasm, 26% with pulmonary disease or heart failure and 20% with alcohol or tobacco consumption. About 71.4% had ≥1 antibiotic multiresistance factor: previous 90-days antibiotic therapy (in 39%, mostly with ≥1 antibiotic group), immunosuppressive therapy (21%), and previous multiresistance bacteria (15%). A gastric content aspiration was described in 14.3%. Most patients (58.3%) were admitted to hospital for a surgical or neurological disease. Late-onset pneumonia was frequent (at average at 17-day admission), and ICU admission occurred before 36 hours. Combination therapy was made in 64.5%, with antibiotic step-up in 28.6% after monotherapy regimens versus 16% with combination. Bacterial agents from bronchial sputum were identified in 39 patients (46.4%): mostly *Staphylococcus aureus* (35.6% with 81% methicillin-resistant, followed by *Pseudomonas aeruginosa* (15.6%, mostly resistant to piperacillin-tazobactam) and 15.4% were polymicrobial. Sixty patients (41%) had bloodstream infection and 61.5% were multiresistant. Intra-hospital mortality was 39.2%. Hospital discharge occurred after 45 days (with an average 12 days in ICU). One year mortality rate was 27.1%, mostly 30 days after discharge.

Conclusion

NIAP seems to be an important cause of intra-hospital mortality, mostly late-onset acquired and with previous identified risk

factors. *Staphylococcus aureus* and *Pseudomonas aeruginosa* were the most frequent agents and multiresistance was high.

#2174 - Case Report

SYNCOPE IN A PREGNANT WOMAN - A SIGN OF CONCERN

Magda Ferreira Costa

Hospital Senhora da Oliveira, Guimarães, Portugal

Introduction

Syncope is defined as transient loss of consciousness due to cerebral hypoperfusion, characterized by a rapid onset, short duration, and spontaneous complete recovery. Can be subdivided in three main groups according with the underlying etiology: reflex, due to orthostatic hypotension and cardiac cause.

Case description

A 31-year-old woman, 8 weeks pregnant, with no prior relevant antecedent, was observed in our emergency service because of a colic abdominal pain in lower quadrants with one day of evolution, with vomiting and nausea. In the morning of admission she had a syncope when she went to the bathroom, with right frontal trauma. At the physical examination she was hypotensive, afebrile and presented a painful abdominal palpation, with no clinical recovery after fluidotherapy, paracetamol and metoclopramide. During the time the patient stayed at the observation room, became more symptomatic and hemodynamically unstable. In the complementary exams, we could observe a 2g/dL drop in hemoglobin in 2 weeks, with no elevation of inflammatory parameters. Electrocardiogram was normal, but the abdominal ultrasound described an empty uterine cavity, with gestational sac in an ectopic location and hematic liquid in intraperitoneal cavity. Internal medicine discussed the case with the obstetrician team and the patient was submitted to an emergent exploratory surgery and a gestational sac implantation in the left fallopian tube was confirmed. After the surgery, the patient presented a favorable evolution.

Discussion

Ectopic pregnancy is defined as a pregnancy that occurs outside of the uterine cavity. The fallopian tube is the most common location of ectopic implantation, accounting for more than 90% of cases. Treatment approaches include expectant, medical (methotrexate), or surgical. Can be complicated by rupture, in which case may present in shock from blood loss and with unusual patterns of referred pain from intraperitoneal blood. If undiagnosed or untreated, it may lead to maternal death due to rupture of the implantation site and intraperitoneal hemorrhage.

#2185 - Case Report

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR-INDUCED ANGIOEDEMA: REPORT OF A CASE

Diogo Ramalho, Ana Canelas, Beatriz Samões, Ingrid Da Costa

Centro Hospitalar Vila Nova de Gaia / Espinho, Vila Nova De Gaia, Portugal

Introduction

Angiotensin-converting enzyme inhibitors (ACEi) are the main cause of pharmacological iatrogenic angioedema, due to their frequent use in patients with arterial hypertension and heart failure disease. Cough is the most common adverse reaction, but in rare occasions patients present angioedema.

The most important risk factors are: female gender, age above 65, African descent, aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) use, previous history of angioedema, smoking and atopy.

Usually, the angioedema occurs in the first week (between the 2nd and 5th day) and involves non-dependent areas asymmetrically (e.g., face, tongue, lips and upper airways in 10% of the cases). Pruritus and urticarial reaction are typically absent.

Case description

A 73-year-old white male patient, with no relevant medical history, was admitted to the emergency department with marked edema affecting the lower lip and left hemiface, and odynophagia after taking perindopril for blood pressure control. Minutes after drug administration, the patient experienced a sudden onset of odynophagia. He took ibuprofen with clinical worsening of said symptom. 10 hours later, lower lip and left hemiface edema emerged. The patient denied pruritus, erythema, wheezing, abdominal pain, fever and known allergies. The physical examination was normal: afebrile, hemodynamic stability and normal cardiopulmonary auscultation. The patient was evaluated by Otorhinolaryngology that found tonsillar pillars, valleculae and aryepiglottic folds edema, sparing the tongue and other the structures of the oral cavity and oropharynx with preserved airway patency. Corticoid and antihistamines drugs were administered with clinical improvement. The patient was discharged with corticoid and antihistamine drugs and recommendations to stop taking ACEi, avoid NSAIDs and reinstate prior non-ACEi antihypertensive drugs.

Discussion

ACEi-induced angioedema is rare, but potentially life-threatening. The diagnosis is clinical-based and is confirmed by complete resolution after ACEi discontinuation.

This case report describes a white male patient with risk factors for ACEi-induced angioedema: advanced age and clinical worsening after NSAID intake.

When discharged, patients must be informed of the possible recurrence in the first months after discontinuation of the culprit drug.

#2191 - Case Report

METFORMIN POISONING - A TALE OF SEVERE LACTIC ACIDEMIA

Ana Hipólito Reis, Marta Pereira, Daniela Coelho, Rui Araújo

Serviço de Medicina Intensiva, Hospital Pedro Hispano - Matosinhos Local Health Unit, Matosinhos, Portugal

Introduction

Acute management of the patient with intentional drug overdose is challenging. As multiple drugs are frequently involved, with synergic and/or antagonical pharmacological profiles and effects, identification of a toxindrome is not always possible. Metformin is a drug of the biguanide family, widely prescribed and generally safe. Lactic acidosis is a well known and dangerous complication in acute and chronic settings, associated with renal insufficiency, critical illness or intentional overdose.

Case description

A 54 year-old woman with recently diagnosed breast carcinoma and depression was admitted in ICU after intentional overdose of high dosed multiple drugs: alprazolam, venlafaxine, propranolol, letrozole, vildagliptin and massive amount of metformin (50 g). She evolved with coma, hypotension, bradycardia with prolonged QT, hypoglycaemia and lactic acidemia (minimum pH of 7.13, maximum lactate 14 mmol/L). Management included airway protection with orotracheal intubation and mechanical ventilation, activated charcoal, dextrose, intravenous fluid and aminergic support. Continuous venovenous hemofiltration (CVVHF) was started. Initial pH and lactate improvement was followed by rebound deterioration. Other hyperlactacidemia causes were excluded, dialysis dosis was improved and CVVHF was maintained over 96 hours with sustained metabolic and renal function improvement. There was not resurgence of hyperlactacidemia after suspension of the technique.

Discussion

Acute management of this patient was challenging, due to severity of presentation and co-ingestion of high dosed multiple drugs. Metformin in particular was worrisome for the massive amount ingested and because its poisoning is a life-threatening condition. It presents with inespecific symptoms, severe lactic acidosis and cardiovascular collapse and is associated with a very high mortality rate (30-50%). Treatment options are limited to supportive care. Extracorporeal treatment is recommended and its benefits go beyond metformin removal, and include improvement of academia and lactate clearance. Intermittent hemodialysis is the preferred method for metformin clearance. In this case we chose a continuous modality as an alternative, due to patient hemodynamic status and UCI experience, with high dialysis dosis. A lactate rebound can occur during or after discontinuation of hemodialysis, due to redistribution of metformin into the intravascular space. As it is unpredictable, our patient acid-base status was monitored closed.

#2197 - Case Report

THE NEED TO REMEMBER: IS THE TREATMENT THE KEY FOR A NEW PROBLEM?Diana Pires Fernandes¹, Sara Faria², Diana Mano³, Andrés Carrascal¹¹ Unidade Local de Saúde do Nordeste, Bragança, Portugal² Hospital Distrital Figueira da Foz, Figueira Da Foz, Portugal³ Centro Hospitalar Universitário do Porto, Porto, Portugal**Introduction**

There are several pathologies and risk factors that make hypocoagulation a fairly common treatment these days. Therefore, the need for this type of therapy should bring with it the search for the most appropriate drug for each patient in order to minimize the risk of hemorrhagic complications without, in this way, avoiding all inherent risks.

Case description

We present a 69-year-old truck driver with a history of hypertension, deep venous thrombosis and pulmonary thromboembolism, reason why he was hypocoagulated with warfarine about 6 months ago.

During one of his work trips, the patient went to the emergency department suffering from neck pain and paraesthesia in his left arm. With no other alterations in the physical exam and no history of traumatism, he was discharged on the same day after analgesia and anti-inflammatory prescription.

The next day, the patient woke up with urinary incontinence, a feeling of weight in the left arm and incapable to move the lower limbs so he returned to the emergency department. Clinical examination showed bradycardia and hypotension, as well as tetraparesis with upper limb folds, indifferent plantar reflexes and abolished osteotendinous reflexes.

In the diagnostic tests stands out a INR of 5 and the presence of a cervical hematoma in the region corresponding to C3-C7 with severespinal cord compression was verified by magnetic resonance imaging (MRI). After revert hypocoagulation and initiation of vasopressor support, the patient was sedated, ventilated and transferred to a central hospital for neurosurgical treatment. Performed laminectomy from C4 to C7 and hematoma removal in the same area. The patient was admitted to the intensive care unit and repeated MRI 5 days later with extensive hypersignal in T2/T2 STIR, from C2-C3 to C7-D1. The patient developed paraplegia of the lower limbs, distal paresis of the upper limbs and difficult ventilatory weaning, so he had to undergo for a tracheostomy before he was transferred to a rehabilitation center.

Discussion

Although, in the absence of trauma, hemorrhagic complications in hypocoagulated patients are not so common, this case showed the importance of not forgetting them at the time we considered the diagnosis. The urgency in the treatment of this type of complications is related with the fast reversal of hypocoagulation and the specific treatment of each problem to avoid permanent consequences, which was no longer possible in this situation.

#2234 - Abstract

ACUTE INTOXICATION IN THE EMERGENCY DEPARTMENT OF A GENERAL HOSPITAL

Gonçalo Mendes, Margarida Madeira, Mafalda Figueira, Ana Catarina Emídio, Daniela Brigas, Francisca Santos, Diana Neto, Eugénio Dias, Clara Rosa, Ermelinda Pedroso
Centro Hospitalar de Setúbal, Setúbal, Portugal

Background

Acute poisoning is a major medical emergency carrying significant morbidity and mortality in all age groups across the world. It may have highly variable clinical presentations depending on the substance involved and this variability can lead to delayed recognition with consequent increased morbidity and mortality.

Methods

With this study, authors aimed to describe the clinical and socio-demographic characteristics of patients admitted to an emergency department (ED) of a general hospital with a diagnosis of poisoning. A retrospective study analyzed patient admissions in the ED from January 1, 2017 to December 31, 2017.

Results

We found a total of 351 admissions, 314 (89.4%) cases were involved in non-deliberate poisoning, whereas 37 (10.6%) were involved in deliberate poisoning. 196 (55.8%) patients were female and 155 (44.2%) male. The mean age was 48.49 ± 19.93 . Analyzing the admission, 5.12% (18) of patients had more than one admission to the ED. 88 (25% of total) admissions were due to benzodiazepines, 27 (7.7%) due to pesticides and insecticides, including 1 case of paraquat and 133 cases (37.9%) were due to ethanol intoxication. Excluding ethanol intoxication, most admissions occurred in winter, January: 28 cases (7.9%); February with 26 cases (7.4%) and December with 29 cases (8.26%). From all the admissions only 5.12% (18 cases) needed to be admitted to the Intensive Care Unit and those patients had a mean stay of 10.8 ± 7.02 days. Total mortality was 1.42% (5 deaths, 4 in the ICU and 1 in the ED).

Conclusion

Most intoxication cases, except ethanol, occurred in the winter. The poisoning was more common in female than in males. Only a small number of cases needed ICU admission and the global mortality rate was low.

With this work authors tried to help physicians to understand the local data in order to promote early recognition and appropriate management, improving outcomes, reducing morbidity and mortality of poisoned patients.

#2250 - Case Report

ALTERED MENTAL STATUS IN A TOXICOPHILIC PATIENT: AN UNEXPECTED DIAGNOSIS

Inês Esteves Cruz¹, Ana Bento Silva¹, Gonçalo Cunha², Eduarda Carmo¹, Francisco Silva¹

¹ Hospital Egas Moniz, CHLO, Lisbon, Portugal

² Hospital Santa Cruz, CHLO, Lisbon, Portugal

Introduction

We present a case in which the unspecific symptoms masked the important diagnosis of a complicated myocardial infarction (MI) with cardiogenic shock and left ventricle (LV) thrombus. Thrombosis was a common complication before the advent of reperfusion, nowadays it occurs only in less than 8% of patients submitted to reperfusion therapy.

Case description

55-year-old Caucasian male, with a known history of epilepsy, dilated cardiomyopathy with low ejection fraction (EF), hepatitis B and C and a cardiorespiratory arrest secondary to opioid overdose a year ago. He had allegedly suspended both his IV drug use and alcoholic habits since then. Treated with levetiracetam 500 mg bid and olanzapine 10 mg id. He presented to the hospital with a 3-month history of fatigue and anorexia, worsened in the preceding 2 weeks leaving him bedridden. On physical examination he was conscious, pale, hypotensive with a normal heart rate (87/63 mmHg 85bpm) and hypoxemic (SpO_2 90% on room air), with a normal heart and lung examination, and hepatomegaly.

Laboratory findings revealed anemia 12.8g/dL, thrombocytopenia 125 mm³/uL, hyponatremia 126 mmol/L, hyperkalemia 5.4 mmol/L, cytocholestatic pattern (total bilirubin 1.98 mg/dL, direct 1.13 mg/dL; AST 476 U/L, ALT 752 U/L, GGT 55U/L), acute kidney injury (urea 122 mg/dL, creatinine 1.27mg/dL), elevated inflammatory markers (leukocytosis 11100/uL, CRP 6.2 mg/dL) and NTproBNP (8218 pg/mL). Abdominal ultrasound showed hepatic steatosis, moderate ascites and bilateral pleural effusion. Within 72h he developed an altered mental status, worsening hypotension and oliguria. ECG revealed a left bundle branch block, chest X-ray showed extensive bilateral pleural effusion, brain CT scan revealed no acute changes and blood tests demonstrated worsening liver and renal function tests, metabolic acidosis with raised lactate and troponin levels (hsTnT 680 ng/mL). He was transferred to the ICU with the diagnosis of MI with cardiogenic shock, starting ventilatory and inotropic support, and dialysis. The echocardiogram revealed an enlarged LV with reduced EF and a large apical thrombus; unfractionated heparin was started. Unfortunately, he ended up dead at 7 days after admission.

Discussion

This case should emphasize the importance of regular patients' follow-up, regardless of their social condition, toxicophilic and alcoholic dependence or therapeutic compliance, particularly in patients with severe pathology with a high probability of unfavorable progression.

ENDOCRINE AND METABOLIC DISEASES

ADIPSIC DIABETES INSIPIDUS SECONDARY TO CRANIOPHARYNGIOMA RESECTION

María Alejandra Pérez Ardila, Juan David Zuluaga, Henry Augusto Millán, Andres Flórez, Fredy Andrés Luna Vela, Juliana Villa
Fundación Cardioinfantil, Bogotá, Colombia

Introduction

Central diabetes insipidus is characterised by decreased vasopressin secretion, with partial deficiency, or in more severe cases, complete deficiency, leading to a hyperosmolar state and increased serum sodium. The diagnosis is based on a diuresis greater than 2 mL/kg/hour or more than 2.5–3 L in 24 hours and a urinary density <1.005. Adipsic diabetes insipidus is a variant in which, following osmoreceptor damage in the circumventricular region, patients lose their thirst mechanism and have an increased risk of complications due to hypernatraemia. Approximately 100 case reports have been presented in the literature.

Case description

24-year-old woman with a history of delayed puberty and hypothyroidism, but no prior study reports. She consulted due to a headache with warning signs associated with altered visual acuity. Brain MRI was performed which showed signs of a non-adenomatous lesion with suprasellar and hypothalamic extension. Following transcranial surgery, she developed diabetes insipidus criteria, with absence of thirst documented during the hospitalisation (Using a visual analogue scale of thirst). The histopathological findings confirmed the diagnosis of craniopharyngioma. The patient was treated with desmopressin and received recommendations regarding rehydration according to the quantification of losses, with electrolyte stabilisation.

Discussion

After the resection of craniopharyngioma the deficit of antidiuretic hormone can occur in 70-90%, however the mechanism of thirst prevails in most of them. Adipsic diabetes insipidus is an infrequent but highly complex disease; complications associated with esta enfermedad include hypernatraemia, venous thromboembolism and obstructive sleep apnoea. Treatment includes desmopressin therapy and patient education in order to maintain an adequate fluid intake.

#41 - Case Report

THYROTOXIC PERIODIC PARALYSIS-A RARE CAUSE OF HYPOKALAEMIA IN PREGNANCY

Érica Barata, Eliseu Ekundi, Ernesto Ulica, Naima Andrade, Gilda Mariano
Clinica Sagrada Esperança, Luanda, Angola

Introduction

The manifestations of hypokalaemia are usually evident throughout the etiological investigation of patients with a history of previous episodes of vomiting, diarrhea or use of diuretics. However, in some cases, the cause of hypokalaemia may prove to be a real challenge when multifactoriality is present.

Case description

A 26-year-old woman, G3P2, previously healthy 16-week pregnant, admitted for hyperemesis. Severe hypokalaemia was identified refractory to correction, palpitations, tachycardia and paresis of the lower and upper limbs. After clinical and laboratorial evaluation, thyrotoxic periodic paralysis was diagnosed, and the therapy with Methimazole and B-blocker was initiated.

Discussion

thyrotoxic periodic paralysis is a rare manifestation of hyperthyroidism. It is a diagnosis to be considered in patients with a history of hyperthyroidism and should also be excluded in patients with severe hypokalaemia refractory to correction. Its identification in pregnant women is rare, however early intervention, correct surveillance and adequate monitoring of the treatment allowed the continuity of pregnancy safely.

#43 - Case Report

HYPOTHYROIDISM AS CAUSE OF HEART FAILURE IN WOMEN WHO HAVE JUST GIVEN BIRTH : A CASE REPORT

Taís Mendes De Lima, Andressa Braga Barros, Giulia Dal-Cin Zanquetto
Federal Hospital of Andaraí, Rio De Janeiro, Brazil

Introduction

Heart failure has the least prevalent causes of hormonal changes related to pregnancy and after given birth. Hypothyroidism

presents complications with pericardial effusion being the most common.

Case description

A 25-year-old woman was referred to the hospital because precordial burning pain seven days ago, ventilator-dependent, without irradiation, continuous. She had no fever or signs of infection and she had given birth five months ago. An electrocardiogram showed sinus bradycardia, PR-segment depression in lead AVR, diffuse ST-segment elevation and T-wave inversion in the precordial leads. A moderate-sized pericardial effusion was seen on echocardiography. In the emergency department, his cardiac-enzyme levels were found to be normal. On echocardiography was seen increased left chambers with left ventricle systolic deficit and increased pericardial fluid. MRI there was no myocardial fibrosis, and the myocarditis hypothesis was declined. A laboratory panel was obtained which was significant for a thyroid stimulating hormone level of 150 mIU/mL and free T4 0.28 ng/dL, confirming the diagnosis of primary hypothyroidism, prompting initiation of levothyroxine. The patient was temporarily treated with ibuprofen and colchicine for pericarditis.

Discussion

Pericardial effusion is reported to occur in 30% to 80% of subjects with hypothyroidism. Thyroid hormones influence homeostasis, altering cardiac output, contractility and blood pressure. Pleural effusion in myxedema leads to restriction of ventricular filling and bradycardia, observed in T3 deficiency, decreasing cardiac output. The screening of pregnant with risk factors and the effective management of cardiac abnormalities aims to improve prognosis and survival.

#47 - Abstract

MANAGEMENT OF TYPE 2 DIABETES IN ELDERLY PATIENTS – 6 MONTHS STUDY IN GERONTOLOGY INSTITUTE

Lazo Jordanovski, Dima Ilievski, Despina Milosevska Evrushoska, Jovanka Jakimovska

PHI Specialized hospital for geriatric and palliative care 13 November, Skopje, Macedonia, Former Yugoslav Republic of

Background

With increasing lifespan of patients, the prevalence of diabetes mellitus is also increasing. The treatment of diabetes in the elderly should be individualized. Glycemic values depend on the risk factors of the individual, and are based on his overall health as well as the planned survival period.

Methods

We created a study in order to see which dual therapy will lead to best reduction in HbA1C values in elderly patients.

Results

100 elderly patients in the study divided in 5 groups each within 20 patients. Average age of the patients was 70.26 years and patients were previous treated with diabetes for 150.4 months. Average HbA1C at the beginning level was 8.24%. First group was treated with metformin and second generation sulfonylurea, second group metformin and DPP4 inhibitor, third group metformin and GLP-1 receptor agonist, fourth group only insulin and the last group metformin and insulin. After 6 months there was overall decreasing in HbA1C level in all groups (7.48%). In the first group decreasing was 0.34%, second 0.47%, third 0.66%, fourth 0.98% and last group 1.34%. 9 patients have hypoglycemic event, 13 patients have increased weight from the beginning, 28 patients have been hospitalized because of worsened health condition. Individually 13 patients after 6 months haven't decrease of HbA1C. These patients have several comorbidities.

Conclusion

Biggest reduction in HbA1C level is noticed when patients are using metformin and insulin therapy but care should be taken when titrating insulin therapy because hypoglycemia in elderly patients may be severe or unrecognized.

#72 - Abstract

RETROSPECTIVE ANALYSIS OF PATIENTS WITH GRAVES ORBITOPATHY TREATED BY PULSES OF METHYLPREDNISOLONE, WITH A FOCUS ON ADVERSE EVENTS

Jan Schovanek, Lubica Cibickova, Zdenek Frysak, David Karasek
Department of Internal Medicine III – Nephrology, Rheumatology, and Endocrinology, Faculty of Medicine and Dentistry, Palacky University Olomouc and University Hospital Olomouc, Olomouc, Czech Republic

Background

Graves orbitopathy (GO) is an extra-thyroidal manifestation of autoimmune thyroid disease. Early treatment with glucocorticoids in appropriately selected patients is recommended for active, moderate to severe, and sight-threatening disease. The recently published European Group on Graves Orbitopathy guidelines re-evaluated the recommended doses of intravenous methylprednisolone (ivMP) in response to the potential for adverse effects. We retrospectively reviewed our patient cohort treated with our ivMP protocol and analyzed the side effects of this treatment when given during hospitalization in our tertiary referral center.

Methods

Between May 2007 and May 2017, a total of 171 consecutive patients with active, moderate to severe, or sight-threatening GO were treated with ivMP in a cumulative dose of 7.5 grams, given monthly in three hospital sessions. Adverse events were reported using Version 4 of Common Terminology Criteria for Adverse Events.

Results

Ninety-two percent of patients who started the treatment were able to finish it; 5% did not finish the study due to adverse events, and 3% did not finish the treatment protocol because of noncompliance. The most common adverse events were asymptomatic changes in laboratory values (liver enzymes), psychiatric disorders, and infectious complications. None of the patients in the study died during the ivMP treatment, including those patients who experienced adverse effects or discontinued the protocol because of noncompliance.

Conclusion

High-dose ivMP for active, moderate to severe, and sight-threatening GO, when applied cautiously in carefully selected and monitored patients, is generally safe during the treatment period.

This study was supported by the Ministry of Health, Czech Republic—Conceptual Development of Research Organization (FNOL, 00098892).

#88 - Abstract

OUTCOMES OF HOSPITALIZED PATIENTS WITH GLUCOCORTICOID-INDUCED HYPERGLYCEMIA

Neele Delfs, Sandra Gafner, Thaddäus Muri, Ciril Bächli, Philipp Schütz, Claudine Blum

Medical University Clinic Kantonsspital Aarau, Aarau, Switzerland

Background

Glucocorticoid-induced hyperglycemia is a frequent side effect in hospitalized patients. Guidelines recommend treat-to-target treatment of glucocorticoid-induced hyperglycemia between 6–10 mmol/l with insulin, but patient-specific outcome has not been well-studied.

Methods

In this retrospective data analysis, all patient records of a Medical University Clinic from January 2014 to April 2018 were screened for glucocorticoid administration. We investigated the incidence of hyperglycemia in hospitalized patients after administration of at least 10 mg prednisolone equivalents daily for at least 3 days. Mortality, cardiovascular events, and infections until 30 days after discharge in patients with or without hyperglycemia were evaluated.

Results

2424 hospitalized patients received systemic glucocorticoids. 623 patients (26%) developed fasting hyperglycemia, and 656 (27%) postprandial hyperglycemia. Glucocorticoid-induced hyperglycemia therefore had an incidence of 34% (812 patients). 511 patients (21%) had a previous diabetes diagnosis. In-hospital hypoglycemia was documented in 45 (1.9%) patients. In-hospital mortality was 46 (2.9%) in patients without

hyperglycemia and 32 (3.9%) in patients with hyperglycemia (OR 1.37 (0.85–2.15), $p=0.18$). Mortality until 30 days after admission was 121 (7.5%) in patients without hyperglycemia, and 70 (8.6%) with hyperglycemia (OR 1.162 (0.85–1.58), $p=0.34$). Cardiovascular events during hospitalization occurred in 155 (9.6%) in patients without hyperglycemia, and 112 (13.8%) in patients with hyperglycemia (OR 1.5 (1.16–1.95), $p=0.002$).

The combined endpoint death, cardiovascular and infections event at day 30 after admission was reached in 584 (25%) patients without hyperglycemia and 372 (16%) with hyperglycemia (OR 0.57 (0.49–0.66), $p<0.0001$).

Infections during hospitalization occurred in 263 (16%) patients without hyperglycemia, and in 170 (21%) patients with hyperglycemia (OR 1.35 (1.09–1.68), $p=0.059$).

Conclusion

Mortality, cardiovascular events and rate of infections were higher in patients with glucocorticoid-induced hyperglycemia than in normoglycemic patients. Rate of in-hospital hypoglycemia rate was low. Whether the treatment of glucocorticoid-induced hyperglycemia has an effect on outcome remains to be shown.

#101 - Abstract

FOUR DECADES WITHOUT DIAGNOSIS: SHEEHAN'S SYNDROME, A RETROSPECTIVE ANALYSIS

Gulistan Alpagat¹, Deniz Gokalp²

¹ Inegol Country Hospital, Bursa, Turkey

² Acibadem University, Eskisehir, Turkey

Background

Sheehan's syndrome (SS) remains a frequent cause of hypopituitarism in undeveloped and developing countries, but due to improvements in obstetric care, it is rare in developed countries. We aimed to retrospectively evaluate the characteristic of SS patients who were diagnosed in our clinic.

Methods

The medical records of 124 patients with SS patients who were followed up in the Endocrinology Department of Dicle University between 1995 and 2015 were assessed retrospectively.

Results

The mean period of diagnostic delay was 20.37 ± 8.34 years on average. 5.7% of patients with SS were literate; 62% of patients delivered at home. Anemia was identified in 64.5% of SS patients. 25 (23.3%) had partially empty sella, and 1 patient had microadenoma and 2 had normal pituitary MRI urgently required to avoid the associated morbidity and mortality.

Mean blood sodium levels were 129.8 ± 11.3 mEq/L. The mean urine densities was 1013 ± 6.5 . Osteoporosis and osteopenia were found in 44 (35.4%) and 71 (57.2%) patients, respectively. According to pituitary MRI analyses, 92 (74.2%) patients with

SS had completely empty sella, (23.3 %) had partially empty sella, and 1 patient had microadenoma and 2 had normal pituitary MRI results.

Conclusion

Improved obstetric care and effective interventions for postpartum hemorrhage have limited the prevalence of SS in developed countries. However, in developing countries like Turkey, SS due to postpartum bleeding remains common. Thus, physician's awareness of the symptoms of SS is urgently required to avoid the associated morbidity and mortality.

#113 - Abstract

RELATIONSHIP OF LEFT VENTRICULAR HYPERTROPHY AND INFLAMMATION IN TYPE 2 DIABETES

Ergita Nelaj, Margarita Gjata, Irida Kecaj, Mihal Tase
University Hospital Center, Tirana, Albania

Background

Type 2 diabetes is associated with accelerated atherosclerosis and increased cardiovascular event rates. The association between diabetes and adverse cardiovascular outcome may be partially explained by the strong independent association of type 2 diabetes with cardiovascular target organ damage, such as left ventricular hypertrophy (LVH), a well-known predictor of cardiovascular events independent of coronary artery disease. We recently reported an independent association of LVH with an elevated fibrinogen level. Inflammation, and in particular elevated fibrinogen, is associated with the development of atherosclerosis and consequent vascular events.

The aim of the present study is to evaluate the relation of LVH to fibrinogen and C-reactive protein (CRP) as markers of inflammation and susceptibility to atherothrombosis.

Methods

We selected 50 adults with type 2 diabetes. 32 were women and 18 were men, mean age 51±14).

Left ventricular (LV) dilatation was determined as cavity volume > 90 ml/m². LV hypertrophy (LVH) was determined by mass index > 110 g/m² in females and > 131 g/m² in males. Concentric LVH (LVHc) has been determined as hypertrophy with normal cavity volume.

Eccentric LVH (LVHe) has been determined as hypertrophy with LV dilatation.

Participant's laboratory data were examined in the morning after an overnight fast 12 h. The levels of CRP and fibrinogen have been measured.

Results

From 50 participants, 22 (44%) presented LVH, which was associated with higher BMI and CRP, fibrinogen levels. Patients with concentric LVH had level of fibrinogen 444±100 mg/dl (P<0.001)

and CRP 15 ± 9 mg/dl (P=0.005), and patients with normal LV mass had fibrinogen 360 ± 66 mg/dl and CRP 6,5 ± 9.0 mg/dl.

Conclusion

The results of the ultrasound heart examinations show: 22 patients presented concentric LVH, 10 patients eccentric LVH, and 18 patients normal LV mass.

Concentric LVH was associated with elevated markers of systemic inflammation and susceptibility to atherothrombosis (CRP and fibrinogen levels) independently of clinically overt cardiovascular disease and traditional cardiovascular risk factors. No correlation was found between CRP and fibrinogen and eccentric LVH.

WHAT A STORM!

Iolanda Oliveira, Sofia Calaça, Mariana Soares, Andreia Bernardino, Francisco Azevedo
Hospital Espírito Santo - Évora, Évora, Portugal

Introduction

Thyroid storm represents a state of thyrotoxicosis that is an endocrine emergency. It is rare, but it is associated with high mortality. It is manifested by the decompensation of various organs and the onset of fever is universal. It is important to investigate the precipitating cause and correct it. The treatment besides support, consists in the reduction of thyroid hormone synthesis and its peripheral effects.

Case description

Female, 84 years old, caucasian, with atrial fibrillation, hypertension, goiter with colloid nodule, and total bilateral knee prosthesis, medicated with diltiazem 60 mg tid, carvedilol 6.25mg bid, apixaban 2.5mg bid and pantoprazole 20mg qd, without known allergies, was admitted in emergency department for dyspnea for small efforts with 2 weeks of evolution, pain in the bilateral neck region with irradiation to the shoulders, intensity 5/10 without relieving or aggravating factors. On observation: BP 198/121 mmHg, HR 145 bpm. EKG: AF with rapid ventricular response. After amiodarone impregnation, she presented sudden dyspnea, exuberant bronchospasm, poor peripheral perfusion, hypertensive peak with SBP 200mmHg and fever of 39°C. Analyses: immeasurable TSH and fT4 1.887 ng/dL. Thyroid storm was admitted, medicated with Hydrocortisone, Propranolol and Propylthiouracil. During the hospital stay she underwent thyroid ultrasound: multiple nodules without suspicious characteristics. She was medicated with 7 day antibiotic course with Ceftriaxone for respiratory tract infection and was discharged 7 days later. Analysis: TSH 0.009 µUI/mL, fT4 3.691 ng/dL, fT3 2.8 pg/mL, medicated for outpatient with Propranolol 40mg qid, Thiamazol 15 mg tid, with scheduled Internal Medicine consultation.

Discussion

Thyroid storm can be precipitated by several factors, like infection,

pregnancy, myocardial infarction or, like in this case, with iodine drugs use such as amiodarone. Prompt recognition is crucial for the patient's therapeutic success and prognosis. In this case, symptomatic control was achieved by using drugs which inhibited hormone synthesis and its peripheral effects.

#148 - Abstract

CLINICAL PROFILE OF DIABETIC PATIENTS WITH HEART FAILURE IN A COUNTY HOSPITAL

Julio Osuna Sánchez¹, Antonio Ubiña Carbonero²

¹ Hospital Comarcal Melilla, Melilla, Spain

² Centro Salud San Andres-Torcal, Málaga, Spain

Background

Carry out a retrospective descriptive study of diabetic patients admitted for heart failure in the Internal Medicine service of our hospital during 2017.

Methods

This is a transversal descriptive analysis of patients admitted to internal medicine for heart failure in 2017 who were diabetic. A detailed study was carried out of all the risk factors presented by patients, the associated comorbidities, as well as personal history. We have analyzed the release reports of our service along with the review of medical records. A descriptive study of the characteristics of patients using frequency measurements has been carried out, analysing the type of sample to see whether or not they remained normal.

Results

There were a total of 120 patients admitted for heart failure, of which 45.8% were diabetics. The average age was 77.47±9.17 years. 9.1% of patients were institutionalized, 18.2% were dependent for all basic activities of daily life. 52.7% were Caucasians and 47.3% Berber. 83.6% had social security. Regarding personal history: 32.7% prior ischemic heart disease; 83.6% HBP; 34.5% A-fib; 9.1% COPD; 38.2% dyslipidemia; 10.9% sleep apnea; 12.7% anemia; prior stroke 10.9% and 10.9% neoplasia (active or not). The most frequent causes of admission were the ischemic cause with 42.9% and valvulopathy with 32.1%. As an important finding 9.1% of patients had cognitive impairment to some degree. 92.7% of patients had 2 or more pathologies at the time of admission. The most frequent medication prescribed was metformin with a DPP-4i (41.2%), followed by metformin (17.6%). 40% patients were treated with insulin. The average stay of the hospital admission was 9.38±7.043 days, being exitus 12.7% of the patients.

Conclusion

Heart failure (HF) is a problem for both public health and the doctor who must face it daily. Once diagnosed, the prognosis becomes ominous as approximately 50% of patients die within the next 5

years. Early diagnosis and treatment of HF is important to prevent its complications, slow its evolution, decrease its symptoms and avoid the need for hospitalizations once the diagnosis is confirmed. This situation gets worse when as a comorbidity we add DM, making it harder to manage and the morbidity and mortality is higher. Patients admitted for acute HF with diabetes mellitus have a pluripatological profile with multiple added diseases which makes them patients with more complicated management in the plant and to whom we should perform a closer follow-up due to higher mortality rate.

#160 - Case Report

AMIODARONE-INDUCED HYPERTHYROIDISM: THE ENDOCRINOLOGIST'S PERSPECTIVE OF A CLINICAL CASE

Patrícia Rosinha, Rosa Dantas, Teresa Azevedo, Isabel Inácio, Sara Esteves Ferreira, Joana Guimarães

Endocrinology Department, Baixo Vouga Hospital Center, Aveiro, Portugal

Introduction

The diagnosis, classification and follow-up of amiodarone-induced thyrotoxicosis (AIT) are challenging. The risk of cardiac injury imposes the need for rapid control of thyrotoxicosis, which might require not only pharmacological therapy but also an emergent thyroidectomy.

Case description

A 67-year-old male with history of hypertension and previous episode of atrial flutter with rapid ventricular response, submitted to electrical external cardioversion (EEC) in 2015, on treatment with rivaroxaban 20 mg/day and amiodarone 200 mg 5 days/week, presented to the Emergency Department on 16th August 2017 complaining of dyspnea for the last 3 weeks. At admission, the EKG showed atrial fibrillation (150-160 beats/min). He underwent chemical cardioversion with amiodarone, unsuccessful, and so EEC was performed and the patient was discharged. A few hours later, he returned with dyspnea, fever (38,8 degrees C), and was admitted with the diagnosis of pneumonia with pleural effusion. Diagnostic thoracocentesis revealed transudate, after which he was transferred to Cardiology. Initial evaluation revealed hyperthyroidism (TSH<0.01 mU/L; FT4 6.19 ng/dL), negative thyroid antibodies and a diffusely heterogeneous thyroid without nodules on ultrasound. Methimazole 5mg and prednisolone 40 mg were initiated with analytical improvement (FT3 3,0nmol/L; T4 4.92ng/dL). Two days later, a new episode of tachycardia and hypertension lead to the reintroduction of amiodarone, with repercussion on thyroid function (TSH <0.01 mU/L; FT4 6.65 ng/dL). Amiodarone was only temporarily withdrawn, due to the difficulty in controlling heart rate. The drug was definitely dropped on 28th August, in face of the worsening of the hyperthyroidism and unresponsiveness to the medical treatment with prednisolone 80 mg/day and methimazole 60 mg/day. Attending to the difficulty

in controlling heart rate (patient already under verapamil 240 mg, bisoprolol 20 mg, digoxin 250 µg daily) and the occurrence of life-threatening arrhythmias, the medical team decided for total thyroidectomy after EEC, performed on 29th September, with cardiac improvement and rapid control of thyroid function. He was discharged under levothyroxine 100 µg, bisoprolol 2.5mg and weaning doses of prednisolone.

Discussion

Due to the difficulty in classifying the type of thyrotoxicosis and deciding which patients should suspend amiodarone therapy, a successful treatment depends on a multidisciplinary approach for these patients.

#163 - Abstract

EFFICIENCY OF ASPIRATIVE CYTOLOGY OF THYROID IN A DISTRICT HOSPITAL: 2014-2017

Sócrates Vargas Naranjo, Rúben Raimundo, José Miguel Silva, Adriano Pacheco, Ana Bela Mateus, Isabel Soles
Hospital Dr. José Maria Grande, Portalegre, Portugal

Background

The thyroid nodules are common as 5% -10% of adult population. The aspiration cytology by fine needle (FNA), can identify 50% or more, of malignant nodules, having positive (VPP) and negative (VPN) values higher than 90%; However, around 35% do not present a definitive diagnosis, so that, we want to validate the effectiveness of FNA to identify malignant thyroid nodules.

Methods

We conducted a cross-section study, in which patients submitted to thyroidectomy were identified between 2014 and 2017. A subsequent observation of FNA and histological results was made. The variables analyzed were sex, age, ultrasound characteristics, cytological and histological diagnosis. SPSS 20.0 was used for statistical analysis. With statistical description, central and dispersion measures were calculated; by Bayes' theorem to identify Sensitivity (Se), Specificity (Sp), VPP and VPN and Efficiency (Ef) for the FNA; The statistical significance used was 0.05.

Results

Identification of 55 patients with thyroidectomy, but 71.0% (n=39) of them had FNA and biopsy results. We observed mostly women (n=37, 94.9%); the average age was 54.2 years (men 48.5 and women 54.5, alpha = 0.419), parameter 32-71 years. TI-RADS scale was not used, despite it, we observed that 66.7% of the ultrasounds had 2 or more nodules and 17.9% of adenopathies. The malignant samples were observed in 7.7% (n=3) with FNA and 10.3% (n=4) with histological samples. FNA showed Se=50.0%, Sp=96.7%, PPV = 66.7%, NPV=93.5% and Ef=91.2%.

Conclusion

In our hospital, the FNA results were within values from other studies, yet, although FNA shown good efficacy, the low VPP can be influenced by the little sample the was used. Is important that TI-RADS scale was not used, because it is a problem if we try to comparisons with others studies.

#196 - Case Report

A CASE OF B12 DEFICIENCY POLYNEUROPATHY IN A DIABETIC YOUNG ADULT

Adriana Bandeira, Diana Castro, Behnam Moradi, Alcina Ponte
Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

Vitamin B12 is an essential dietary nutrient and plays a fundamental part in hematopoiesis and in the maintenance of the integrity of the nervous system. Below we report a case of B12 malabsorption due to intrinsic factor deficiency presenting as polyneuropathy and bicytopenia in a young adult with a diabetes diagnosis of unclear etiology.

Case description

A 44-year-old male patient, with recently diagnosed diabetes with poor metabolic control despite a daily cumulative dose of 40 U aspart insulin, is referred to the hospital due to a 2 months history of insidious onset paresthesias, starting at the soles of the feet ascending to the inguinal region. When questioned patient mentioned transient complaints of nocturnal paresthesias at the hand level, dysesthesia and proprioceptive changes in both feet. In addition, he describes episodes of spontaneous bladder incontinence and constipation. No complaints of dysphagia, no other relevant history. Physical exam revealed pale, mildly icteric and malnourished patient, grade 3 distal muscle strength, errors in the positioning of both hallux and ataxic gait, of right predominance. Initial blood work revealed bicytopenia with erythrocyte macrocytosis and anisopoikilocytosis, platelet anisocytosis, elevated LDH and bilirubin with a negative DAT and IAT. Of the tests conducted we highlight: severe vitamin B12 deficiency and positive IF antibodies suggesting pernicious anemia as well as positive GAD antibodies and so LADA was inferred. MRI showed T2 and STIR hypersignal extending from C1 to D11, with greater expression in the dorsal segment and no spinal expansion or signal enhancement after gadolinium; normal EMG. Upper endoscopy revealed an atrophic and micronodular gastric mucosa, histologically compatible with chronic gastritis with lymphocytic infiltrate, negative H.pylori. The patient was treated with a course of intramuscular injections of cyanocobalamin followed by oral supplementation and adjustment of the insulin therapy.

Discussion

In this case, the implementation of the B12 supplementation followed by clinical improvement excludes diabetic neuropathy

as a probable cause of patient symptoms. Pernicious anemia is estimated to be more frequent in patients with diabetes, whether due to the use of metformin in T2DM, or, in this case (LADA/T1DM) due to the common presence of IF antibodies in patients with positive GAD antibodies - the latter leading to an association of autoimmune conditions and development of autoimmune polyglandular syndromes.

#200 - Abstract

DEVELOPMENT AND MULTI-COHORT VALIDATION OF A CLINICAL SCORE FOR PREDICTING TYPE 2 DIABETES MELLITUS

Vanessa Kraege¹, Marie Mean¹, Stephen Sharp², Maite Vallejo³, Masoud Mirzaei⁴, Pedro Marques-Vidal¹

1. Department of Medicine, Internal Medicine, Lausanne University Hospital, Lausanne, Switzerland
2. MRC Epidemiology Unit, University of Cambridge School of Clinical Medicine, Box 285 Institute of Metabolic Science, Cambridge Biomedical Campus, Cambridge, United Kingdom
3. Tlalpan 2020 Study, Department of Socio-Medical Research, National Institute of Cardiology, Ignacio Chávez, Mexico City, Mexico
4. Shahid Sadoughi University of Medical Sciences, Yazd, Iran

Background

Many countries lack resources to identify people at risk of developing Type 2 diabetes mellitus (diabetes). We aimed to develop and validate a diabetes risk score based on easily accessible clinical data.

Methods

Prospective study including 5277 participants (55.0% women, 51.8±10.5 years) free of diabetes at baseline. The selection of the variables to be included in the score was performed using logistic regression, and scoring was based on the multivariable-adjusted odds ratio for each variable. To facilitate scoring, categories were preferred to continuous data. Comparison with two other published diabetes risk scores (the first with five and the second with eight clinical variables) and validation on three cohorts: Europe (n=61,595), Iran (n=9975) and Mexico (n=1203) was performed.

Results

After a mean follow-up of 10.9 years, 405 participants (7.7%) developed diabetes. Our score was based on age, gender, waist circumference, diabetes family history, hypertension and physical activity. The area under the curve (AUC) and corresponding 95% confidence interval (95% CI) was 0.772 (0.750-0.794) for our score, vs. 0.748 (0.726-0.770) (p<0.001) and 0.774 (0.753-0.796) (p=0.668) for the other two. Using a 13-point threshold, sensitivity, specificity, positive and negative predictive values (95% CI) of our score were 60.5 (55.5-65.3), 77.1 (75.8-78.2), 18.0 (16.0-20.1) and 95.9 (95.2-96.5) percent, respectively. The number needed to screen to detect one case of diabetes was 22 for our score vs. 129

for the first score and 20 for the second. Despite differences in the definition of some variables such as physical activity, our score performed equally well or better than the other two in the Iranian [AUC 0.542 vs. 0.564 (p=0.476) and 0.513 (p=0.300)] and Mexican [AUC 0.791 vs. 0.672 (p<0.001) and 0.778 (p=0.575)] cohorts. In the European cohort, it performed similarly to the first score but worse than the second [AUC 0.788 vs. 0.793 (p=0.091) and 0.816 (p<0.001)].

Conclusion

Our clinically-based score shows encouraging results compared to other scores and can be used in populations with differing diabetes prevalence.

#202 - Abstract

EVALUATION OF CARDIOVASCULAR RISK WITH ARTERIAL STIFFNESS IN PATIENTS WITH NON-FUNCTIONING PITUITARY ADENOMA

Yavuz Çağır¹, Mustafa Altay², Büsra Betül Çağır³, Erman Çakal⁴, Tolga Akkan⁵, Canan Yıldız⁵

1. Çankiri Çerkes State Hospital, Çankiri, Turkey
2. Sağlık Bilimleri Üniversitesi (University of Health Sciences) Keçiören SUAM, Department of Endocrinology and Metabolism, Ankara, Turkey
3. Sağlık Bilimleri Üniversitesi (University of Health Sciences) Diskapi Yildirim Beyazit SUAM, Department of Internal Medicine, Ankara, Turkey
4. Sağlık Bilimleri Üniversitesi (University of Health Sciences) Diskapi Yildirim Beyazit SUAM, Department of Endocrinology and Metabolism, Ankara, Turkey
5. Sağlık Bilimleri Üniversitesi (University of Health Sciences) Keçiören SUAM, Department of Internal Medicine, Ankara, Turkey

Background

Nonfunctioning pituitary adenoma (NFPA) accounts for 30% of all pituitary adenomas, and its incidence has been increasing compared to previous years. Increased risk of cardiovascular effects shown in recent studies is noteworthy in patients with NFPA diagnosis, but the number of studies on the subject is limited. In this study, we aimed to assess possible cardiovascular effects and risk via arterial stiffness measurements in patients diagnosed with NFPA.

Methods

We performed arterial stiffness measurements for 30 patients diagnosed with NFPA and 30 healthy volunteers and compared the results to explore the relationship between arterial stiffness parameters, hormone levels, and adenoma size.

Results

Systolic blood pressure (SBP), diastolic blood pressure (DBP), mean blood pressure (MBP), central SBP, central DBP, augmentation index corrected for a heart rate of 75 beats per minute (AIx@75),

and pulse wave velocity (PWV) values of the patients with NFPA diagnosis were significantly higher than the control group. PWV was found to have a significant and negative correlation with growth hormone and insulin-like growth factor 1 (IGF-1). A significant and positive correlation was found between adenoma median short-axis length and PWV. IGF-1 was found to have a significant and negative correlation with adenoma median long- and short-axis length. In multivariate linear regression analysis, we found that IGF-1 was an independent predictor of PWV.

Conclusion

Both arterial stiffness parameters such as $Alx@75$ and PWV and peripheral SBP, DBP, and MBP values were found to be high in NFPA patients with no cardiovascular risk factors. Our findings suggest increased cardiovascular effect and risk in patients with NFPA diagnosis, and therefore, we recommend that patients are monitored closely in this respect.

#212 - Abstract

VISCERAL FAT ACCUMULATION IN MALE PATIENTS WITH TYPE 2 DIABETES AND HEART FAILURE

Eva Hoskova, Jan Kopecky, Jiri Veleba, Katerina Velebova, Vojtech Melenovsky, Terezie Pelikanova

Institute for Clinical and Experimental Medicine, Prague, Czech Republic

Background

Metabolic effect of visceral fat accumulation is connected with insulin resistance and type 2 diabetes (T2D) with its complications. Specifically android type of body fat accumulation is associated with high cardio-metabolic risk. Our aim was to evaluate the associations between the location of fat accumulation, heart failure (HF) and T2D.

Methods

A cross-sectional comparative trial with 53 male subjects in 4 age and BMI matched groups - 10 patients with HF without diabetes (HF+T2D-), 11 patients with diabetes alone (HF-T2D+), 19 patients with type 2 diabetes or prediabetes and heart failure (HF+T2D+) and 13 healthy subjects without metabolic syndrome (HF-T2D-). The patients underwent number of laboratory tests including lipid profile, insulin sensitivity measured as metabolic clearance rate of glucose (MCG) during a hyperinsulinemic isoglycemic clamp, and dual-energy X-ray absorptiometry (DEXA) using a GE Lunar Prodigy.

Results

MCG was lower in the groups of patients with T2D compared to HF-T2D- ($p=0.01$), while HF did not affect MCG significantly (HF-T2D-: 5.79 ± 2.3 ; HF+T2D-: 5.99 ± 2.48 ; HF-T2D+: 3.4 ± 1.57 ; HF+T2D+: 3.73 ± 1.71 ml/kg.min). Despite there was the significant negative correlation between MCG and percentage of android fat in the whole group ($r=-0.49$; $p<0.001$), we did not found any

difference in android/gynoid fat percent ratio between the groups (HF-T2D-: 1.34 ± 0.11 ; HF+T2D-: 1.3 ± 0.15 ; HF-T2D+: 1.36 ± 0.15 ; HF+T2D+: 1.32 ± 0.2).

Conclusion

Insulin sensitivity was significantly affected by type 2 diabetes, but not by heart failure. Diabetes or heart failure did not significantly alter the body fat distribution in our carefully selected BMI and age matched groups.

#277 - Abstract

STUDY OF CUTANEOUS SURROGATE OF VISCERAL ADIPOSITY AMONG INDIAN PHENOTYPE

Ananda Mohan Chakraborty, Soumitra Ghosh, Srabani Ghosh
IPGMR, Kolkata, India

Background

Appraisal of certain cutaneous markers may lead clinician to ascertain underlying pathology well before its clinical manifestation. Obesity and consequent insulin resistance and dyslipidaemia may lead to cutaneous manifestations like Acanthosis nigricans (AN) and xanthelasma. Visceral adiposity viz Hepatic steatosis, epicardial adipose tissue, are the major determinants of organ dysfunction. Objective of the present study is to study the association between AN, xanthelasma and cutaneous adiposity with visceral adiposity.

Methods

A cross-sectional observational study was conducted among overweight and obese patients determined by South East Asian BMI criteria. Visceral fat was determined by impedance body composition measurement, presence of hepatic steatosis, and Epicardial adipose tissue thickness (EAT). Acanthosis nigricans, xanthelasma, subcutaneous fat, and region-specific fat thickness was considered as cutaneous surrogate of adiposity.

Results

Among 149 patients studied, 28% had AN, 21% had Xanthelasma, 77% had hepatic steatosis and 78 % had excess visceral fat. Mean EAT was 6.12 mm (SD: 1.830). Subcutaneous fat had statistically significant relation with visceral fat (Chi-squared (trend) 12.460; $P=0.0004$) but not with EAT ($P=0.2172$) and presence of hepatic steatosis (Chi-squared (trend) 1.809; $P=0.1786$). Both the cutaneous surrogate had statistically significant association with Visceral fat percentage (two tailed t test, $P<0.0001$) and EAT (two tailed t test, $P<0.0001$). Among all the regional distribution of fat, only subscapular ($P=0.032$) and supra-iliac fat ($P=0.034$) had statistically significant relation with EAT.

Conclusion

Cutaneous surrogate like AN and Xanthelasma was a predictor of

visceral adiposity in this study. Among regional distribution of fat instead of waist circumference and waist hip ratio, subscapular and supra-iliac fat was related with EAT. Study of cutaneous surrogate like AN and xanthelasma, skinfold thickness can predict visceral adiposity early which is of immense importance in resource poor country like India.

FAHR SYNDROME: CASE REPORT

Raquel Costa, João Costelha, Tiago Mendes, Joana Fontes, Marta Matos Pereira, Vitor Costa, Manuel Barbosa, Elsa Araújo, Joana Serôdio, Liliana Costa

ULSAM - Hospital Conde de Bertandos, Ponte De Lima, Portugal

Introduction

Fahr syndrome is a rare, chronic disease characterized by bilateral and extensive deposition of calcium in the basal ganglia, thalamus, cerebral cortex, cerebellum and hippocampus, and neuropsychiatric manifestations. The most common metabolic cause of Fahr syndrome is hypoparathyroidism.

Case description

66-year-old woman with history of hypertension and dyslipidemia. The patient presented to the Emergency Department (EM) because of intense holocranial headache and nausea. Referring also paresthesias of the hands and feet with several months of evolution, mnesic changes and periods of uninhibited behavior. In the EM, the patient had a generalized convulsive crisis, being medicated with levetiracetam (1000 mg/day). She performed a cranioencephalic tomography that showed "calcifications of the basal ganglia, cerebellum and frontal region, extensive and bilateral". In the analytical study, severe hypocalcemia was detected and electrocardiographic alterations were also observed, with prolongation of the QT interval. She began calcium replacement, and there was normalization of electrocardiographic changes.

During hospitalization, the patient was diagnosed with primary hypoparathyroidism as the cause of hypocalcemia. Electroencephalogram confirmed the diagnosis of epilepsy. Thyroid and parathyroid ultrasonography were normal. She was discharged for the consultation of Internal Medicine and Endocrinology for the etiological study of hypoparathyroidism. The patient had a favorable evolution and no new seizures in the last year.

Discussion

Fahr syndrome, although rare, should incorporate the list of differential diagnoses of neuropsychiatric disorders and epileptic seizures. The calcifications of the basal ganglia, despite being a suggestive finding of an evolved disease, may be an imaginative finding of enormous value since they can immediately guide the diagnosis and allow rapid treatment of hypocalcemia and hypoparathyroidism.

#292 - Case Report

A CASE OF AUTOIMMUNE ADDISON'S DISEASE: THE IMPORTANCE OF EARLY DIAGNOSIS.

Elisa Martinelli

AOU Careggi (University Hospital Careggi), Florence, Italy

Introduction

the most common form of adrenal insufficiency is autoimmune adrenalitis. It is, more often than not, associated with other autoimmune disorders, such as Hashimoto thyroiditis, Graves' disease or celiac disease.

The autoimmune destruction of the adrenal gland is usually a slow process that develops over many years and by the time the patient develops low serum cortisol levels (necessary for the diagnoses) adrenal destruction is essentially complete. Nevertheless several symptoms can occur early on in the disease and Addison's should always be taken in to consideration while working on the differential diagnosis in patients presenting fatigue, weight loss and gastrointestinal complaints, depression and electrolyte disorders (specifically hyperkalaemia and hyponatremia). A failure to recognize the disease can lead to devastating consequences, such as shock and coma, two possible outcomes of an adrenal crisis.

Case description

a 63 year old woman, with a history of Hashimoto disease, diabetes, psoriasis and asthma was admitted to the ER lamenting nausea, fatigue and anorexia. Her blood test showed severe hyperkalaemia, hyponatremia and metabolic acidosis. The patient had been admitted to the ER 4 times over the previous year, each time presenting the same signs and symptoms. Upon her arrival the patient was hypotensive. She manifested a lack of initiative and apathy and presented hyperpigmentation of the back and legs. Given that her clinical picture was highly suggestive of adrenal insufficiency her morning cortisol (76,2 nmol/L at 08:00 am) and ACTH (539,50 ng/L) were measured and tested for antiadrenal antibodies which resulted positive. To further confirm our diagnosis, once the patient started specific treatment with hydrocortisone not only was there a normalization of the vital parameters and electrolytes, but also an improvement of her mood and initiative. The patient was discharged with the diagnoses of Addison's disease over a year from the first appearance of the symptoms.

Discussion

because of the nonspecific early signs and symptoms, chronic adrenal insufficiency can often be overlooked. Taking into consideration that this disease can be easily diagnosed and treated, but can also be potentially lethal if unrecognized, a rapid and correct interpretation of the clinical manifestations is fundamental to achieve the best possible outcome for the patient, by improving quality of life and reducing hospitalization.

#296 - Case Report

HASHIMOTO'S THYROIDITIS: A RARE AND SEVERE CLINICAL PRESENTATION

Filipe J. Machado, Rita Maciel

Centro Hospitalar Entre Douro e Vouga, Santa Maria Da Feira, Portugal

Introduction

Hashimoto thyroiditis is a chronic autoimmune thyroiditis that constitutes a major cause of acquired primary hypothyroidism. The clinical onset usually develops insidiously however, very uncommonly, severe untreated hypothyroidism may present with a myriad of simultaneous characteristic signs and symptoms, some of them extremely rare that urge attempted diagnosis and treatment.

Case description

We reported a case of a 68-year-old woman that was conducted to the emergency department with decreased mental status and facial oedema with periorbital swelling. On physical examination she was bradycardic and hypothermic. Facial oedema was confirmed and other fans and skin changes noticed. An hemogram and metabolic panel reported a pancytopenia (with normocytic normochromic anemia), creatinine kinase elevation, hyponatremia and hypercholesterolemia. Thyroid function tests were consistent with primary hypothyroidism and it was presenting with myxedema and myxedema coma. Intravenous levothyroxine replacement therapy was started. Thyroid ultrasound performed revealed signs supporting a thyroiditis process, with diffuse parenchymal heterogeneity, and thyroid peroxidase antibodies analysis was 411.31 UI/mL. It was established the diagnosis of Hashimoto's thyroiditis, the most common cause of primary hypothyroidism, with a rare exuberant clinical presentation.

Discussion

Primary hypothyroidism accounts for more than 95% cases of hypothyroidism and Hashimoto's thyroiditis accounts for the most common cause. The clinical manifestations of hypothyroidism are highly variable, depending upon the age at onset, duration and severity of thyroid hormone deficiency but usually develops insidiously. Our case report presents a rare exuberant presentation of hypothyroidism, with a myriad of clinical pearls that are rare and severe, such as myxedema and myxedema coma. The authors pretended to raise attention to the clinical manifestations of hypothyroidism so that clinicians can diagnose it timely and initiate treatment immediately.

#302 - Case Report

FROM VERTIGO TO CONN'S SYNDROME: ABOUT A CLINICAL CASE

Ana Correia De Sá, Ana Cerqueira, Liliana Oliveira, Rui Fernandes, Jorge Cotter

Hospital da Senhora da Oliveira, Guimarães, Portugal

Introduction

Conn's syndrome, also known as primary aldosteronism (PA), has been reported in >5-10% of hypertensive patients, englobing a group of disorders in which aldosterone production is inappropriately high for sodium status. It is relatively autonomous from the major regulators of secretion and thus, non-suppressible by sodium loading. This causes hypertension, cardiovascular damage, sodium retention, suppression of plasma renin and increased potassium excretion. Only a minority of patients with PA presents with hypokalemia. Hypertension and spontaneous or diuretic-induced hypokalemia is one of the cases when it is recommended to measure the plasma aldosterone/renin ratio (ARR). Moreover, all patients with PA should undergo adrenal computed tomography to exclude carcinoma. Unilateral laparoscopic adrenalectomy is recommended for patients diagnosed with unilateral PA.

Case description

A 60-year-old male was admitted for dizziness and vertigo, with imagiologic documentation of stroke in the posterior cerebral fossa (Oxford Stroke Classification – POCI; TOAST Classification -Small-vessel occlusion). He had a medical history of poorly controlled arterial hypertension under antihypertensive therapy (a beta receptor antagonist, a angiotensin receptor blocker, a calcium channel blocker and mineralocorticoid receptor antagonist) and occurrence of stroke at the age of 51 years. During his hospitalization he maintained a poorly controlled blood pressure and hypokalemia (initially of 2.69 mEq/L) refractory to the endovenous and oral supplementation. Moreover, blood measurement showed a high ARR of 978.31, with a plasma aldosterone concentration of 81.2 ng/dL. The MRI performed highlighted a 10 mm nodule in the right adrenal gland, whose characteristics were suggestive of adenoma. Two confirmatory tests were performed, namely saline infusion and captopril challenge test. Results obtained in both tests were consistent with Conn's syndrome. As a result, he was referred to general surgery for unilateral adrenalectomy. Prior to surgery, both hypertension and hypokalemia should be well controlled, so verapamil and spironolactone were added as therapeutic.

Discussion

This case aims at drawing attention to the importance of the accurate cardiovascular risk evaluation of a patient with stroke. The revision of the patient's risk factors, and further assessment and investigation, led to the final diagnosis.

#311 - Abstract

GLUCOSE DYNAMICS IN DIABETIC PATIENTS TREATED WITH GLP-1 RECEPTOR AGONISTS: IMPROVING THE YIELD OF CGM ANALYSISAna Colás¹, M. Augusta Guillén-Sacoto², Carmen Rodríguez², Borja Vargas², Paula González², Manuel Varela², Luis Vigil²¹ Hospital 12 de Octubre, Madrid, Spain² Hospital Universitario de Móstoles, Móstoles, Spain

Background

The introduction of Continuous Glucose Monitoring (CGM) systems into clinical practice has allowed a deeper understanding of glycaemic dynamics. In the present work:

We explore the effects of long-acting GLP-1 receptor agonists (GLP-1RA) on glucose dynamics through the analysis of glycaemia time-series.

We evaluate the potential role of two CGM-derived variables (percentage of time under 110 mg/dL -TU110- and area over the threshold of 180 mg/dL -AO180-) to classify patients according to the predominance of primary failure of tonic glycaemic control or of postprandial glucose excursions management.

We search for basal variables that may predict which patients would have a better response to GLP-1RA.

Methods

Seventeen patients with type 2 diabetes and poor metabolic control were included. A CGM system was implanted at inclusion before a GLP-1RA was introduced and after 6 months follow-up. Glucose Management Indicator (GMI) was calculated for each registry as an HbA1c estimation based on CGM data. Two dynamical variables were defined, reflecting tonic control (TU110) or postprandial excursions (AO180).

Changes in quantitative variables were evaluated by paired Wilcoxon. Correlation among changes in dynamical variables and changes in GMI and search for predictive variables were performed through Spearman's correlation analysis.

Results

Significant improvement was observed after the addition of GLP-1RA in both conventional variables (fasting blood glucose (FBG): 155 vs. 139 mg/dL, $p < 0.01$ and HbA1c: 7.5 vs. 6.6%, $p < 0.01$) and CGM-derived metrics (GMI: 6.75 vs. 6.56, $p = 0.02$; mean CGM glycaemia: 143.9 vs 136, $p = 0.01$ and TU110: 0.08 vs 0.17, $p = 0.05$). Despite a trend towards a fall in AO180, no statistical significance was reached.

Changes in both phasic (AO180) and tonic control (TU110) showed good correlation with GMI decrease ($\rho = 0.804$ ($p < 0.01$) and $\rho = 0.559$ ($p = 0.02$), respectively).

Basal AO180 displayed the best correlation with the change in GMI ($\rho = 0.744$, $p < 0.001$). Patients with higher basal AO180 showed a more pronounced change in GMI after GLP-1RA treatment.

Conclusion

The addition of GLP-1RA induced a significant metabolic improvement. CGM-metrics seem to be a good tool for the measurement of this response in our cohort of patients.

TU110 and AO180 may have a role in identifying the relative contribution of tonic/phasic control failure in patients with diabetes.

CGM-derived variables (mainly AO180) may help to identify more suitable candidates for GLP-1RA treatment.

#340 - Case Report

CHRONIC DIARRHEA: NOT ALWAYS SO SIMPLE

Catarina Cascais Costa¹, Joana Paixão², Joana Costa²

¹ Centro Hospitalar Baixo Vouga, Aveiro, Portugal

² Centro Hospitalar Universitário de Coimbra, Coimbra, Portugal

Introduction

Neuroendocrine tumors are originated in secretor cells in the diffuse endocrine system and may include a variety of subtypes such as pancreatic, gastrointestinal or pulmonary. Neuroendocrine tumors of the pancreas are the second most common solid organ tumor in the pancreas, yet rare, occur in about 1-2% of all patients with pancreatic lesions. One of the most common manifestations of carcinoid syndrome, associated with hormonal hypersecretion, is diarrhea.

Case description

The authors describe the clinical case of a 70-year-old male patient who is referred to the Internal Medicine appointment with diarrhea complaints with about 1 year of evolution, daily rhythm, pasty stools and associated fecal urgency and incontinence.

It is a patient with no relevant medical history. On objective examination he did not present alterations except a discrete weight loss of approximately 3kg in the last year. He performed an analytical and stool study, only highlighting the presence of elevation of chromogranin (618.5 ng / mL (N <85)), colonoscopy was normal and abdominal-pelvic CT scan that showed a nodular lesion of 11 mm, with peripheral enhancement in the tail of the pancreas. In this context PET scan was also performed and identified a neuroendocrine neoplastic lesion with high expression of somatostatin receptors. It was proposed for surgical evaluation and the presence of neuroendocrine tumor of the tail of the pancreas was confirmed in histological analysis.

Discussion

Pancreatic neuroendocrine tumors may have a wide range of clinical and imaging manifestations. They are rare, sporadic and tendentially solitary tumors. The only treatment that offers a cure is surgery, which highlights the importance of an early diagnosis for that we need a high degree of suspicion in patients, often with nonspecific complaints.

#342 - Case Report

MUCORMYCOSIS: A RARE COMPLICATION OF DIABETES

Mafalda Ferreira, Mariana Lavrador, Luciano Almendra, Helder Esperto

Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Mucormycosis is an invasive and uncommon fungal infection caused by a fungus of the order of Mucorales, with *Rhizopus* being

the most commonly associated. It is an invasive and almost always lethal disease, with a mortality rate of approximately 40% to 60%. It affects preferentially immunocompromised individuals and may also occur in poorly controlled diabetic patients. It can present as cutaneous, pulmonary, renal or rhino-orbitocerebral forms, the latter being the most commonly diagnosed, reaching the nasal mucosa and adjacent structures.

Rhino-orbitocerebral mucormycosis is an emergency that requires aggressive surgical treatment with local debridement, antifungal therapy with amphotericin B and control of the underlying diseases.

Case description

A 65-year-old male, type 2 diabetic, poorly controlled with oral medication, who started complaining of pain and facial edema on the right side. He was initially diagnosed with a dental abscess and completed 7 days of oral antibiotic therapy with amoxicillin and clavulanic acid. There was a progressive worsening of the complains which led to the observation in the emergency department. He presented proptosis and complete ophthalmoplegia of the right eye, retinal necrosis and blindness of the right eye. CT imaging showed right ocular proptosis, periorbital soft tissue and right malar region swelling, ethmoidal and right sphenoid-maxillary sinus inflammation. He initiated amphotericin B, ceftriaxone and metronidazole 10 days after symptoms onset. Biopsy of the nasal fossae cultured *Rhizopus* spp. Subsequently, in the first days of hospitalization, neurological signs worsened, with new focal neurological signs. At this moment it was identified a lesion in the right hemi-palate with a necrotic fundus and a moldy appearance. Cranioencephalic MRI identified multiple ischemic lesions in the territory of the right internal carotid artery, as well as a direct invasion of the artery. Despite the treatment the patient died after 61 days of hospitalization.

Discussion

This case includes many distinctive characteristics of this pathology. Our images illustrate clearly the typical palate lesion as well as a widespread angioinvasion.

The clinical evolution of these patients is usually poor. This leaves the alert for potentially fatal complications in populations at risk, which if identified in a timely manner may modify its prognosis.

#351 - Case Report

WHEN DIABETES HIDES THE REAL PROBLEM

Jéssica Chaves, Carolina Morna, Catarina Nóbrega, Luís Marote Correia, Augusto Barros, Maria Da Luz Brazão

Hospital Central do Funchal, Funchal, Portugal

Introduction

Diabetes mellitus (DM) is characterized by hyperglycemia (HG) and various degrees of deficiency and insulin resistance. The main ethiological factors are the dysregulation of the pancreatic-hepatic axis caused by pancreatic beta cell dysfunction due

to an immunological attack (type 1) or after compensatory hyperfunctioning state to an insulin resistance (type 2). However other factors, such as metabolic dysregulation caused by neoplasias, may disrupt this axis leading to HG.

Case description

We present two case reports reflecting this phenomenon. The first one, a 55-year-old male patient was admitted after being observed in our emergency department (E.R.) for complains of lower limb oedema, dyspnea, asthenia, anorexia and weight loss (about 8 kg in one month). He was a heavy smoker (25 packs-year). He was diagnosed with type 2 DM and was medicated with canaglifozin in the previous two months. The physical exam revealed bilateral crepitations in the pulmonary auscultation, painful hepatomegaly, ascitis, lower limb oedema and caquexia. The blood work found glucose 352 mg/dl, K⁺ 2.4 mEq/L, GPT/GOT 809/541 U/L, γ GT 821 U/L, FA 285 U/L, and the computed tomography (CT) showed an heterogeneous left mediastinal mass sizing 8x6cm and an enlarged liver filled in numerous lesions suggesting metastasis. After bronchofibroscopy, a biopsy identified a small cell lung carcinoma. The second patient, a 57-year-old female was referenced to the E.R. for poor diabetic control by her attending general practitioner. She was medicated with metformin and linagliptin. At the admission she was tachypneic, pale and dehydrated. The epigastric palpation revealed a mass of hard consistency. The blood analysis showed pH 7.28 glucose 572 mg/dL, and hemoglobin 5.0 g/dL. After stabilizing the diabetic ketoacidosis, a CT found a 9x9cm tumor originating from the gastric antrum, invading surrounding structures. The biopsy was showed a moderately differentiated adenocarcinoma. Both patients were guided by Oncology.

Discussion

It is intended to emphasize that the diagnosis of a common pathology can hide a cause with important clinical and therapeutic implications. The presented cases demonstrate that a new onset of DM or the aggravation of a known DM justifies a careful study of its ethiology.

#354 - Abstract

FACTORS ASSOCIATED WITH MICRO AND MACROVASCULAR COMPLICATIONS IN TYPE 2 DIABETES PATIENTS

Cristina Carvalho Gouveia, José Guia, Vanisa Do Rosário, Vanda Jorge, Irene Verdasca, Patrícia Vicente, Luís Campos

Hospital de São Francisco Xavier, Centro Hospitalar de Lisboa Ocidental, Lisbon, Portugal

Background

Type 2 Diabetes mellitus (T2DM) is widely recognized as an emerging epidemic that has a cumulative impact on almost every country, age group and economy across the world. It is associated with microvascular (retinopathy, neuropathy and nephropathy) and macrovascular (peripheral arterial disease, cardiovascular

and cerebrovascular) complications, which are responsible for significant morbidity and mortality. We aim to study the possible factors associated with increased incidence of complications in a group of outpatients being followed in a diabetes clinic.

Methods

Retrospective study of outpatients with T2DM who were consulted in a diabetes clinic between January and December 2018. The population was separated according to the presence of complications associated to diabetes in 2 groups: A – T2DM with complications and B – T2DM without complications.

Results

99 patients were included. 55.6% (n=55) of them had complications: 52.7% had nephropathy, 32.7% ischemic heart disease, 20% cerebrovascular disease, 16.4% retinopathy, 14.5% peripheral artery disease and 11% of patients had neuropathy. Group A was older (71.1 vs B: 67.4 years-old), had a higher percentage of male patients (54.5 vs B: 27.3%), higher time since the diagnosis of diabetes (14.2 vs B: 11.5 years) and higher percentage of patients taking insulin (36.4 vs B: 27.3%). Additionally, group A had a higher prevalence of other cardiovascular risk factors (98.2 vs B: 90.9%), namely: dyslipidemia (87.3%), high blood pressure (81.8%), overweight and obesity (25.5%), tobacco and alcohol use (25.4%) and sedentary lifestyle (12.7%). Glycated hemoglobin was 7.3% in group A and 7.1% in B.

Conclusion

In our study, we only included patients who were already being treated for T2DM and its associated complications. Despite this, the prevalence of complications is noteworthy. The older age, male gender, longer time of disease evolution and presence of other cardiovascular risk factors seemed to be associated with increased incidence of complications. The increased motivation for healthy behaviors might be an effective strategy to achieve better outcomes.

HYPERTRIGLYCERIDEMIA-INDUCED ACUTE PANCREATITIS IN A YOUNG MAN

Miguel Rodrigues Monteiro, Ana Catarina Brás, Filipa Gomes
Hospital Professor Doutor Fernando da Fonseca, Amadora, Portugal

Clinical summary

This picture depicts a blood sample collected from a 24 year-old man, who presented to the emergency department with persistent severe epigastric pain radiating to the back, nausea, vomiting, diarrhea and weight loss in the last month. A history of severe chronic alcohol abuse was reported. The diagnosis of acute pancreatitis was confirmed by abdominal ultrasonography, which revealed a volume increase of the head of the pancreas. The blood sample had a lactescent coloration due to hypertriglyceridemia of 2282 mg/dL. After centrifugation, three layers in the blood

sample can be observed, corresponding to triglycerides, serum and red blood cells. Despite the severity of the disease, the patient recovered with vigorous hydration with no need for therapeutic plasma exchange.

PHOSPHORUS, IRON AND FGF-23: THE GOOD, THE BAD AND THE UGLY

Ivo Cunha, Ana Oliveira, Sandra Silva

Hospital Pedro Hispano, Matosinhos, Portugal

Introduction

The association between hypophosphatemia and iron replacement, although without clinical relevance in the majority of the cases, has been recognized since the 1980s.

Case description

We report the case of a 39-year-old female submitted to total thyroidectomy due to a multinodular goiter. In the immediate post-operative period there was documentation of a severe hypocalcaemia and posteriorly, histological confirmation of one of the parathyroid glands removal. In the subsequent years she developed non-specific genicular pain and a mild depressive syndrome; laboratory results documented mild hypocalcaemia; there was no evaluation of the serum phosphorus and no specific treatment was done. At 2018, after discontinuation of a contraceptive pill, she started abundant menorrhagia

with anemia and iron and folic acid deficiency. She required intravenous replacement with 1g of ferric carboximaltose due to gastrointestinal intolerance. Thereafter she evolves with myalgias, joint pains, generalized paresthesias and cramps of nocturnal predominance. Analytically, she had a serum phosphorus value of 1mg/dL and an ionized calcium of 0.8mg/dL, and initiated IV and oral replacement, and vitamin D supplementation. Workup, including PTH, calcidiol, calcitriol, mioglobin, serum magnesium and alkaline phosphatase were normal; urine summary exam without alterations and a calculated fractional phosphorus excretion of 20%. Bone and parathyroid scintigraphy, as well as x-rays of the long bones, revealed no changes. She was discharged a week later, with compensated ionic values under oral supplementation.

Discussion

Phosphorus's renal excretion is mostly controlled by PTH and FGF-23. This last one, seems to play a crucial role in iron supplementation induced hypophosphatemia, which, in a simple way can be explained by its role as a "phosphatonin". FGF-23 also inhibits the conversion of calcidiol to calcitriol, which, in turn, has contributed to the worsening of chronic hypocalcaemia by decreasing intestinal absorption. Another concurrent mechanism seems to be the fact that iron deficiency will induce the production of FGF-23 by osteocytes which immediately convert it into an inactive form of FGF-23. Iron carboximaltose interrupts this cycle, thus leading to the increase of "active" FGF-23. This effect is not "class dependent" and does not appear to occur with other formulations. Therefore, iron-carboximaltose's induced hypophosphatemia should be taken into account prior to this type of treatment.

#377 - Abstract

HYPERCALCEMIA: A RETROSPECTIVE STUDY IN CENTRO HOSPITALAR UNIVERSITÁRIO COVA DA BEIRA

Clara Jorge¹, Sónia Coelho¹, Pedro Carlos¹, Catarina Chaves², Marlene Louro³, Leopoldina Vicente³

¹ Centro Hospitalar Universitário Cova da Beira, Covilhã, Portugal

² Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal

³ Centro Hospitalar Universitário Cova da Beira,, Covilhã, Portugal

Background

Hypercalcemia (HC) is a common electrolyte disorder. It is closely regulated by PTH, vitamin D and calcitonin. Clinical symptoms are nonspecific, and there are a multitude of clinical manifestations (cardio-vascular, neurological, renal and gastro-intestinal).

Methods

Retrospective, observational and analytical study. Patients with severe hypercalcemia (SHC: ionized calcium > 5.6 mg / dl) were enrolled, in the period from 1 January 2017 to 31 December 2017. In order to study the underlying etiology, further study was made

using cervical ultrasound, parathyroid scintigraphy, vitamin D assay, serum and urinary phosphate and urinary calcium/24H assays, radiography of the skeleton, medullary/ bone biopsy and imaging of neoplasia.

Results

A total of 26 308 patients had HC, among which 50 had SHC. From these, only 31 patients exhibited SHC maintained over time. The mean age was 76.7 years, with a ratio female/male of 1.8 / 1. The main etiology was neoplastic (42%) (61.5% from solid tumors and 38.5% from multiple myeloma). The most frequent neoplasms were from ENL, esophagus, stomach, colon and bladder; must be highlighted that many of them already had bone metastases. Primary hyperparathyroidism (HPTH) due to parathyroid adenoma was diagnosed in 22.6% of cases. This is followed by 16.1% of patients with chronic renal disease in which the diagnosis of tertiary HPTH was admitted. In 3.2%, immobilization was the cause. In the remaining 16.1% the cause remained uncertain. Although they were not accounted, transient SHC was mainly due to an iatrogenic cause (hydrochlorothiazide, indapamide, calcitriol), and due to renal failure in a dehydration context.

Conclusion

HC is a common clinic finding in the hospital. Its study and treatment is crucial to prevent further complications. Primary HPTH and neoplasms represent the main causes of HC, as reported in the literature. In this study, the neoplastic etiology prevails 3.25 times, because SHC is more frequent than in primary HPTH, and it is also associated with a more hospital admissions since it is more symptomatic, and consequently more easily diagnosed.

#388 - Case Report

HUNGRY BONE SYNDROME

Joel Pinto, Paulo Almeida, Flávio Godinho, Daniela Meireles, Fani Ribeiro, Susana Cavadas

Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

Introduction

Calcium homeostasis is regulated by the action of parathyroid hormone (PTH) and vitamin D at the renal, bony and intestinal levels. Hypocalcemia after parathyroidectomy or thyroidectomy is a common, though usually transient situation. However, in some cases, hypocalcemia may be severe and prolonged, especially in patients who have developed significant bone disease previously to surgery, due to prolonged exposure to elevated PTH levels. These cases are referred to as Hungry Bone Syndrome.

Case description

The authors present the case of a 69-year-old woman who went to the emergency department due to face and members paresthesia, nausea and vomiting with 15 days of evolution. She denied cough, dyspnea, dysphagia, dysarthria, diarrhea or urinary complaints. She had been submitted to parathyroidectomy 2 months before,

due to primary hyperparathyroidism. She had fever, but no other abnormalities were found in physical examination. Blood tests revealed hypocalcaemia (7.0 mg/dL), hypomagnesemia (1.10 mg/dL), hypokalemia (2.9 mEq/L), hypoalbuminemia (2.89g/dL), vitamin D deficiency (7.8 ng/mL) and C-reactive protein of 20.66 mg/dL. Viral serologies were negative, thyroid function markers and PTH were normal, and blood gas test showed a type 1 respiratory failure. An opacity in the left lung base was visible in the chest X-ray. Correction of hydroelectrolytic disorders and empirical antibiotic treatment was started, being admitted with the diagnosis of lobar pneumonia and Hungry Bone Syndrome. She presented a favorable evolution during hospitalization with regression of inflammatory parameters and normalization of the electrolytes. Septic screening was negative. She was then discharged medicated with calcium carbonate and calcitriol, maintaining previous follow-up in Endocrinology and Internal Medicine consultations.

Discussion

Hypocalcaemia may be responsible for a wide spectrum of clinical manifestations such as paresthesia, muscle spasm, tetany (Trousseau and Chvostek sign), seizures, QT prolongation or cardiac arrhythmias. It is more frequent after thyroid and parathyroid surgery and that's why its prevention and postoperative clinical and analytical surveillance is fundamental. It should be noted that the development of this syndrome can occur even with normal or increased PTH levels.

#413 - Abstract

DATA MINING ANALYSIS OF TYPE 2 DIABETES MELLITUS AND CARDIOVASCULAR DISEASE MORTALITY IN MEXICO

Sonia Citlali Juárez Comboní¹, Jorge Antonio Aldrete-Velasco², Salvador Durán-Coyote³, Scarlett Enríquez-Ramos²

¹ Los Ángeles Acoxa Hospital, Mexico City, Mexico

² Paracelsus S.A. de C.V., Mexico City, Mexico

³ Grupo ANLTYK, Mexico City, Mexico

Background

In Mexico, Diabetes Mellitus is the first cause of death in women and the second cause in men, after cardiovascular disease (CVD). Moreover, CVD is not only the first cause of death in the world, in Mexico also represents one of the most important causes of disability. For this reason, the National Health System considers these diseases as the principal health issues in the country. The principal objective of this study was to describe and analyze type 2 diabetes mellitus (T2DM) and CVD mortality in Mexico through data mining technique.

Methods

3 105 975 death certificates were consulted on the most updated registries of the health sector from January 2011 to December 2015. Death registries associated to T2DM and CVD were defined

as stated by the International Classification of Diseases (ICD-10). Age groups were analyzed according to its possible economic activity, mortality range per year and mortality by federal state.

Results

290 708 of the 3 105 705 death certificates were associated to T2DM and 132 148 to CVD, during January 2011 to December 2015. Population proportion was the measure used to obtain death frequency by T2DM, which had an increase from 8.38 to 10.24% during the analyzed lapse. Meanwhile, CVD proportion decline from 4.46 to 4.31%. Similarly, mortality range by T2DM showed a considerable annual increase compared to CVD deaths. Significant predominance by sex was not observed in any of the studied diseases. However, a comparing between economically active populations of 25 to 65 years old was performed, in which a significant difference (15.35 and 13.58% in 2011 and 2015, respectively) was reported when T2DM deaths were compared with CVD ones.

Eventually, T2DM and CVD distribution by federal states were studied, showing that states with higher mortality of both diseases were Mexico City, Mexico State and Veracruz.

Conclusion

Mortality by T2DM has been increasing in an exponential way and this affects to the economically active population importantly. Although CVD remains the first cause of death in Mexico, this condition had become more preventable and, therefore, mortality rate of CVD has decreased in last years.

These study results can orientate about the epidemiology of this conditions in Mexico. Due to the use of data mining, the impact of T2DM mortality in Mexico was highlighted. This analysis allows to see how important and urgent is to control and prevent T2DM.

#423 - Case Report

REFRACTORY HYPONATREMIA – A CASE OF AN EMPTY SELLA SYNDROME

Cláudia Isabel Góis Lemos, Sara Beatriz Santos Da Silva, Ana Carlota Policarpo Gouveia Vida, Sofia Patrícia Dinis Ferreira, António Manuel Rosa Oliveira, Ema Da Conceição Abreu Ferreira Teles Freitas, Maria Da Luz Reis Brazão
Hospital Central do Funchal, Funchal, Portugal

Introduction

Hyponatremia is the most common electrolytic disturb in clinical practice and is one of the manifestations of empty sella turcica syndrome, which is very rare and there is little clinical experience in the management of this pathology, as well as its complications.

Case description

Female, 77 years old, caucasian with personal history of hypertension, obesity, type 2 diabetes, stroke, medicated for her comorbidities. She went to the emergency services with a case of prostration, anorexia and vomiting with two weeks evolution.

Analytically, she presented severe hyponatremia, 110 mmol/L, so she was admitted in the enfermary of Internal Medicine. Since it was refractory to therapy, the team asked for an extensive study to discover possible causes, which revealed primary hypothyroidism and primary adrenal insufficiency. With the support of the Endocrinology team, the patient initiated treatment with levothyroxine and hydrocortisone. The CT scan of the pituitary gland showed invagination of the tank above-seal inside of the sella turcica, stipulating compression of the pituitary and erosion of the pavement seal, i.e., empty sella turcica. During the internment, analytically results were: low T4, T3 and TSH, ACTH and prolactin levels normal. Cortisol in the morning and afternoon were reduced. In the urine of 24h, increased urinary sodium (476 mEq/24h). The remaining parameters, such as, potassium, chlorine, osmolality, creatinine, and glucose levels were within the normal limits. The patient was discharged with total correction of natremia, medicated with letter and hydrocortone.

Discussion

The empty sella turcica Syndrome, congenital, primary or secondary etiology, is an uncommon entity that is characterized by filling of the sella turcica with cerebrospinal fluid due to herniation of the arachnoid, leading to compression of the pituitary tissues against the wall seal, which confers the radiological appearance of empty sella turcica. The typical patients affected are females, in the mid-fifties, multiparous, obese and hypertensive. Despite the vast majority of patients did not present alterations in the pituitary hormone levels, this entity is responsible for a non neglecting number of cases which may lead to a delay in diagnosis with serious consequences for the patient. In conclusion, the authors expose this case, evoking its rarity and its scarce literature.

⁴ Biochemistry Laboratory, Constantine Hospital, Constantine, Algeria

⁵ Laboratory Of Biology And Molecular Genetic, Faculty of Medicine Constantine University, Biochemistry Laboratory, Constantine Hospital, Constantine, Algeria

Background

Type 2 diabetes is a public health problem and is considered

today the evil of the century. It is characterized by a combination of deficiency and insulin resistance. Several mechanisms are envisaged to explain these concepts, an insufficient intake of magnesium, and consequently a deficit of magnesium within the cells would promote this insulin resistance.

The purpose of this study is to evaluate and compare magnesium levels in non-insulin-dependent diabetics with those of the control population.

Methods

-The study that we have undertaken is a control-case type. It involved 30 controls, 38 diabetics and 68 unbalanced diabetics.

- All our subjects have benefited from a biochemical report that counts a fasting glucose test, magnesium, calcium, albumin, phosphorus, urea, creatinine, triglycerides, total cholesterol, cholesterol HDL, LDL cholesterol and glycated hemoglobin.

Results

The mean serum magnesium level is lower in patients with unbalanced diabetes (21.69±3.47 mg / l) compared with controls (21.91±1.3 mg / l) and balanced patients (21.90±3.41 mg / l). But, this decrease is not significant.

We could not find any significance between mean serum magnesium levels versus diabetes seniority.

A positive correlation between magnesium plasma concentration and presence of hypertension, physical activity (in controls) and diet was found. Our results show that fasting blood glucose, glycated hemoglobin, calcium, albumin and triglycerides were significantly elevated in diabetics. Phosphorus, urea, creatinine, total cholesterol were low in patients.

Conclusion

Our results do not find a strong correlation between hypomagnesemia and type 2 diabetes (T2D). Larger scale studies will be needed to provide stronger evidence, and to elucidate the role of hypomagnesemia in Algerian type 2 diabetics, on the one hand and to support the possible inclusion of magnesium supplements in the guidelines for managing T2D. Especially in patients who are not able to achieve the desired glycemic standards.

- ⁴ Laboatory Of Biology And Molecular Genetic, Medicine Faculty Constantine University 3, Constantine, Algeria

Background

A synergistic effect of thrombophilia with several cardiovascular risk factors such as diabetes, obesity, and hyperlipidemia seems to have existed.

The purpose of the present study is to investigate a possible association between diabetes and Factor II and factor V Leiden mutations. The role of these two mutations in venous thromboses is well established, in contrast to that in arterial thromboses that remains controversial until then.

Methods

The study included 97 diabetics and 190 healthy controls. The DNA was extracted by the NaCl method. Both mutations were determined by real-time PCR.

Consent was obtained from all participants in the study.

Results

Genotype and allelic frequencies of the G20210A mutation of the prothrombin gene (factor II)

Our results show the predominance of the wild-type GG allele in the 2 groups, controls and patients with respective frequencies of 98.6% and 97.6%. While the heterozygous GA genotype is only found at 1.4% and 2.4% respectively. No homozygous mutated AA genotype was found in either group.

The G allele is predominant in both groups, 98.8% in patients and 99.32% in controls. The frequency of the mutated A allele is only 1.20% in patients and 0.68% in controls. Genotypic and allelic frequencies of the factor V gene mutation G1691A

Our patients are exclusively of wild GG genotype with a genotypic frequency of 100%, whereas in our controls this genotype predominates with a frequency of 97.4%, the heterozygote genotype GA with a frequency of 2.6%. No homozygous mutated genotype AA was found in our study population.

The G (wild) allele is predominant in our controls with a frequency of 98.68%; Allele A accounts for only 1.32% in this group. In our patients, only the wild allele is present (100%).

Conclusion

Our results found no significant association between the G20210A mutation of the prothrombin gene (factor II) and the G1691A mutation of the factor V gene and complicated type 2 diabetes

PRIMARY HYPERPARATHYROIDISM

Ana Catarina Dionísio, Ana Branco, Dalia Estêvão, Artur Gama, Leopoldina Vicente
CHUCB, Covilhã, Portugal

Introduction

Primary hyperparathyroidism is in most situations caused by parathyroid adenomas (81%). They are more common in women and diagnosis is common in the 3rd and 4th decades of life. The symptoms are often non-specific (fatigue, depression, mental confusion, anorexia, nausea, constipation, renal tube defects, polyuria, a short QT interval and arrhythmias), so the high rate of suspicion is important.

Case description

A 79-year-old female patient has been referred to the Emergency Department for anorexia, nausea and vomiting for 1 month, weight loss of about 10% of habitual body weight, constipation and marked asthenia.

No changes were identified at the objective examination. Analytically, she presented severe hypercalcemia (18.8 mg/dL). Performed an electrocardiogram that showed no abnormalities.

She was hospitalized for etiological study and normalization of serum calcium values with electrocardiographic monitoring.

Analytically, had a high PTH value. The hypothesis of primary hyperparathyroidism was made and a thyroid ultrasonography showed a solid nodule, most likely a parathyroid adenoma.

After the institution of the therapy it presented good clinical and analytical evolution with resolution of anorexia and improvement of the remaining symptoms. After cervical computed tomography and parathyroid scintigraphy, left upper parathyroidectomy was performed.

Patient was medicated with cinacalcet 30mg twice daily until surgery.

Discussion

Severe hypercalcemia (>15mg/dL), can be a medical emergency, leading to coma and cardiac arrest. In the cases of adenomas of the parathyroids the definitive treatment passes through surgical intervention with great operative potential.

AN ATYPICAL CASE OF ANASARCA IN A NEWLY DIAGNOSED TYPE 1 DIABETIC

Marc Hai Liang Wong, Tharmmambal Balakrishnan
Singhealth, Singapore, Singapore

Introduction

Lower limb swelling is a common occurrence in the acute medicine clinic. Here, we report a 40-year-old woman who was newly diagnosed with type 1 diabetes and commenced on insulin (Actrapid and Lantus) and subsequently developed lower limb swelling.

Case description

A 40-year-old woman was admitted for symptoms of polyuria and polydipsia and found to have hyperglycemia, fortunately not in crisis. She was previously well without any medical history and was subsequently found to have type 1 diabetes mellitus and was initiated on a basal-bolus regimen of insulin (Actrapid and Lantus). Tolerating her insulin therapy well, she was promptly discharged and planned for outpatient evaluation.

Two days after she was initiated on insulin therapy, she represented with bilateral lower limb swelling till the level of the mid shins and her edema progressed inpatient to anasarca. She gained more than 10 kgs within a short span of 2 weeks and subsequently had complications of acute pulmonary edema requiring high doses of intravenous furosemide for adequate dialysis.

Significant differentials of cardiac disease, liver disease, renal disease, and obstructive causes were evaluated requiring many investigative tests such as transthoracic ultrasound of the heart, a computed tomography scan of the abdomen and pelvis and a plethora of blood tests. Even after completing the initial investigations, the cause of the lower limb swelling remained a mystery leading to evaluation for a wider array of differentials which included autoimmune causes and drug causes.

Finally, after this thorough screen was negative, the rare complication of insulin usage resulting in edema was entertained. The doses of Actrapid and Lantus was titrated and finally switched to a combination of Apidra and Lantus. Fortunately, the massive fluid retention resolved thereafter and the patient was discharged well.

Discussion

The majority of reported cases of insulin edema have occurred in patients with Type 1 diabetes and patients have typically presented between 2 and 4 weeks following an initial presentation of DKA. Insulin is commonly known to cause weight gain and has been attributed to increased vascular permeability and altered renal sodium handling in addition to its anabolic action. However, the rare side effect of significant fluid retention is probably an underreported physical finding. We present this case of unusual lower limb swelling and a review of the literature and mechanisms surrounding insulin edema.

#548 - Abstract

EFFECTS OF SGLT2 INHIBITORS ON THE RENAL FUNCTION OF TYPE 2 DIABETICS: OUR EXPERIENCE AFTER ONE YEAR

Daniel Marín Dueñas¹, Juan Mora Delgado¹, Manuel Cayón Blanco², Patricia Rubio Marín¹, Ana Ruiz Arias¹, Alfredo Michan Doña¹

¹ Internal Medicine, General Hospital of Jerez de la Frontera, Jerez De La Frontera, Spain

² Endocrinology and Nutrition, General Hospital of Jerez de la Frontera, Jerez De La Frontera, Spain

Background

Type 2 diabetes mellitus 2 is already a worldwide epidemic, in addition, diabetic nephropathy has become the leading cause of end-stage renal failure.

Methods

The objective was to know the changes produced in HbA1c and impact on renal function after one year of treatment with iSGLT2. Observational and descriptive study, transversal. Patients with type 2 diabetes are selected in treatment with iSGLT2 for at least one year, excluding those with chronic kidney disease. Demographic characteristics, HbA1c and renal function are analyzed at the beginning of treatment and after one year of treatment

Results

The average age was 62.13 +/- 8.91, with 54.1% males. At the beginning they presented an Hb1Ac of 7.84 +/- 1.42 and after one year of treatment 6.9 +/- 1.17 (-0.93 +/- 1.19). Glomerular filtration increased by 62.2% in the treated patients (1.4 +/- 12.62). The albuminuria at the beginning was 19.6 +/- 35.7, and after one year it increased to 12.78 +/- 17.23 (-5.37 +/- 27.89). The albumin / creatinine ratio initially marked 32.38 +/- 31.68 with respect to 32.3 +/- 26.73 after one year of treatment (-0.08 +/- 27.97).

Conclusion

The use of iSGLT2 in patients without chronic kidney disease causes a decrease in HbA1c and could have benefits from the renal point of view. In our patients there is an increase in glomerular filtration and decrease in albuminuria.

#553 - Case Report

APPLICATION OF GLUCAGON-LIKE PEPTIDE-1 ANALOGUES: KIDNEY AND CARDIOVASCULAR RISK FACTORS

Juan Mora Delgado, Daniel Marín Dueñas, Patricia Rubio Marín, Ana María Ruiz Arias, Alfredo Michan Doña

Internal Medicine, General Hospital of Jerez de la Frontera, Jerez De La Frontera, Spain

Introduction

Glucagon-Like Peptide 1 analogues suggest having a protective

role in cardiovascular risk factors besides improving glycemic control, compared to placebo and to standard diabetes therapies, and have a positive impact on cardiovascular risk factors otherwise not addressed by most standard diabetes therapies.

Case description

A 66-year-old male smoker with a daily package (40 packages/year); with a history of high blood pressure; hypercholesterolemia; obesity type I. Diabetes type 2 of 15 years of evolution in treatment with oral antidiabetics. Stable chronic ischemic heart disease (stents more than 15 years ago). Chronic kidney disease stage 3A. Weight 91.3 kg; size 1.70 m; BMI 31,591. BP: 133/77 mmHg. Analysis: glucose 213 mg/dl; HbA1c 8.6%; total cholesterol 218 mg/dl, LDL-C 115 mg/dl, HDL-C 37 mg/dl and TGs 320 mg/dl; FGe 44 (CKD-EPI). His antidiabetic treatment was metformin 500 mg (every 12 hours) and sitagliptin 50 mg (daily).

We remove sitagliptin, initiating liraglutide, increasing weekly until the maintenance dose. At 3 months his HbA1c was 7.4% (-1.2%) and the weight of 86.7 kg (-4.6 kg). With this, we obtained the goal of glycemic control that we set ourselves. Six months later, he presented a new decrease in his HbA1c (-0.3%) and weight (-3.5 kg).

Discussion

This patient presents a moderate risk of hypoglycaemia due to CKD, a duration of T2DM between 10-20 years of evolution, microvascular and macrovascular complications and a patient's attitude that is not too active. Thus, a correct control of HbA1c would be between 7-7.5% (currently 8.6%), so we accept poor control.

When intensifying with a third drug, we look at the consensus document on the treatment of diabetes in patients with CKD: first choice is metformin and / or repaglinide and that associated with these could be used basal insulin, pioglitazone and aGLP1. These three options would be correct, but not all behave the same from a cardiovascular point of view. Pioglitazone did not find statistically significant benefits in its PROactive study and basal insulin glargine showed in the ORIGIN study its non-inferiority against placebo. In this sense, superiority is shown by liraglutide, which becomes the drug of choice according to the recommendations of the AACE in patients with CVD. We made the decision to start the treatment described based on the consensus of CKD in the patient with DM2, in the clinical practice guide of the AACE and in the LIRA-RENAL study.

#596 - Case Report

ADRENAL INSUFFICIENCY IN PATIENT WITH CEREBRAL METASTASES - CASE REPORT

Paulo Ferreira¹, Vanessa Machado¹, Cristina Ramalho¹, Hilda Freitas², Natalia Oliveira², Antonio Cabral²

¹ TrofaSaude Hospital Braga Centro, Braga, Portugal

² TrofaSaude Hospital Braga Sul, Braga, Portugal

Introduction

Adrenal insufficiency is a rare disorder, occurring in up to 144/1000000 of the population. Autoimmune adrenalitis is responsible for 70/90%, with the remainder being caused by other infectious diseases, replacement by metastatic cancer or lymphoma, adrenal hemorrhage or infarction, or drugs. Adrenal insufficiency can be caused by diseases of the adrenal gland (primary), interference with corticotropin (ACTH) secretion by the pituitary gland (secondary), or interference with corticotropin-releasing hormone (CRH) secretion by the hypothalamus (tertiary).

Case description

The authors describe a clinical case of 63 years old men, independent, with a history of Hypertension, Diabetes 2, Low Grade Papillary Urothelial Carcinoma and Melanoma (Oncology considered cured). He went do emergency room because confusion. He had Broca aphasia and dysmetria in the right finger test nose. Laboratory studies revealed hyponatremia. TAC CE sowed "multiple nodular, supra and infratentorial lesions, mostly hyperdense, some with central necrotic area. In the supratentorial compartment, they are mostly surrounded by a halo of vasogenic edema. Correspond to very likely brain metastases. He had axillary adenopathy of 2 cm. He was medicated with steroid therapy .Cortisol in the morning 1.5 and repeated: <1 (5.0-25.0); Cortisol in the afternoon 1.3 and repeated: 1.1 (1.7-14.1), before beginning of corticoids. Brain Cranial Resonance performed: "multiple expansive lesions suggestive of metastatic lesions". An aspiration biopsy was performed on axillary adenopathy. He improved mental confusion. Metastasis of melanoma confirmed in axillary ganglia cytology. According to decision of family members intended not to carry out any treatment directed to the disease, only being in treatment of symptoms.

Discussion

Tertiary adrenal insufficiency refers to causes that related to hypothalamic abnormalities that reduce corticotropin-releasing hormone (CRH) secretion. Any process that involves the hypothalamus and interferes with CRH secretion will result in tertiary adrenal insufficiency. Such processes include: tumors, infiltrative diseases such as sarcoidosis, and cranial radiation. In young adults, the presence of nonspecific and mild symptoms, besides laboratory studies at the threshold of normal, can let pass potentially treatable conditions that can improve survival and life-quality for these patients. In these cases, the Internist assumes a preponderant role.

#609 - Abstract

EFFECT OF METFORMIN ON BODY FAT DISTRIBUTION AND SERUM LIPID PROFILE IN PATIENTS WITH TYPE 2 DIABETES AND CHRONIC HEART FAILURE

Jan Kopecký, Eva Hošková, Jirí Veleba, Katerina Velebová, Vojtech Melenovský, Terezie Pelikánová

Institute for clinical and experimental medicine, Prague, Czech Republic

Background

Treatment with metformin (MET) in type 2 diabetic patients (T2D) with chronic heart failure (HF) is associated with better cardiovascular outcomes. Android type of body fat accumulation is associated with high cardio-metabolic risk factor profile. The aim of the study was to evaluate the effects of MET on body fat distribution and serum lipid profile during the meal test.

Methods

A randomized, double-blind, placebo-controlled, crossover study in a total time of six months testing the effect of 3-month usage of MET (2 g/day) vs placebo. A group of 40 treatment naive patients with T2D and HF were included. At the beginning and at the end of each intervention period body fat distribution was assessed by Dual Energy X-Ray Absorptiometry (DEXA; GE Lunar Prodigy) and serum lipid profile during meal test was measured. In addition, hyperinsulinemic-isoglycemic clamp was done and HbA1c was measured to assess the effect on glucose metabolism.

Results

MET did not significantly change android vs gynoid body fat composition as measured by DEXA. Fasting serum lipid profile (Tg, Chol, HDL, LDL, FFA) was also not altered. During a meal test, there was a trend to decrease area under curve of free fatty acids by metformin (statistically significant only vs baseline at $p < 0.05$, not vs placebo), triglyceride concentrations were not significantly altered.

MET significantly reduced HbA1c compared to placebo ($p < 0.01$). Insulin sensitivity, measured as a metabolic clearance rate of glucose (MCR) during the clamp, improved significantly with MET ($p < 0.001$) but also, although less significantly, with placebo ($p < 0.05$), difference between MET and placebo was not significant.

Conclusion

Our results on unique group of patients with heart failure and diabetes showed expected changes in glucose metabolism but did not find statistically significant changes in lipid metabolism and body composition.

GLIBENCLAMIDE-INDUCED THROMBOCYTOPENIA: A CASE REORT

Yosra Cherif^{1,2}, Baya Chatti Amal^{1,2}, Maroua Mrouki^{1,2}, Fatma Ben Dahmen², Meya Abdallah^{1,2}

¹ Tunis El Manar University Faculty of Medicine of Tunis, Tunis, Tunisia

² Regional Hospital Ben Arous, Internal Medicine Department, Ben Arous, Tunisia

Introduction

Drug-induced thrombocytopenia is a common side-effect. Up to 25% of thrombocytopenia in critically patients are drug-induced. We report a glibenclamide-induced thrombocytopenia in an elderly woman.

Case description

A 75-year-old woman was admitted for headache. She had mellitus diabetes, high blood pressure and coronary insufficiency. She was treated with glibenclamide, metformine, aspirin, molsidomine and captopril. Physical examination showed global cardiac failure. She had no features of bleeding. Laboratory tests showed thrombocytopenia with a thrombocyte count at $42000/\text{mm}^3$, hemoglobin levels of 14 g/dL and leucocytes at $7910/\text{mm}^3$. Renal and liver fonction were within normal range. Abdominal ultrasound was normal. Hepatitis B and C and human immunodeficiency virus serologies were negative. Glibenclamide was withdrawn. Three days after the withdrawal of glibenclamide, platelets count increased with normal levels at $174000/\text{mm}^3$.

Discussion

The etiological analysis of glibenclamide-induced thrombocytopenia is not obvious. Different mechanisms were uncertain including auto-immune disease, bone marrow failure and impaired platelet production. Severe bleeding can occur. Therefore, platelet count should be monitored when patient are treated with glibenclamide.

#690 - Abstract

APPROACH AND TREATMENT OF HYPERGLYCAEMIA IN HOSPITALIZED PATIENTS (WITH NON-CRITICAL ILLNESS) - HOSPITAL CLINICAL ORIENTATION NORM AUDIT

Francisca Saraiva Santos, António Eliseu, Carolina Palma, Filipa Silva, Susana Marques, Julieta Sousa, Ermelinda Pedroso
Centro Hospitalar de Setúbal, Setúbal, Portugal

Background

The joint recommendations of Portuguese Society of Diabetology and Portuguese Society of Internal Medicine about the Approach and Treatment of Hyperglycaemia in Hospitalized Patients (with non-critical illness), published in May 2015, were adapted into a Hospital Clinical Orientation Norm at the health institution where the authors are collaborators.

Methods

Three years after their publication, the authors present the results of a clinical audit of this norm implementation, in the form of a cross-sectional cohort, carried out at the various in-patient departments of the concerned health institution, involving non-critical patients, in order to verify the penetration of the aforementioned norm into clinical activity.

On January 29, 2019, an audit grid was applied to Medical and Surgical, excluding the Obstetric, Pediatric and Psychiatry ones, comprising a total of 275 patients, of whom 94 presented hyperglycemia during hospitalization. Of these, 89 were under insulin therapy.

The data were collected without prior notice in order to evaluate the usual clinical practice, following the entire circuit from its identification, therapeutic prescription and pharmacological administration.

Results

From the results analysis, it was concluded that: the use of oral antidiabetic medication is practically non-existent; most patients (85%) were under basal-bolus scheme; the review of insulin doses in cases of poor metabolic control is still deficient (and in only 47.1% of the cases the review was verified in the appropriate timing, constituting an important gap that need to be corrected). From the overall analysis, a positive compliance rate of 80.4% was obtained.

Conclusion

The analysis of results and their internal presentation will certainly allow us to correct deviations from the good practice and to involve all professionals, in order to better comply with the institutional norm, ensuring that patients receive the best possible approach during hospitalization, and in some cases, after hospital discharge.

#694 - Abstract

SEVERITY OF DIABETIC KETOACIDOSIS IN PATIENTS ADMITTED IN THE EMERGENCY DEPARTMENT OF A PORTUGUESE HOSPITAL: A CROSS-SECTIONAL STUDY

Joana C F Lima¹, João Aguiar², Margarida Paixão Ferreira¹, Rita Calixto¹, Vera Cesário¹, José Vaz¹

¹ Hospital José Joaquim Fernandes, Beja, Portugal

² Instituto de Investigação do Medicamento (iMED.Ulisboa), Faculdade de Farmácia, Universidade de Lisboa, Lisboa, Portugal

Background

Diabetic ketoacidosis (DKA) are one of the most serious acute metabolic complications of diabetes. The triad of uncontrolled hyperglycemia, metabolic acidosis, and increased total body ketone concentration characterizes DKA. Our aims were: a) to characterize the degree of severity of DKA episodes in a diabetic population from a Portuguese hospital; and b) to evaluate the correlation between HbA1c and the degree of severity of DKA episodes.

Methods

A cross-sectional study was undertaken in a Portuguese hospital in Beja from 2016-2017. Patients (aged 18 years or older) with DKA who were admitted in emergency room were included in the study. Data was extracted from medical charts, which included sociodemographic and clinical variables (e.g. serum ketones, arterial pH, serum bicarbonate, and anion gap). The degree of severity of DKA episodes was divided in three groups (mild, moderate, and severe), according to American Diabetes Association. Data analysis was performed using uni- and bivariate statistics (IBM SPSS v.20.0).

Results

A total of 20 patients were included, with a mean age of 54±18.9 years old and 75% (n=15) were female. From those, 55% (n=11) were type 1 diabetics and were firstly diagnosed in the last 16.9±7.9 years {0;37}. Microvascular complications were identified in 45% (n=9) of the sample, macrovascular complications in 5% (n=1), and 10% (n=2) presented both. Previous history of DKA episodes were identified in 20% (n=4) of the patients. A total of 43 DKA episodes were identified during the study period (mean of 2.2 episodes per patient {1;19}). Mild, moderate, and severe DKA episodes were present in 9% (n=4), 58% (n=25), and 33% (n=14), respectively. Ten patients (23%) were admitted to the intensive care unit. The mean HbA1c was 11.9±1.5 {5.5;17.3}. According to our data, there was no correlation between HbA1c and the degree of severity of DKA episodes (p=0.227).

Conclusion

Data suggest that one third of episodes were associated with severe DKA; however, only 2% of the overall patients followed-up annually in the diabetes department of the hospital experienced DKA episodes. Even though there was no correlation between HbA1c and the degree of severity of DKA episodes, this may be explained by the small sample size. Further studies would be necessary to evaluate possible correlations between severity of DKA episodes and metabolic control.

#698 - Abstract

THE ASSOCIATION BETWEEN HBA1C AND THE PRESENCE OF METABOLIC COMPLICATIONS IN DIABETIC PATIENTS: A STUDY IN A PORTUGUESE HOSPITAL

Joana C F Lima¹, João Aguiar², Margarida Paixão Ferreira¹, Rita Calixto¹, Vera Cesário¹, José Vaz¹

¹ Hospital José Joaquim Fernandes, Beja, Portugal

² Instituto de Investigação do Medicamento (iMED.Ulisboa), Faculdade de Farmácia, Universidade de Lisboa, Lisboa, Portugal

Background

Metabolic complications of diabetes mellitus (DM) are associated with a decrease in patients' quality of life and increased costs. Disease control is crucial to prevent those complications.

Therefore, our aim is to evaluate the association between HbA1c and the presence of metabolic complications.

Methods

A cross-sectional study was undertaken in a diabetes appointment of a Portuguese hospital from January to September of 2018. Patients (aged 18 years or older) with DM who are followed-up in this appointment were included in the study. Data was extracted from medical charts, which included sociodemographic and clinical variables (e.g. type of DM, disease duration, and HbA1c). Good glycemic control was defined as HbA1c \leq 7.0%. The strength of the association was estimated with logistic regression and expressed as adjusted odds ratio (aOR) with corresponding 95% confidence interval (95%CI) (IBM SPSS v.20.0).

Results

A total of 113 patients were included, where 55% (n=62) were female with a mean age of 59.4 \pm 15.5 years old {23;90}. From those, 39% (n=44) were type 1 diabetics, and 61% (n=69) type 2 diabetics. The prevalence of metabolic complications in type 1 diabetics was 68% (n=30), whereas in type 2 diabetics was 71% (n=49). Microvascular complications were identified in 67% (n=53) of the sample, macrovascular complications in 9% (n=7), and 24% (n=19) presented both. Macrovascular complications were more prevalent among type 2 diabetic patients. Patients who had poor glycemic control were associated with higher odds of metabolic complications (aOR=1.13; 95%CI 0.38-3.32) when compared to patients with good glycemic control. When analyzing by DM type, patients with type 1 DM and poor glycemic control had a 31% increased risk of having complications when compared to good glycemic control. In type 2 DM, this risk was slightly lower (aOR=1.11; 95%CI 0.31-3.96); however, none of these results were statistically significant.

Conclusion

Data suggest that may exist an association between HbA1c and metabolic complications in both types of DM analyzed. The high prevalence of macrovascular complications among type 2 diabetics may be explained by the presence of other cardiovascular risk factors. However, to confirm this association prospective studies and additional covariates are needed.

#712 - Abstract

OUTPATIENT MANAGEMENT OF TYPE 2 DIABETES MELLITUS - A 6 MONTH HOSPITALAR OUTPATIENT CLINIC REVIEW

Adriana Bandeira, Miguel Gonzalez Santos, Behnam Moradi, Alcina Ponte

Centro Hospitalar de Leiria, Leiria, Portugal

Background

Diabetes mellitus type 2 is a common disease with systemic impact. Though treatable with many available medications and

their multiple combinations, some patients remain a challenge to obtain glycemic control. Though indications for hospital referral and further in-hospital continuity of diabetes care may differ, the heavy burden of comorbidities, polymedication as well as uncontrolled diabetes are the main causes for this decision.

Methods

Retrospective study consisting of process review of all patients followed by one care team in the hospital's outpatient diabetes clinic during the second semester of 2018.

Results

Between July and December 2018, 224 consultations were carried out, of which 8% were family doctor referrals and the remaining 91% were follow-up appointments, corresponding to 131 patients.

Appointment intervals varied, though the majority of patients were re-evaluated within 8,2 weeks of latest appointment.

The majority of patients were male, with a medium age of 67,8 years (SD \pm 11.5) with an average of 13.5 years of disease evolution. The mean value of hemoglobin A1c in the patients referred to consultation was 8,97% and 7,08% at the time of discharge. 77% of patients were insulin-treated, of whom 69% were concomitantly medicated with at least one oral glucose-lowering agent. 87% of patients were prescribed statins and all patients over 65 years of age were taking low dose aspirin daily, 83% of them as primary prevention of cardiovascular events.

Approximately 61% of the patients had diabetes-related complications, namely diabetic nephropathy (32%), diabetic retinopathy (31%) and diabetic foot (19%). All patients received regular foot examination to identify high-risk foot conditions and if needed were forwarded to a specialized consultation. 36% of patients with diabetic foot were diagnosed with peripheral vascular disease and 28% with diabetic neuropathy as main cause of diabetic foot. During this 6 month period, 5 patients were admitted in order to do broad-spectrum antibiotics for active foot ulcer.

Conclusion

Despite all the limitations of an outpatient setting, we still find benefits of an in-hospital approach to diabetic patients mainly those without stable/controlled disease. A multidisciplinary approach, with the support of subspecialty physicians and nurses, facilitated in a hospital setting, may be especially beneficial to this patients.

#715 - Case Report

SYMPTOMATIC BISPHOSPHONATE-INDUCED HYPOCALCEMIA IN A PATIENT WITH PAGET DISEASE AND PRIMARY HYPOPARATHYROIDISM - A CASE REPORT

Roberto Calças Marques¹, Anabela Malho Guedes¹, Mafalda Aveiro², Ana Ribeiro³, António Veiga Moura³

¹ Nephrology Department, Centro Hospitalar e Universitário do Algarve, Faro, Portugal

² Family Medicine, USF Ossónoba, ACES Algarve Central, Faro, Portugal

³ Internal Medicine Department, Centro Hospitalar e Universitário do Algarve, Faro, Portugal

Introduction

Intravenous bisphosphonates are widely used in the management of metabolic bone diseases and appear to be safe in most cases. The rate of development of hypocalcemia is related to the potency and dose of bisphosphonate. If unrecognized or poorly treated, hypocalcemia can lead to a life-threatening state. We report a patient who exhibited profound symptomatic hypocalcemia after receiving intravenous zoledronic acid as treatment for Paget disease.

Case description

We present a case of an 88-year-old caucasian woman who had recently been diagnosed with active Paget disease. She also had a history of primary hypoparathyroidism of unknown cause for which she was taking vitamin D, calcitriol and calcium supplements. The patient was assessed for calcium status prior to intravenous zoledronic acid therapy and was within the normal range. She came to the emergency department one week post-intravenous bisphosphonate treatment with generalized body ache, perioral numbness and acral paresthesias. There was also a description of muscle spasms and cramps at home by a family member. Physical examination was negative for Chvostek's and Trousseau's signs. Her corrected calcium level was low at 5.1 mg/dL. Magnesium, phosphorus and renal function were within the normal range. Alkaline phosphatase was elevated at 1120 U/L, related with biochemical active Paget disease. She was acutely managed with intravenous calcium gluconate. Therapeutic doses of oral calcium and vitamin D therapy were also initiated. After two days, the corrected calcium levels increased to 9.0 mg/dL and her symptoms remarkably subsided. She was discharged from the hospital and advised to continue oral supplements of calcium, vitamin D and calcitriol and to follow-up with her endocrinologist on a monthly basis.

Discussion

Most patients who developed symptomatic hypocalcemia following intravenous bisphosphonate had one or more risk factors predisposing them to low calcium levels. Despite accurate monitoring of plasma calcium levels at the time of zoledronic acid therapy for management of Paget disease, she had an underlying condition that impaired the homeostatic response to

bisphosphonates and contributed to the severe hypocalcemia. We call attention to the possible increase in the number of cases reported, particularly after the recent approval for their management in more common diseases like osteoporosis.

#728 - Case Report

MARINE-LENHART SYNDROME - A RARE CAUSE OF HYPERTHYROIDISM

Joana Maurício, Marta Arriaga Rocha, Susana Heitor, Ricardo Fonseca

Hospital Prof. Doutor Fernando Fonseca, Amadora, Portugal

Introduction

Marine-Lenhart Syndrome, described in 1911, is characterized by the coexistence of Graves' Disease and a functioning autonomous nodule (Plummer's Disease) or toxic multinodular goiter. This is a rare cause of hyperthyroidism, with a reported prevalence of 0.8-2.7% in patients with Graves' Disease.

Case description

We describe the case of an 88 years old female, with shortness of breath, exertional dyspnea, nonproductive cough, and edema of the lower limbs, with one-week duration. She also complained of diarrhea, dysphonia and heat intolerance, with six weeks duration. At physical examination, she presented with high blood pressure and tachycardia, arrhythmic cardiac sounds, crackles at lung bases and symmetrical lower limbs edema. She also had a slightly enlarged thyroid gland, with bilateral nodules that were difficult to delimit, and no signs or symptoms of ophthalmopathy. The complementary diagnostic exams showed an elevated NT-proBNP (2932 pg/mL), suppressed TSH (<0.005 mUI/L), elevated fT4 (3.34 ng/dL) and fT3 (14.3 pg/mL); the electrocardiogram revealed new-onset atrial fibrillation (AF) with a heart rate of 122 bpm; the chest radiography revealed interstitial edema. It was assumed the diagnosis of acute heart failure, in a patient with de novo AF, in a context of hyperthyroidism. It was initiated diuretic, beta-blocker and anticoagulation, as well as thiamazole therapy. The anti-TSH receptor antibodies (TRAb) was positive (27.8 UI/L). Thyroid ultrasound showed an enlarged thyroid gland, with a substernal goiter component, with a diffusely heterogeneous, multinodular echostructure. Thyroid gland scintigraphy with technetium-99m showed multinodular goiter with hyper and hypofunctioning nodules in both lobes. The diagnosis of Marine-Lenhart Syndrome was thus assumed. Although the patient had a formal indication for cold nodule cytology and definitive treatment, due to age, comorbidities and low-risk malignancy thyroid nodules, it was decided to maintain conservative thiamazole therapy and vigilance.

Discussion

Marine-Lenhart Syndrome is still a controversial and underestimated etiology of hyperthyroidism. Its identification importance is the need for definitive therapy with radioactive

iodine or total thyroidectomy. Although autoimmune testing and thyroid ultrasound pattern confirms the etiology of the majority cases of Graves' disease, scintigraphy with technetium-99m may be useful in selected cases of coexistence of multinodular goiter.

#751 - Case Report

PERSISTING HYPONATREMIA IN AN ELDERLY WOMAN: A SHEEHAN'S SYNDROME CASE

Carla Falcão, Rita Grácio, Gaspar Pereira, Pedro Neves Tavares, Catarina Duarte Santos, João Coucelo, Diana Fernandes
Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

Sheehan syndrome is a condition characterized by hypopituitarism due to necrosis of the pituitary gland caused by severe postpartum hemorrhage. Patients with this syndrome exhibit a variety of signs and symptoms that contemplate the varying degrees of anterior or, less commonly, posterior pituitary dysfunction resulting from the deficiency of multiple pituitary hormones. It may be manifested immediately postpartum, with a more severe presentation, or develop years after the delivery.

Case description

A 72-year-old woman, with a medical history of arterial hypertension, obesity and dyslipidemia, was admitted in the ER complaining of malaise, nausea, vomiting, anorexia, dizziness and fatigue for several months. She was being treated with aliskirene 300mg plus hydrochlorothiazide 12.5 mg, betahistine 24 mg and fenofibrate 145 mg, for arterial hypertension, dizziness and dyslipidemia.

Her blood panel was normal for glucose levels and renal function, but her sodium levels were low (125 mmol/L), as well as, the osmolality levels (266 mOsm/Kg), urine sodium and osmolality were high (64 mmol/L and 441 mOsm/Kg). She was treated with hyponatremia correction measures and referred to an internal medicine consultation. During follow-up, the patient admitted having had a past medical history of a severe hemorrhagic delivery of a stillborn child and research of hormone levels and brain MRI were performed. Her hormone levels were: TSH 2.66 μ UI/mL, free T4 5.2 pmol/L, free T3 3.5 pmol/L, cortisol 6.2 μ g/dL, ACTH 4.76 pg/mL, somatomedin C-IGF1 <25 μ 7L and normal levels of renin e aldosterone and the brain MRI showed a reduced asymmetric pituitary parenchyma. She responded well to the hormone substitution treatment.

Discussion

Hyponatremia approach to the elderly remains a challenge considering the innumerable possible causes, especially in patients taking diuretics. Being an obstetric complication, Sheehan's syndrome is not usually considered as differential diagnosis in older patients and might be overlooked and untreated. The past medical history is of the utmost importance and even the smaller details might make the difference.

#771 - Case Report

A CASE REPORT OF A 70 YEARS OLD WOMAN WITH FAMILIAL CHYLOMICRONEMIA SYNDROME

Virginia Esteve Luque¹, Isabel Rodrigues Gonçalves², Bernat Villanueva Cutillas¹, Lluïsa Guillem Tió¹, Xavier Pintó Salas^{1,3,4}, Xavier Corbella Virós¹

¹ Hospital Universitari de Bellvitge, Barcelona, Spain

² ABS Roquetes-Canyelles, Barcelona, Spain

³ Ciber-OBN, Barcelona, Spain

⁴ IDIBELL, Barcelona, Spain

Introduction

Familial chylomicronemia syndrome (FCS), is a rare autosomal recessive monogenic disease caused by mutations in genes that encode for key molecules: LPL, ApoA5, GPIHBP1, ApoC2 and LMF1.

Patient should be considered possibly affected by FCS when we see fasting triglycerides (TG) levels >10mmol/L, a ratio of total triglycerides to total cholesterol >2,2 mmol/L and low levels of apoB. Symptom onset is usually during childhood. Physical findings are eruptive xanthomas, lipemia retinalis and hepatosplenomegaly. Recurrent pancreatitis is often present and is the most life-threatening complication.

The mainstay for management of FCS is a severely restricted in fat diet which has a negatively impact on patient quality of life.

Case description

We report a 70y/o woman followed in our cardiovascular risk unit. She had one miscarriage followed by a stillbirth. During her third she had her first episode of acute hypertriglyceridemic pancreatitis (TG >33 mmol/L) under no treatment.

Throughout her medical record she had many other episodes of recurrent hypertriglyceridemic pancreatitis.

In order to achieve further dietary compliance the patient was hospitalized. Recommendations of dietary fat restriction and use of medium chain fatty acid were prescribed. Treatment with plasmapheresis was required on a couple of occasions managing reductions of triglycerides values. Other medications such as fibrates and niacin were previously prescribed with poor results. Family history of hypertriglyceridemia were found in her mother, brother and daughter.

Physical examination indicated esplenomegaly and lipemia retinalis.

Earlier diagnosis of chylomicronemia was made by the determination of LPL activity in plasma after an intravenous administration of heparin (<8%). Currently we are awaiting genetic analysis.

Nowadays she is under medical treatment with beta-fibrate.

Discussion

Our patient had typical findings of FCS: severe hypertriglyceridemia and acute relapsing hypertriglyceridemic pancreatitis.

In our case genetic analysis will shed light on the cause of the disease, detecting the mutation responsible.

The main focus of current therapy is low fat diet. Up until now existent medication were quiet ineffective except for plasmapheresis. Future medications are expected to be an important improvement.

This report aims to underline the importance of recognising manifestations in these individuals and the necessity to refer the patient to a lipids expert for further assessment.

#780 - Case Report

TETANY - A SERIOUS AND RARE PRESENTATION OF PRIMARY HYPERALDOSTERONISM.

Micaela Manuel, Andreia Tavares, Luisa Salgueiro, Raquel Almeida, José Meireles

Centro Hospitalar de Entre Douro e Vouga, Santa Maria Da Feira, Portugal

Introduction

Primary hyperaldosteronism is a frequent cause of secondary hypertension. Usual manifestations are resistant hypertension, hypokalaemia and metabolic alkalosis. Rarely, atypical manifestations can occur, such as myalgia, tetany or muscle paralysis, mimetizing neuromuscular diseases and making the diagnosis more difficult.

Case description

A 64-year-old man, physician, with a history of poorly controlled hypertension since he was 45 years old; currently was on nebivolol + hydrochlorothiazide (5 mg + 25 mg once daily). He had previously studied by a Neurologist for transient episodes of myalgia and muscle weakness, whose study included electromyography, muscle biopsy and genetic test for SCN4A, but the results were inconclusive.

In August/2018, he presented to the emergency department for myoclonus; the positive remarks of the physical examination were tetany and generalized fasciculations, blood pressure 197/102 mmHg; laboratory data revealed increase in serum muscular enzymes (creatinine phosphokinase 2250 U/L and myoglobin 788.6 ng/mL), renal impairment (creatinine 1.8 mg/dL), severe hypokalaemia (potassium 1.6 mmol/L) and hypomagnesemia (magnesium <0.25 mmol/L) and low ionized calcium (0.76mmol/L). He was admitted for correction of ionic disorders and hypertension control. A possible primary aldosteronism was suspected with further study showing a positive result for plasma aldosterone/renin ratio (ARR 142) and abdominal computed axial tomography showing heterogeneous nodular capillary formations in both adrenal glands. The saline overload test was positive, confirming the diagnosis of primary aldosteronism.

The patient was started on spironolactone, magnesium and potassium supplementation, with subsequent control of muscular symptoms and with blood pressure control to date.

Discussion

This clinical case demonstrates an atypical and severe presentation of an endocrine disorder - primary aldosteronism - with predominantly neuromuscular symptoms. Knowing the pathophysiology of the disease and its broad clinical spectrum may contribute to a timely diagnosis and appropriate treatment.

#790 - Abstract

PREVALENCE OF MICROVASCULAR COMPLICATIONS AMONG PATIENTS WITH DIABETES MELLITUS TYPE 2 AT A RURAL HOSPITAL IN NORTH GREECE

Triada Exiara¹, Dimitrios Tsiolpidis¹, Christina Kotsiari¹, Palmyra Tsiftsi¹, Asimina Migdalia¹, Chasan Ali¹, Elisavet Makridou¹, Savvas Katsaridis², Berkay Mollagiousoufoglou¹, Vasilios Tsipizidis¹, Argyrios Tsatsakoulis¹, Paschalis Karagiozakis¹

¹ General Hospital of Komotini, Komotini, Greece

² Alexander Technological Educational Institution of Thessaloniki Department of Nutrition and Dietetics, Thessaloniki, Greece

Background

Microvascular complications are the major outcome of Diabetes Mellitus Type 2 (DM2) which reduce the quality of life and increase diabetic mortality. The aims of this study were to assess the prevalence of microvascular complications among patients with DM2 in our area and to identify the association between these complications and clinical characteristics.

Methods

993 outpatients with DM2 and treatment for at least one year, 584 (58.8%) female and 409 (41.2%) male, with mean age of 56±8.7 years, were included. All subjects underwent a standard evaluation to detect diabetic retinopathy (fundus photography), neuropathy (vibration pressure threshold), and nephropathy (microalbuminuria/macroalbuminuria). Demographical, clinical and laboratory characteristics of patients registered and analyzed. Statistically analysis was done using SPSS version 20.

Results

332 (33.4%) patients had at least one microvascular complication and of those 187(56.3%) were female and 145 (43.7%) male. The prevalence of neuropathy, nephropathy and ocular lesions were: 172 (17.3%), 137 (13.8%) and 152 (15.3%), respectively. Of the 137 subjects with nephropathy conditions, 92 (9.3%) had single microalbuminuria, 16 (1.6%) macroalbuminuria, 12 (1.2%) renal hypofunction and 27 (2.7%) renal failure. Of the 152 subjects with ocular complications, 118 (11.9%) had cataract and 83(8.4%) retinopathy. 207 (62.3%) of the patients with microvascular complications had poor glycaemic control (HbA1c>7). The overall prevalence of complications significantly increased with disease duration, increasing age, female gender and presence of hypertension (p<0.001, p<0.001, p=0.002 and p<0.001, respectively).

Conclusion

Nearly one third of our patients with DMT2 had at least one microvascular complication. Disease duration, poor glycaemic control, age, gender and hypertension were associated with the presence of microvascular complications.

#793 - Case Report

AN ODD CASE OF PANHYPOPITUITARISM

Rita Gamboa Cunha¹, Mariana Certal¹, Ana Rafael¹, Ana Saavedra², Sandra Tavares¹

¹ CHTMAD - Hospital de Chaves, Chaves, Portugal

² CHTMAD, Vila Real, Portugal

Introduction

Hypopituitarism is a deficiency of one or more of the hormones produced by the pituitary gland. It usually occurs congenitally but it may also be acquired through replacement by tumors, infarction, infiltrative disorders, autoimmune diseases, trauma, and infections.

Case description

60-year-old Caucasian male with history of cranial multinevritis in October 2018 with a starting point on an acute sphenoidal sinusitis subjected to a sphenoidectomy. Since then he referred weakness, anorexia, weight loss and adynamia being committed twice, the first in December 2018 where he developed a hypovolemic shock due to a pseudomembranous colitis that evolved favorably. He was admitted in the emergency room in February 2019 with a loss of consciousness due to hypoglycemia. At observation he was confused, with slurred speech and a blood sugar level of 14 mg/dL. The head CT revealed no acute endocranial injuries. He was admitted in the ward to investigate the cause of the hypoglycemia. The laboratory studies revealed a panhypopituitarism (free T3 1.76 pmol/L, free T4 2.9 pmol/L, TSH 1.23 mUI/L, total testosterone 0.23 ng/mL, FSH 2.70 mUI/mL, LH 3.44 mUI/mL, PRL 12.0 mUI/L, ACTH 2.7 ng/L, cortisol 9.4 nmol/L, glucose 68 mg/dL, insulin 0.4 mcU/mL, C-peptide 0.20 ng/mL). He began hormonal therapy with cortisol and levothyroxine with no more episodes of hypoglycemia. The magnetic resonance imaging (MRI) discovered a lesion in the anterior lobe of the pituitary gland with 1x0.6 cm, that could be related with the previous inflammatory process given that the MRI of October showed an enlarged pituitary gland with contiguity to the sphenoidal sinus. The patient developed hypernatremia of 157 mEq/L that resolved without intervention 6 hours later. This sodium levels fluctuated, so the patient performed a fluid deprivation test. He presented an elevated seric osmolarity of 353 mOsm/L (>298 mOsm/L) 2h after the beginning confirming a diabetes insipidus and was administered 4mcg of desmopressin. Then the urinary osmolarity elevated > 9%, diagnosing the patient with partial central diabetes insipidus. He began desmopressin and was discharged maintaining the hormonal therapy.

Discussion

In this patient, we have a panhypopituitarism that, although

symptomatic, remained undiagnosed for at least 4 months. It is important to increase awareness among physicians of the risks of sphenoidal sinus diseases related with endocrinopathies and the need for appropriate endocrinological testing and substitutive therapies.

#795 - Abstract

PREVALENCE OF MACROVASCULAR COMPLICATIONS AMONG PATIENTS WITH DIABETES MELLITUS TYPE 2 AT A RURAL HOSPITAL IN NORTH GREECE

Palmyra Tsiftsi¹, Dimitrios Tsiolpidis¹, Christina Kotsiari¹, Chasan Ali¹, Elisavet Makridou¹, Asimina Migdalia¹, Savvas Katsaridis², Theodoros Kostakis¹, Bilal Bilal¹, Vasilios Tsipizidis¹, Berkay Mollagiousoyoglou¹, Argyrios Tsatsakoulis¹, Paschalis Karagiozakis¹, Alexandros Kakaris¹, Triada Exiara¹

¹ General Hospital of Komotini, Komotini, Greece

² Alexander Technological Educational Institution of Thessaloniki Department of Nutrition and Dietetics, Thessaloniki, Greece

Background

Chronic complications are the major outcome of diabetes mellitus type 2 (DMT2). Macrovascular disease that includes Coronary Heart Disease (CHD), Cerebrovascular Disease (CVD) and Peripheral Vascular Disease (PVD) is the leading cause of mortality in people with DM2. The aim of this study was to determine the prevalence and risk factors of macrovascular complications among patients with DM2 in our area.

Methods

993 outpatients with DMT2 and treatment for at least one year, 584 (58.8%) female and 409 (41.2%) male, with mean age 54±9.2 years, were included in this cross-sectional study. Cases were screened for macrovascular complications as per ADA criteria. Interviews, sociodemographical data, clinical characteristics and laboratory findings of patients registered and analyzed. Statistically analysis was done using SPSS version 20.

Results

274 (27.6%) patients had at least one macrovascular complication. The prevalence of CHD, CVD and PVD were: 231 (23.3%), 106 (10.7%) and 62 (6.3%), respectively. 581 (58.5%) patients had poor glycaemic control ((HbA1c>7) and 623 (62.7%) had hypertension. The risk factors for CHD were: hypertension (p<0.001), female gender (p=0.04), disease duration (p=0.002) and increasing age (p=0.04). The predictive risk factors for PVD were: male gender (p<0.001), increasing age (p<0.001), duration of diabetes (p<0.001) and hypertension (p=0.01). The risk factors for CVD were: increasing age (p=0.02), hypertension (p=0.001) and poor glycaemic control (p<0.01).

Conclusion

Nearly one third of our patients with DM2 had at least one

macrovascular complication and the most common is CHD. Greater awareness and screening to the macrovascular complications in patients with DM2 in our area is needed.

#806 - Abstract

AUTOIMMUNE PATHOLOGY AND DIABETES MELLITUS

Leonor Pereira Amaral¹, João Alves Correia^{1,2}

¹ Faculty of Health Sciences, University of Beira Interior, Covilhã, Portugal

² Sousa Martins Hospital, Guarda, Portugal

Background

The term autoimmune diabetes refers to a group of chronic diseases resulting from the interaction between genetic and environmental factors that predispose an individual to an abnormal immune response, which destroys beta cells, causes insulin deficiency and hyperglycemia. The destruction of these cells may be sudden in young people resulting in a permanent need for insulin (type 1 diabetes mellitus, DMT1) or be slower in adults, resulting in requiring insulin for at least 6 months after diagnosis (diabetes latent autoimmune in adults, LADA). The autoimmune process of pancreatic cells can progress and affect other organs, developing other autoimmune pathologies. This research aims to characterize the most frequently associated autoimmune diseases and emphasize the importance of its early detection.

Methods

An observational retrospective study was performed through consulting clinical processes of diabetic patients of the Internal Medicine and Pediatrics Service of the Sousa Martins Hospital from May 2018 to April 2019. All patients with a diagnosis of DMT1 and LADA were included in the study. The sample had 74 patients with DMT1 and 24 patients with LADA. Relevant data of the process were collected, such as, age, sex, age of the onset of diabetes, antidiabetic therapy, HbA1c, BMI, presence of autoantibodies and associated autoimmune diseases. The statistical analysis was performed using SPSS Statistics version 24.

Results

Autoimmune diseases were found in 24.32% of patients with DMT1 and in 41.67% of patients with LADA, affecting a total of 28 patients. Comparing the two groups, no significant difference was found regarding the percentage of patients with autoimmune diseases. The most common disease in the sample studied was autoimmune thyroiditis, found in 17 patients. Other diseases have also been reported, such as vitiligo, ulcerative colitis, autoimmune hepatitis, autoimmune gastritis, Graves' disease, systemic lupus erythematosus, rheumatoid arthritis and celiac disease. GADA-65 was the most common autoantibody, being more frequent in the LADA group (94.12%).

Conclusion

This study showed a high proportion of autoimmune diseases in

patients with autoimmune diabetes. Regular screening of these patients for autoimmune diseases is needed. Only the combination of demographic, immunological and genetic characteristics makes possible to increase the ability to predict autoimmune diseases associated with diabetes, which will allow better treatment and better glycemic control.

#807 - Case Report

RAPIDLY PROGRESSIVE DEMENTIA AS A MANIFESTATION OF INSULINOMA

Marília Santos Silva, Cristina Rodrigues

Hospital Pedro Hispano - Matosinhos local Health Unit, Matosinhos, Portugal

Introduction

The occurrence of repeated or persistent episodes of hypoglycemia in a well-nourished non-diabetic patient is not a common finding and demands careful evaluation.

Case description

Here is presented the case of an 84-year-old male patient, with progressive cognitive impairment being investigated at Neurology Consult, who is admitted to the Emergency Department with the diagnosis of respiratory and urinary sepsis and with hypoglycemia only controlled with glucose infusion at 30%, between 21 and 42 ml/h. The family mentioned progressively more frequent episodes of irritability and aggressiveness, followed by apathy, over the previous years. Those episodes appeared to be most frequent in periods of longer fasting and improved with sweetened water. Increased eating habits were also noted, with consequent weight gain. In the previous four months, interpersonal relations were minimized.

Considering the high index of suspicion for endogenous hyperinsulinism, insulin and C peptide were measured after permission of hypoglycemia, both being raised. Considering these findings, the diagnosis of insulinoma was assumed, with greater glycemic decontrol in the context of sepsis that came to be fatal to this patient.

Discussion

This case reminds us of the need to keep a high index of suspicion for this kind of diagnosis, easily mistaken for dementia, especially in the elderly. The early diagnosis may have a great impact on prognosis.

#808 - Case Report

SCHIMDT'S SYNDROME

Alejandra García García, Isabel Jimenez Hinarejos, John Molina Torres

Hospital General Universitario Gregorio Marañón, Madrid, Spain

Introduction

We present the case of a 39-year-old woman with hyperpigmentation, abdominal pain and hypothyroidism

Case description

We present a 39-year-old woman from Paraguay who was diagnosed 9 years ago with hypothyroidism and early menopause. She went to the emergency room due to a progressive clinical picture of nausea, vomiting and abdominal pain, associated with severe asthenia, loss of 11 kg of weight in the last 4 months.

On examination she has a blood pressure of 90/60 mmHg, mucosal hyperpigmentation at the gums, hard palate, peribuccal region and also on the back of both hands, feet, breast areoles and elbows.

Laboratory tests include sodium 126 mmol/L, potassium 5.7 mmol/L, standard high-dose ACTH stimulation test with basal and 60-minute after injection serum cortisol levels both <0.1 mcg/dL with baseline ACTH levels 397.7 ng/L confirming the diagnosis of primary adrenal insufficiency.

Other test included TSH levels 50.74mUI/L, free T4 0.7ng/dL, HbA1c 6.2%, Autoimmunity studies with anti-thyroglobulin antibodies > 4794 IU / mL, anti-TPO > 1542 IU / mL, anti-iodide peroxidase > 1130 IU / mL, anti-adrenal antibodies IFA positive 1/10 and study of celiac disease negative. The body CT-scan did not show adrenal or any other focal lesions.

Empirical treatment with hydrocortisone was started at a dose of adrenal crisis with symptom resolution.

Discussion

The autoimmune type 2 polyglandular syndrome, Schmidt's syndrome, is a disease with low prevalence that is characterized mandatory by the presence of primary adrenal insufficiency, thyroid autoimmune disease (usually chronic autoimmune thyroiditis but Grave's disease may also be present) and/or type 1 diabetes mellitus. As for the treatment, it is based on hormonal replacement therapy for each individual disorder.

#810 - Abstract

THE PREVALENCE OF SKIN DISORDERS IN TYPE- 2 DIABETIC PATIENTS IN A REGION OF NORTH GREECE

Christina Kotsiari¹, Dimitrios Tsiolpidis¹, Palmyra Tsiftsi¹, Vasilios Tsipizidis¹, Argyrios Tsatsakoulis¹, Elisavet Makridou¹, Chasan Ali¹, Paschalis Karagiozakis¹, Asimina Migdalia¹, Berkay Mollagiousoufoglou¹, Theodoros Kostakis¹, Savvas Katsaridis², Triada Exiara¹

¹ General Hospital of Komotini, Komotini, Greece

² Alexander Technological Educational Institution of Thessaloniki Department of Nutrition and Dietetics, Thessaloniki, Greece

Background

Patients with diabetes mellitus often show skin manifestations. The aim of this study was to evaluate the frequency of skin lesions in type-2 diabetic patients (DM2) in our area and their relationship with control of diabetes.

Methods

483 outpatients with DM2, 298 (61.7%) female and 185 (38.3%)

male with mean age of 57±13.6 years, during a three-year period, were included in this study. The mean duration of diabetes was 9±6.4 years. All patients underwent physical examination for detection of skin disorders with help of dermatologist and culture/biopsy of skin was performed when it was necessary. Hematological examinations and glycated hemoglobin were performed in all patients. Student's t-test was used for statistical analyses.

Results

332 (68.7%) patients had at least one skin disorder and 228 (68.7%) of them had poor glycaemic control (HbA1c>7.0). The lesions registered for the first time in 257 (77.4%) cases. 13 (64.2%) patients had a combination of skin lesions. The most frequent skin manifestations were: fungal infections in 187 (38.7%) cases, bacterial infections in 78 (16.1%), pruritus in 59 (12.2%), hyperkeratosis, skin xerosis, eczemas in 54 (11.2%) cases (mostly neurodermatitis), diabetic dermopathy in 92 (19.1%), acanthosis nigricans in 81 (16.8%) cases. Tinea pedis (82/187) was the commonest fungal skin infection followed by tinea unguium (63/187) and Candida albicans (42/187). Higher frequency of skin lesions was found to be associated to aging processes. Fungal infections were more common in patients with poor glycemic control.

Conclusion

Skin disorders are common with varied manifestations in patients with DM2. Systematic dermatological examination, frequent follow up and good glycemic control are the keys to confront the skin lesions in diabetics.

#832 - Case Report

CONN'S DISEASE WITH NORMAL ALDOSTERONE

Reem Musa, Loay Al Dhahir

Dr.Sulaiman Al Habib Medical Group, Riyadh, Saudi Arabia

Introduction

Primary hyperaldosteronism is a common cause of secondary hypertension and hypokalaemia, caused by aldosterone-producing adenomas or bilateral adrenal hyperplasias. It's an underdiagnosed cause of hypertension where diagnosis confirmed with elevated aldosterone to plasma renin ratio.

The authors present unusual case of hypokalemic hypertension but normal aldosterone despite frequent checking, finally diagnosis turns out to be Conn's syndrome as the patient cured with adrenalectomy and histopathology confirms Conn's.

Case description

41 years old Asian male, presents with recurrent symptomatic hypokalaemia required many hospital admissions for intravenous potassium despite being on oral supplement.

He reports no diuretic, laxative or alcohol abuse, no history of

chronic diarrhoea or vomiting. No family history of hypokalemic periodic paralysis and he is lifelong non-smoker.

Apart from hypertension normal physical examination, he started on Spironolactone with good blood pressure control and normal potassium level for 4 years.

The normal renin, cortisone along with normal examination and MRI put Cushing's, Liddle's and renal artery stenosis out of differential.

CT abdomen with contrast showed right adrenal lipid rich adenoma (1.7x1.23cm) with almost same size after 2 years, but again with normal aldosterone

Patient refused biopsy or adrenalectomy and prefers to continue on spironolactone. He responds well and after 4 years of conservative treatment agreed for surgical intervention although there was no guarantee that adrenalectomy will cure his condition. Laparoscopic Adrenalectomy done and histopathology reported as Adrenocortical adenoma, patient discharged home on no medications, follow up visits revealed normotension with normal potassium levels 6 months postoperatively.

Discussion

Conn's treated with adrenalectomy in those with unilateral disease. Bilateral adrenal hyperplasia or poor surgical candidates can be treated with mineralocorticoid antagonists and antihypertensive. Morbidity and mortality are related to hypertension leading to cardiovascular disease or hypokalemia induced arrhythmias.

We report that Conn's disease may presents with hypokalemic hypertension despite normal aldosterone and the standard management remains effective.

#870 - Case Report

SUNCT SYNDROME SECONDARY TO MACROPROLACTINOMA

Carolina Paiva, Paulo Carvalho Ferreira, Filipe Correia, Helena Greenfield, Raquel Santos, Rui Mõço

Hospital Pedro Hispano, Matosinhos Local Health Unit, Matosinhos, Portugal

Introduction

Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) is usually a primary headache disorder. However, some cases are potentially secondary to intracranial lesions, mostly of them located in the posterior fossa or in the pituitary gland. Regarding this last one, it has been described in patients both with micro and macroadenomas, with attacks occurring on the side ipsilateral to the site of the tumor.

Case description

The authors present a case of a 48-year-old male, with no relevant pathological history, who presented to the emergency department with complaints of pain with about 2 months of evolution in the left wing of the nose with irradiation to the ipsilateral supraorbital region, with "saw-tooth" attacks of

continuous pain with multiple superimposed stabs. In association he reported nasal obstruction, rhinorrhea, and lacrimation of the left eye. At the objective examination, nothing to be highlighted. Cerebral magnetic resonance imaging was performed and showed an expansive lesion of larger diameters 29x39x45 mm with left parasellar extension, compatible with pituitary macroadenoma. The hormonal study revealed hyperprolactinemia of 13427.44 ng/mL with LH decreased 0.47 mUI/mL and without further changes (TSH: 1,029 uUI/mL, FT3: 2.25pg/mL, FSH: 1.55mUI/mL, PTH: 30.8pg/mL, ACTH: 26.17pg/mL). He was medicated with dopaminergic agonist in an increasing dose up to 1mg 2x/week. At three months of follow-up without new episodes of headache and runny nose; analytically with prolactin in descending profile 2482,83 ng/mL, and normalization of LH 1.61 mUI/mL; Brain imaging showing a reducing size prolactinoma 36x34x24mm.

Discussion

The diagnosis of SUNCT is based on clinical history and the semiology of the headache presented here is highly suggestive. Medical treatment of the prolactinoma led to a resolution in headache symptoms, that were ipsilateral to the lesion. This suggests that the prolactinoma was triggering the symptoms.

#901 - Abstract

PREVALENCE OF MICROVASCULAR COMPLICATIONS AMONG PATIENTS WITH NEWLY DIAGNOSED DIABETES MELLITUS TYPE 2 IN OUR AREA

Dimitrios Tsiolpidis¹, Palmyra Tsiftsi¹, Christina Kotsiari¹, Savvas Katsaridis², Berkay Mollagiousoufoglou¹, Asimina Migdalia¹, Elisavet Makridou¹, Vasilios Tsipizidis¹, Theodoros Kostakis¹, Paschalis Karagiozakis¹, Argyrios Tsatsakoulis¹, Bilal Bilal¹, Triada Exiara¹

¹ General Hospital of Komotini, Komotini, Greece

² Alexander Technological Educational Institution of Thessaloniki Department of Nutrition and Dietetics, Thessaloniki, Greece

Background

Diabetes Mellitus Type 2(DM2) is associated with an increased risk for a number of serious macrovascular and microvascular complications which reduce the quality of life and increase diabetic mortality. The aim of this study was to determine the prevalence and clinical profile of microvascular complications in newly diagnosed DM2 patients in our area.

Methods

118 newly diagnosed DM2 patients according to ADA criteria, 67 (56.8%) female and 51 (43.2%) male with mean age of 52.7±9.4, during one-year period, were included in this cross-sectional study. All subjects underwent a standard evaluation to detect diabetic retinopathy (fundus photography), neuropathy (vibration pressure threshold), and nephropathy (microalbuminuria/macroalbuminuria). Demographical, clinical and laboratory data

of patients registered and analyzed. Statistically analysis was done using SPSS version 20.

Results

67 (56.8%) patients had at least one microvascular complication. The prevalence of neuropathy, nephropathy and retinopathy were: 19 (16.1%), 38 (32.2%) and 29 (24.6%) respectively ($p=0.358$, $p=0.003$ and $p=0.02$, respectively). Of the 38 subjects with nephropathy conditions, 33(28%) had single microalbuminuria, 5 (4.2%) macroalbuminuria and 3(2.5%) renal hypofunction. 27 (22.9%) cases had nonproliferative diabetic retinopathy and 2 (1.7%) cases had proliferative retinopathy. 89(75.4%) patients had poor glycaemic control ($HbA1c>7$). Incidence of retinopathy and nephropathy was significantly higher in patients who had $HbA1c>7\%$ than patients with $HbA1c\leq 7\%$ ($p<0.05$).

Conclusion

Nearly half of our patients with DM2 had at least one microvascular complication at diagnosis. There is high prevalence of nephropathy and retinopathy at diagnosis of DM2, which is statistically significant. Screening all newly diagnosed DM2 patients for complications is essential to identify them at an early reversible stage.

#952 - Case Report

LIFE-THREATENING ANTACID? A CASE OF EXTREME METABOLIC ALKALOSIS

Estela Ferrão, Francisca Pulido Valente, Rodrigo Pereira Andrade, Maria José Grade, Luísa Arez
Algarve University Hospital Center; Hospital de Portimao, Department of Internal Medicine, Portimão, Portugal

Introduction

Although metabolic alkalosis is a common electrolytic disturbance, its extreme form is not as common. A serum pH higher than 7.6 is associated with a mortality rate up to 80%.

There is a wide differential diagnosis concerning this condition. The diagnosis is particularly difficult in the absence of a reliable clinical history and if concurrent comorbidities act as potential confounding factors.

Case description

A hypertensive 50-year-old man was brought to the Emergency Room because of a 2 weeks history of vomiting, diarrhea, decreased oral intake, weight loss and general weakness. He had a generalized tonic-clonic seizure on admission.

The wife reported he had been intermittently taking an antacid (sodium bicarbonate) for the last 10 years, sometimes in a daily basis, to relieve pyrosis due to an alleged not treated peptic ulcer. On physical examination described as disoriented, confused. BMI 19. Sunken eyes, dry skin and mucous membranes. Anuric.

Laboratory results: urea 80 mg/dl, creatinine 4.2 mg/dl. ABG test (ambient air): pH 7.7 pCO_2 64 mmHg, pO_2 37 mmHg, K^+ 2.9 mmol/l HCO_3^- 82 mmol/l

Abdominal X-ray, ultrasound and CT: signs of gastric and duodenal distension.

ECG: Sinus rhythm, QT prolongation.

Head CT: no alterations.

He was transferred to the intensive care unit with severe volume depletion and hydroelectrolytic disturbance, and an acute oliguric kidney injury with acute tubular necrosis, requiring intravenous HCL and dialysis. After an extensive investigation a definitive diagnosis of metabolic alkalosis caused by sodium bicarbonate intake was made.

Discussion

This case highlights how challenging the differential diagnosis of metabolic alkalosis can be, and the importance of obtaining a reliable clinical history.

The difficulty obtaining the definitive diagnosis was worsened because the triad of hypertension, metabolic alkalosis and hypokalemia pointed to the possible presence of an aldosterone-producing tumor among other conditions.

The dyspepsia and past ulcer history suggested a pyloric stenosis. It also emphasizes the dangers of over-the-counter medicines, assumed as not having medical significance and that can be life threatening and culminate in death. Because of its availability without a prescription, the use of antacids is common and must be considered as a potential cause of metabolic alkalosis, especially if there is a history of dyspepsia or gastro esophageal reflux.

#959 - Abstract

DEVELOPMENT OF METABOLIC SYNDROME IS ASSOCIATED WITH BIOLOGICAL AGING PROCESS

Beom Jin Kim¹, Hyun Kang¹, Sang-Jung Kim²

¹ Chung-Ang University Hospital, Seoul, South Korea

² Bundang Jesaeng Hospital, Seongnam, South Korea

Background

Metabolic syndrome (MetS) is a cluster of metabolic abnormalities, which increase with age. Biological age (BA) determined by physiology reflects the functional state of the body. To date, no worldwide studies have been conducted to estimate the clinical utility of BA as a new indicator in MetS.

Therefore, the aim of the present study was to evaluate the development of MetS in terms of biological aging.

Methods

A consecutive series of asymptomatic subjects aged ≥ 30 years who underwent routine check-ups were enrolled. Clinical profiles such as physical, biochemical, and hormonal parameters for calculating BA were collected. BAs were calculated using the MEDIAGETM Biological Age Measurement System. Specially, body shape BA was calculated as following: $-137.388 + 224.964$ (Waist-hip ratio) $- 0.245$ (Height) $+ 0.631$ (Hip circumference) $- 0.2$ (Lean body mass%) $- 0.123$ (Waist circumference). This measurement system

has been used as an adjunctive measure for easily predicting individual differences in health and aging status with the use of clinical parameters that are commonly used at many health check-up centers in Korea.

Results

A total of 2,677 subjects were investigated. The mean chronological age (CA) was 46.0 years and the mean BA was 44.7 years. MetS was diagnosed in 216 subjects (8.1%). The prevalence of MetS increased with increasing BA ($P < .001$). Especially, the gradient of prevalence of MetS in BA was higher than that in CA. When the subjects were divided into two groups based on an age gap between BA and CA, Biologically older group ($BA-CA \geq 0$) and biologically younger group ($BA-CA < 0$), the incidence of MetS in the biologically older group was significantly higher than in the biologically younger group ($P < .001$). When the subjects were categorized into quartiles according to age gap between BA and CA, the prevalence of MetS increased with increasing quartiles of age gap between BA and CA ($P < .001$).

Conclusion

Development of MetS is affected by biological aging process. Therefore, measurement of BA may help to estimate the risk of MetS among the general population.

AN UNUSUAL CAUSE OF DYSPNEA.

Sandra Piqueras Ruiz, Lucía Ordieres Ortega, Sergio De Santos Belinchón, Juan Carlos Cano Ballesteros
Hospital General Universitario Gregorio Marañón, Madrid, Spain

Introduction

Graves-Basedow disease (GBD) is an autoimmune disease, which is the most frequent cause of hyperthyroidism. We present a case with one of the less common symptoms, pulmonary hypertension, sometimes difficult to diagnose if thyroid symptoms are scarcely present.

Case description

A 74-year-old male with a medical history of gastroesophageal reflux disease (GRD) arrives at the Emergency Department with a main complaint of progressive dyspnea in the previous two weeks, chest pain (similar to his previous GRD episodes), odynophagia, dizziness and a constitutional syndrome with unquantified weight loss.

Upon physical examination, he presented an oxygen saturation of 91%, sinus tachycardia of 120 bpm and bibasal crackles. An electrocardiogram confirmed sinus tachycardia, a chest X-ray and blood test were normal (NT-proBNP 94 pg/ml).

The patient was admitted into the Internal Medicine ward to complete the study. A transthoracic echocardiogram showed the existence of pulmonary arterial hypertension (PAH), with a pulmonary artery pressure of 58 mmHg. A computerized

tomography (CT) of the pulmonary arteries relinquished the presence of pulmonary thromboembolism. A spirometry showed mild airflow obstruction (Tiffeneau Index 73%), with a negative bronchodilation test. A blood test exhibited primary hyperthyroidism (TSH < 0.01 ng/dl, T4 7.5 ng/dl), with positive antithyroid antibodies (Ac-anti-TPO 332.3 IU/ml, Ac-Anti-TSH 10.2 IU/L). A thyroid gammagraphy was thus performed, demonstrating diffuse hypercaptation compatible with GBD. The patient presented a good clinical and symptomatic evolution, after the initiation of antithyroid and beta-blockers treatment. He is currently asymptomatic.

Discussion

Although GBD is a common cause of hyperthyroidism, it may present with rare manifestations, including the one presented in this manuscript. An association between PAH and hyperthyroidism has been described, and PAH may be detected in up to 40% of patients with thyroid dysfunction. However, the treatment of thyroid disease can improve PAH, and for this reason, in patients with an unknown etiology of PAH, thyroid dysfunction should be ruled out.

#980 - Case Report

PITUITARY APOPLEXY AFTER ACUTE PULMONARY THROMBOEMBOLISM

Rute Sousa Martins, Sara M. Rocha, Fátima Farinha
centro hospitalar universitário do Porto, Porto, Portugal

Introduction

Pituitary apoplexy is a rare, life-threatening syndrome caused by acute pituitary hemorrhage or pituitary infarction, usually in an adenoma pituitary gland; it can occur acutely, with headache, neuro-ophthalmological symptoms and death, or subacute with evolution from days to weeks.

Case description

A 65-year-old woman with dyslipidemia, obesity, and degenerative osteoarticular disease, admitted to the emergency department for dyspnoea and chest pain; was diagnosed with a acute pulmonary thromboembolism at intermediate risk of mortality, having started hypocoagulation (low molecular weight enoxaparin). On the 5th day of hospitalization cephalic and paresis clinic of the third right pair, having EC MRI that revealed pituitary hemorrhage, apparently grafted previously unknown macroadenoma. It was evaluated by Neurosurgery, with indication for emergent surgery, but for suspension of hypocoagulation and insertion of vena cava filter. After serial evaluations and for maintaining stability of hemorrhagic lesion, returned to treatment with oral hypocoagulation. Evolution with hypopituitarism with anterior pituitary attainment and the need to initiate supplementation with levothyroxine and hydrocortisone (initiation of intravenous later orally). Table of polyuria-polydipsia of post-event onset, it was not possible to carry out the water restriction test (logistic question). Suspicious of central diabetes insipidus, and therefore

initiated desmopressin with improved symptomatic. She was highly oriented to ophthalmology reassessment consultation, neurosurgery and endocrinology.

Discussion

Pituitary apoplexy is a potentially fatal neuroendocrine emergency that requires immediate therapy. This entity must always be considered as a differential in a patient who presents with sudden, intense headache and neuro-ophthalmologic. A multidisciplinary approach, as described in the above case, is treatment and follow-up.

A CASE OF KIKUCHI FUJIMOTO DISEASE AND QUERVAIN'S THYROIDITIS

Liliana Filipa Ribeiro Dos Santos, Ana Teresa Melo*, Ana Fúrao Rodrigues, Rita Pinto Medeiros, Ana Paula Vilas
Serviço de Medicina 2B- Hospital de Santa Maria - Centro Hospitalar Lisboa Norte, Lisboa, Portugal

Introduction

The association of weight loss, fever and enlarged lymph nodes may be due to several clinical conditions, mainly infectious diseases or lymphoproliferative and autoimmune disorders. Diagnosis is often difficult and a long term follow-up is warranted.

Case description

A 36-year-old Indian woman was referred to our Internal Medicine Department because of an one-month history of fatigue, weight loss, fever, sore throat and dry cough, along with multiple cervical painful lymphadenomegalies. An atypical upper respiratory infection had been suspected and azithromycin had been prescribed with no improvement. On examination, she had a painful stone-like mass on her central lower neck and some rubbery nodules in the left antero-lateral cervical lymph nodule chain. Her blood tests showed a persistent elevation of inflammatory markers (CRP 7.64 mg/dL and ESR 120mm/hr) and a new onset hyperthyroidism (TSH 0.017 uU/dL (RV 0.30-4.2); FT4 2.86 ng/dL (RV 0.93-1.7) with negative thyroid antibodies. On the prior year she had been diagnosed with lymph node tuberculosis (TB) and she had been treated with isoniazid, rifampicin, pyrazinamide and ethambutol with complete remission. TB recurrence and thyroid TB were therefore suspected. Investigation, however, ruled out tuberculosis. The neck ultrasound scan showed a heterogeneous and infiltrative thyroid and adenomegalies on the left antero-lateral cervical chain. The CT scan only showed another 2cm adenopathy on the celiac territory. The histological study of the fine-needle aspiration of the neck mass diagnosed a subacute thyroiditis (Quervain's thyroiditis) and immunophenotyping excluded a lymphoproliferative disorder. She was discharged but a couple of weeks later new tender lymph nodes appeared on the neck. An excisional biopsy of the largest nodule diagnosed necrotizing histiocytic lymphadenitis (Kikuchi Fujimoto's disease). Remission was achieved only with symptomatic treatment.

Discussion

Kikuchi-Fujimoto's disease (KFD) is a rare, benign and self-limited disease. The etiology and pathogenesis of KFD is still not completely understood. However, two hypothesis have been proposed: a viral infection hypothesis and an autoimmune hypothesis. In the presented case, a viral infection is the probable trigger for both diseases, KFD and Quervain's thyroiditis. Although there are several reports on the association of autoimmune thyroiditis and KFD, this is, as far as we know, the first case of KFD in a patient with QT.

IMPACT OF DEMOGRAPHIC AND CLINICAL CHARACTERISTICS ON DIABETIC NEUROPATHY

António José Santos Assunção¹, Dina Manuela Soeiro Marinho De Campos², Rui Marques³, César Matos⁴, Patrícia Santos⁵, Ana Teresa Bogalho Rebelo⁶, Inês Cunha³

¹ USF Viriato, Mundão, Portugal

² USF Viriato, Viseu, Portugal

³ Centro Hospitalar Tondela Viseu, Viseu, Portugal

⁴ UCSP Azeitão, Azeitão, Portugal

⁵ USF Sobreda, Almada, Portugal

⁶ USF Cidade Jardim, Viseu, Portugal

Background

Diabetic neuropathy is one of the most devastating complications of diabetes; however, unlike other countries, there aren't any studies to evaluate the impact of the demographic and clinical characteristics of this pathological entity in Portugal. The present study aimed at evaluating the impact of gender, age, metabolic control, and onset of disease with symptoms of neuropathic pain.

Methods

This study was conducted on a sample of 359 patients from several medical centers. Data was analyzed using a quantitative method, with the statistical software package Statistical Package for Social Science 24. The p value defined to consider a statistically significant result was $p < 0.05$. To determine the relationship between categorical variables, the Spearman correlation coefficient (r) was determined.

Results

There was no statistically significant difference in the prevalence of diabetic neuropathy between gender ($p=0.633$ and $r=0.025$). There was a statistically significant correlation between the value of HbA1c and diabetic neuropathy, with $p=0.010$ and $r=0.136$. There is a correlation between the age and symptoms of neuropathic pain, with a $p=0.034$ and $r=0.112$. Furthermore, there is a correlation between time since onset of disease and symptoms of neuropathic pain, with a $p=0.020$ and $r=0.112$.

Conclusion

The prevalence of neuropathic pain in diabetics is not negligible

and is associated with modifiable risk factors, thus being preventable. The correct approach of these patients implies screening and early treatment and contributes decisively to the improvement of functionality and life quality.

#1029 - Abstract

MULTICENTER STUDY: REGISTRATION OF HYPERGLYCEMIA IN INTERNATIONAL INTERNAL MEDICINE (REGLUMI)

Pascual Valdez¹, Darío Leff¹, Julio Wacker¹, Andrea Odzak¹, Luis Alberto Cámara², Mauricio Fiori², José Daher², Oscar Caravelo², Diana Fernandez², Adrian Cruciani², Carlos Perez², Cecilia Vanzetti², Martina Calvo², Pablo Kuschner², Cristian Panigadi², Paula Castro², Ana Cantillo²

¹ Research Council of the Argentine Society of Medicine (SAM), Caba, Argentina

² Research Council of the Argentine Society of Medicine (SAM), Buenos Aires, Argentina

Background

Objectives is to determine the prevalence of hyperglycemia in patients admitted to a medical clinic.

Methods

Prospective-observational-longitudinal-analytical study. Included are patients admitted to a medical clinic, multicenter study in 42 centers, with 2 years of recruitment. Consecutive sampling.

Results

Recruited 5925. Male gender 50.3%. Age 60.66 ± 0.25 years. Stay 12.61 ± 0.24 days, higher in surgery (15.45 ± 0.67 vs 11.76 ± 0.23, $p < 0.00001$). 23% received surgical treatment. Mortality 9.26%. BMI: 27.88 ± 0.65. 41.4% presented hyperglycemia more than once. Mean higher glycemia: 163.50 ± 1.23 (in DBT 2: 255.39 ± 3.04, in DBT 1: 199.81 ± 15.12). Mortality was higher with blood glucose higher than 110 ($p < 0.02$). Required Insulin: 31.37%. Corticosteroids use: 25.40%. Corticosteroids were associated with greater insulin use (35.34% vs 30.02%, $p < 0.0001$) and more infections (45.98% vs 42.01%, $p < 0.007$). Glycosylated Hb: 7.92 ± 0.08 (8.44 ± 0.09 in known diabetics and 9.63 ± 0.31 in unknown). 46% were categorized as normoglycemic, 4% as stress, 21% were not typified, 29% were diabetes. The use of insulin was associated with more symptomatic hypoglycemia (3.44% vs 0.44%, $p < 0.00001$) and asymptomatic hy

Conclusion

Conclusions: prevalence of hyperglycemia 54%, several new diagnoses of diabetes. Diabetes was not predictive of mortality in the multivariate analysis.

FROM HYPO TO HYPERTHYROIDISM - AN INCARCACTERISTIC EVOLUTION

Vanda Conceição, Alexandra Ávila, José Sousa, Nuno Vieira, Maria José Grade, Luisa Arez

Serviço de Medicina 3 - Unidade Hospitalar de Portimão do Centro Hospitalar Universitário do Algarve, Portimão, Portugal

Introduction

Toxic thyroid adenoma is one of the major etiologies of hyperthyroidism, as well as Graves' Disease and the Toxic Multinodular Goiter and it can be defined as a functioning autonomic nodule. Clinically and analytically similar to other forms of thyrotoxicosis. This diagnosis is confirmed by the presence of a warm nodule in thyroid scintigraphy. The timely treatment allows the avoidance of complications of hyperthyroidism, such as cardiac dysfunction, loss of bone mass or tracheal compression caused by large nodularities.

Case description

A 65-year-old woman, with comorbidities of Arterial Hypertension, Dyslipidemia and Depressive Syndrome, had a history of Hypothyroidism and Multinodular Goiter diagnosed 10 years ago and medicated daily with 200 µg of levothyroxine. In July 2018 she began to suffer from dyspnea, sensation of a foreign body and dysphagia, anxiety and palpitations. Analytically with evidence of de novo hyperthyroidism (TSH 0.01 µUI / mL, T4L 18.79 ng / dL), for which Levothyroxine was discontinued.

The thyroid ultrasonography revealed the right lobe mostly occupied with nodular lesion of a solid isoecogenic component with 36mm. Reassessment of thyroid function 3 months after suspension of levothyroxine revealed persistence of hyperthyroidism (TSH 0.02 µIU / mL, T4L 18.5 ng / dL and Negative antithyroid antibodies).

For better clarification it was used the Thyroid Scintigraphy that demonstrated a voluminous hot nodular formation to the right that slows the surrounding tissue (Autonomous Node), thus diagnosing the new appearance of a Toxic Adenoma with Hyperthyroidism in previously hypothyroid patient. It was initiated anti-thyroid therapy. With clinical and analytical improvement.

Discussion

Primary hyperthyroidism de novo in a previously hypothyroid patient, associated with the appearance of a toxic adenoma as occurred in this case, is an uncharacteristic and rare development in patients with chronic hypothyroidism. However, this case alerts us to the importance of the clinical and analytical monitoring of these patients, since a rapid investigation and its therapeutic adjustment will allow us to reach the euthyroid state more quickly, avoiding the complications associated with the thyroid dysfunction.

#1066 - Case Report

QUERVAIN'S THYROIDITIS MANIFESTED AS AN INDETERMINATED FEBRILE SYNDROME

Vanda Conceição, Alexandra Ávila, José Sousa, Nuno Vieira, Maria José Grade, Luísa Arez

Serviço de Medicina 3 - Unidade Hospitalar de Portimão do Centro Hospitalar Universitário do Algarve, Portimão, Portugal

Introduction

Thyroiditis of Quervain is an inflammatory condition of the thyroid, probably of viral etiology. This diagnosis is complicated, because of the great variability of presentation, which can range from hyper to hypothyroidism, associated with systemic symptoms and cervical pain. We present a case that stands out for its exuberant presentation as a persistent febrile syndrome with intense systemic repercussion.

Case description

A 52-year-old woman, with no comorbidities or any relevant previous medical history, started a high fever, predominantly in the evening, accompanied by profuse sweating, malaise, myalgias and migratory polyarthralgia without inflammatory signs. She also mentioned anterior cervical pain and odynophagia. The observation points out an increase in the cervical perimeter and palpable cervical adenomegalies.

In ambulatory, the blood analyses revealed clinical hyperthyroidism with anti-thyroid negative antibodies. Thyroid ultrasound showed an heterogeneous thyroid with thyroid nodules and cervical adenomegalies. The aspiration cytology revealed a follicular lesion of undetermined significance and a Thyroid Scintigraphy demonstrated generalized hypocaptation. The hypothesis of primary hyperthyroidism due to destructive thyroiditis was chosen and the patient started symptomatic treatment with nonsteroidal anti-inflammatory drugs.

There was an unfavorable evolution with persistent fever and a breakdown of the general condition of the patient that led to her hospitalization at the end of one month of fever to exclude other causes for the febrile syndrome. The study was negative for other causes. The fever subsided after about two and a half months coinciding with the improvement of complaints of cervical pain. Analytically, clinical hyperthyroidism evolved to clinical hypothyroidism and finally the patient became euthyroid, without the need for anti-thyroid or levothyroxine therapy.

Discussion

The present case is illustrative of Quervain Subacute Thyroiditis, which typically presents by the association of cervical pain, systemic symptoms and three - phase evolution of thyroid function (Hyper - Hypo - Euthyroidism). However, the intensity and persistence of fever and other systemic symptoms that justify the differential diagnosis with other conditions associated with a febrile syndrome of undetermined origin are emphasized.

#1082 - Case Report

DIABETIC KETOACIDOSIS, IN THE CONTEXT OF SGLT2 INHIBITORS - ABOUT A CLINICAL CASE

Rosana Maia, Marta Moreira, Pedro Pinto, Miguel Costa, Duarte Silva, Edgar Torre, Carmélia Rodrigues, Diana Guerra

ULS Alto Minho - Hospital de Santa Luzia - Viana do Castelo, Viana do Castelo, Portugal

Introduction

Inhibitors of SGLT2 (iSGLT2) lower serum glucose levels through urinary excretion, and are recommended for the treatment of Type 2 Diabetes Mellitus (DM). Diabetic ketoacidosis (CAD) in the context of these drugs is rare, with an incidence of 1/1000 people/year.

Case description

Female, 67 years old, with type 2 DM and dyslipidemia, treated with empaglifozine 25 mg and atorvastatin 20 mg, is referred to the Emergency Department for nausea, polydipsia, asthenia and malaise. At the previous day, vomiting, followed by dizziness, with a fall, without loss of consciousness. In addition, chest pain, palpitations, dyspnoea and hypersudoresis. In the prehospital evaluation by emergency medical team, Atrial fibrillation (AF) with rapid ventricular response (RVR) was identified, with frequency control after metoprolol. Physic examination: dehydrated and polypnea. Blood pressure 126/70 mmHg, oxygen saturation (SatO₂) 96% (FiO₂ 21%), glycemia 317 mg/dL. Cardiac Auscultation (A): S1 and S2 present, arrhythmic. Pulmonary A: normal. Analysis: Hgb 16.3 g/dL, Leukocytes 11.92x10⁹/L, Platelets 274x10⁹/L, Urea 49 mg/dL, Creatinine 1.18 mg/dL, Glucose 326 mg/dL, normal hepatic profile and myocardial necrosis markers. Venous gasometry: pH 6.97, pCO₂ 24 mmHg, HCO₃ 5.5 mmol/L, Lactates 4.4 mmol/L. Urinary sediment with ketone bodies and glucose. Abdominal ultrasound: possible focal steatosis. Admitted to the Intermediate Care Unit for CAD, in the context of empaglifozine intake, with the follow possible triggers - AF with RVR and dehydration. Fluidotherapy, insulin and sodium bicarbonate were initiated, with clinical and analytical improvement, and later transferred to Medicine Service on the 4th day of hospitalization. At the time of discharge, gasometry without acidemia (pH 7.52) and HgbA1C 8.3%. There were made teachings of insulin administration and dabigatran was initiated. Follow up: HgbA1C 7% without complaints. Metformin was initiated and discharged to follow up with the family doctor.

Discussion

CAD occurs more frequently in women, and is a potentially life-threatening disease. Given that iSGLT2 is a pharmacological class with clinical potential in the approach to type 2 DM and in the reduction of cardiovascular events, it is important not to forget the possibility of the occurrence of CAD as a rare adverse event, its non-hyperglycemic presentation, as well as the identification of possible triggering factors.

#1085 - Case Report

NEUROLOGICAL COMPLICATIONS OF DIABETES

Vera Seara, Juliana Chen Xu, Gonçalo R. Mesquita, Sónia Da Costa Fernandes, Lilian Maia, Teresa Pinto
CHPVVC, Vila Do Conde, Portugal

Introduction

Neuropathy is one of the most frequent and disabling complications of diabetes mellitus. Diabetic mononeuropathies can affect cranial, peripheral nerves or nerve roots.

Case description

A female aged 54 with a 10-year history of uncomplicated type 2 diabetes mellitus reported severe occipital headache of sudden onset and constant for 2 weeks. The squeezing pain was relieved after taking paracetamol. She also complained of blurred vision and polyuria, polydipsia and polyphagia. Her previously controlled glycemia had become uncontrolled for four months (HbA1c 7,9%). The neurologic assessment revealed horizontal rotary nystagmus on levoversion, horizontal diplopia on fatigue tests and right internuclear ophthalmoparesis, as well as right dysmetria in the finger-to-nose test and instability on the heel to toe and tandem gaits. The ophthalmic examination excluded diabetic retinopathy. The blood tests showed hyperglycemia (576 mg/dl) and glycosuria with no other abnormalities, namely normal immune and thyroid function test, negative HIV, HBV, HCV markers and VDRL. The cerebral CT scan, MRI and MR angiography were normal, as well as the thoracoabdominopelvic CT. Myasthenic syndromes were excluded with normal electromyography studies and negative anti-acetylcholine receptor and muscle-specific kinase antibodies. CSF excluded central nervous system infection and the oligoclonal bands were negative. Treatment with amitriptyline 10mg daily was started. Glycemic control was achieved by starting insulin. A progressive weaning was possible, and the patient was discharged on oral antidiabetic medication. On the one month follow up, there was total relieve of the headache and vision complains and optimal metabolic control. The exclusion of other causes led to the diagnosis of diabetes associated neuropathy.

Discussion

Diabetes causes a wide variety of acute, chronic, focal, and diffuse neuropathy syndromes that usually happen in older individuals with longer duration of diabetes and are related with bad metabolic control.

This case demonstrates that although uncommon, diabetic neuropathy should be considered in the presence of signs and symptoms of cranial nerve disturbance when other causes are excluded. It also shows that in acute presentations, a good glycemic control can reverse the nerve injury. Treatment of painful diabetic neuropathy includes tricyclic antidepressant drugs, such as Amitriptyline and has a therapeutic effect within 2-6 weeks.

#1086 - Case Report

ALLGROVE SYNDROME IN THE PRACTICE OF ENDOCRINOLOGIST

Natalya Volkova, Ilya Davidenko, Igor Reshetnikov, Snezhana Brovkina
Rostov State Medical University, Rostov-On-Don, Russia

Introduction

Allgrove syndrome (triple A syndrome) is a rare autosomal recessive multisystem disease characterized by adrenal insufficiency, alacrimia and achalasia. It is caused by a mutation in the AAAS gene (12q13) encoding the protein ALADIN. This syndrome is often associated with neurological dysfunction. Prevalence:<1/1000000. The first description was in 1978.

Case description

18 years old, appealed to the city endocrinological center with complaints of fatigue, weakness, darkening of the skin. Anamnesis of life: born from the first pregnancy without complications, weight 3200g. Parents often turned to the pediatrician with complaints: lethargy, frequent regurgitation, ARVI up to 6-7 times a year. Objectively he noted slow weight gain, dyspeptic syndrome (nausea, vomiting). At the age of 3, the boy entered the surgical department with acute abdomen, fever, vomiting. Achalasia was revealed, reconstructive surgery was carried out. In the diagnostic search for the causes of body weight loss he was directed to the endocrinologist. There were an increase in ACTH 470 pg/ml (0,0-46 pg/ml), cortisol 0.05 µg/DL. Diagnosis: primary chronic adrenal insufficiency; the dose of hydrocortisone 10 mg/day did not change with age. An in-depth anamnesis found: the patient never cried with tears.

Objectively: asthenic body type, BMI 16.5 kg/m², hyperpigmentation of the palms, armpits; weakness in the proximal muscles of the limbs. Laboratory studies: ACTH 95 PG/ml, cortisol 0.1 µg/DL (3.7-19.4 µg/DL), normal aldosterone-renin ratio. Optometrist: injected conjunctiva, sclera. Schirmer's test: mild alacrimia. It allowed to make the diagnosis: "Primary chronic adrenal insufficiency. Condition after surgery for achalasia (1997). Alacrimia. Allgrove Syndrome." The dose of hydrocortisone was increased to 17.5 mg/day.

In 2019, the patient complained of a sharp deterioration of health, darkening of the skin. The dose of hydrocortisone was increased to 25 mg/day (15 mg at 8.00, 10 mg in the afternoon). The optometrist noted an increase in the severity of alacrimia, artificial tear drops was recommended. The diagnosis was confirmed by pathogenic mutation c.43C>T of the AAAS gene.

Discussion

Despite the full clinical picture, the right diagnosis was made only after 14 years. We shown the difficulty of diagnosis is due to the lack of awareness of clinicians about the disease, the importance of interdisciplinary interaction, as well as the need for follow-up of such patients.

#1098 - Abstract

THE BODY MASS INDEX AS A MAIN TARGET FOR GLYCATED HEMOGLOBIN REDUCTION

Miguel Granado Seixal, Maria José Grade, Luísa Arez

Centro Hospitalar Universitário do Algarve - Unidade de Portimão, Portimão, Portugal

Background

Diabetes mellitus is considered the biggest pandemic disease of the 21st century, and glycated hemoglobin (HbA1c) is still the best method to measure metabolic control. In this study we intend to determine the predictors of HbA1c control in diabetic patients.

Methods

Retrospective study of a population of diabetic patients attending Diabetes consultation in a hospital unit during 2018. Data collected from a database, highlighting (i) sex, (ii) age, (iii) number of medical appointments, (iv) Body Mass Index (BMI), (v) years of Diabetes evolution, (vi) total cholesterol (TC), (vii) triglycerides (TG) and (viii) variation of HbA1c. Assessment of the relationship among the previously described factors in HbA1c variation through multivariate linear regression, using SPSS Software(v23), with statistical significance set for p-value <0.05.

Results

It was obtained data from 33 patients (mean age 64.1 years, 60.6% male). The model that better predicts HbA1c reduction considers (i) gender, (ii) age, (iii) BMI and (iv) TC (p =0.002, r²=0.613). The factors that most contribute for HbA1c reduction are BMI (p=0.006) and CT (p=0.007), and a reduction of BMI by 1 kg/m² is associated with a decrease in HbA1c by 0.3%.

Conclusion

The authors highlight the need to strengthen non-pharmacological therapeutic on metabolic control in Diabetes Mellitus, since weight loss only per se significantly reduces HbA1c. In addition to this effect, weight loss has synergistic effects in reducing other cardiovascular risk factors and, thus, in reducing cardiovascular morbimortality.

#1099 - Case Report

SECONDARY ADRENAL INSUFFICIENCY: AN OVERLOOKED EFFECT OF INHALED CORTICOSTEROIDS

Carla Pereira Fontes, Andreia M. Teixeira, José Moura Meireles

Centro Hospitalar de Entre o Douro e Vouga (CHEDV), Santa Maria Da Feira, Portugal

Introduction

Adrenal insufficiency (AI) is one of the most serious adverse effects of inhaled corticosteroids (IC). Despite the reduced risk, its occurrence is particularly associated with IC with higher lipophilicity, longer half-life or at high doses. The clinical

presentation spectrum varies widely, ranging from non-specific symptoms to acutely life-threatening adrenal crisis, requiring a high degree of suspicion for diagnosis.

Case description

A 74-year-old male with a history of controlled hypertension, dyslipidemia, and long course asthma under beclomethasone 1000 µg/day, presented with nausea and vomiting for 1 week, associated with acute alteration of consciousness and hypotension. A previous flu syndrome was mentioned. On examination, the patient was confused, afebrile, hypotensive and slightly tachycardic. The remainder exam was unremarkable. Laboratory investigations showed a serum sodium level of 116 mmol/L (135 to 145 mmol/L), with no other hydroelectrolytic disorders or associated renal injury. The urinary osmolality was reduced and serum osmolality was superior to 300 mOsm/L. The blood levels of total protein, glucose and thyroid function tests were all normal. In view of sustained hypotension and hypotonic hyponatremia, IRS hypothesis has been raised and intravenous hydrocortisone initiated with improvement of the hemodynamic profile, correction of natremia and restitution to patient's basal neurological state. Further investigations (without corticoid), pointed out a basal corticotrophin of 15,0 ng/L (7,2 to 63,3 ng/L), a low morning serum cortisol levels and an inadequate response to tetracosactide stimulation test, with a 60-minute peak cortisol of 297,5 nmol/L. Abdominal computed tomography revealed normal thickness of adrenal glands, with no nodules or calcifications, and brain magnetic resonance imaging was normal. Secondary AI due to suppressed hypothalamic-pituitary-adrenal axis by chronic IC administration has been enlightened in a context of infectious intercurrent. The patient was later discharged with daily prednisone in a weaning scheme; the IC was also changed to one of less systemic bioavailability

Discussion

IC, such as beclomethasone, are widely used in chronic lung diseases. Despite its favorable pharmacokinetic profile (less lipophilicity), if the clinical course is compatible, a differential diagnosis of secondary AI is required. The awareness to the potential risk for AI and its prompt diagnosis is imperative in clinical practice.

#1126 - Case Report

HYPOPITUITARISM: A FINDING IN THE HEART FAILURE APPROACH

Diana Isabel Dias, Ana Mafalda Silva

Entre Douro and Vouga Hospitalar Center, Santa Maria Da Feira, Portugal

Introduction

Hypopituitarism has an incidence of 4 per 100 000 populations and may be caused by hypothalamic or pituitary dysfunction with an insufficient pituitary hormones secretion and consequent endocrine peripheral glands dysfunction. Hypothyroidism

contributes to heart failure decompensation and thyroid function should be assessed in heart failure (HF) patient's approach. Central hypothyroidism detection must imply the assessment of the remaining hypophyseal function.

Case description

We report a 72-year-old female patient's with breast cancer many years ago and dyslipidemia. The only chronic medication was a statin. She complained of 1 week small exertion dyspnea, orthopnea, productive cough and 2-days vomiting. Additionally she had asthenia since a few weeks and cold intolerance. At admission she had fever (38°C), mild polypnea (26 cpm) and heart rate 55 bpm, crackles in both lung bases, peri-orbital edema and low extremities simmetrical non-pitting edema. From the initial study she had type 1 respiratory insufficiency, elevation of BNP and inflammatory parameters. It was assumed low respiratory infection and began empirical antibiotherapy, diagnosis and therapeutic approach to acute heart failure. From the complementary study was found low TSH (0.01 uUI/mL) and low free T4 (7.6 pmol/L) values, suggesting an central hypothyroidism. The thyroid ultrasonography had no alterations. Looking for a central cause for hypothyroidism, the remaining pituitary endocrine axes study was performed verifying low morning cortisol (30 nmol/L), low morning ACTH (6.49 pg/mL), LH (0.04 mUI/mL) and FSH (0.25 mUI/mL). Hypophyseal MRI was performed, revealing a Turkish saddle enlargement occupied with heterogenic material with an arachnocello suggestive aspect without compromise of the stem. Thus, the patient was hydrocortisone and levothyroxine supplemented and oriented to neurosurgical specialty for decision about invasive approach of the lesion.

Discussion

We highlight the thyroid function assessment importance in decompensated heart failure patients since thyroid dysfunction often competes for the difficulty of obtaining clinical stability in those patients and may be an etiology contributing in acute HF or still be a distinct edema and vomiting cause. In this case, we must also highlight how the early diagnosis of the pituitary dysfunction may have avoided importante systemic consequences.

MYXEDEMA COMA, A LATE POSTOPERATIVE COMPLICATION - THE ODDS OF RARITY

Marta Soares Carreira¹, Ana Cunha¹, Marta Couto¹, Paulo Ramalho²

¹ Centro Hospitalar Universitário do Porto, Porto, Portugal

² Hospital CUF, Porto, Portugal

Introduction

Acromegaly is a rare disease that results from hypersecretion of growth hormone, which in turn stimulates hepatic secretion of insulin-like growth-factor 1 (IGF-1), responsible for most of the clinical manifestations of acromegaly.

Clinical features are usually typical, and include macrognathia, enlargement of hands, feet, and face bones. The most common cause for acromegaly is a pituitary tumour. Transsphenoidal surgery (tumour resection) is the first line treatment, however, deficiency of one or more pituitary hormones may become apparent after surgery.

Case description

An 85-year-old male patient, with type 2 diabetes mellitus, a prior history of acromegaly treated with transsphenoidal surgery 20 years ago and and panhypopituitarism presented to the emergency department with coma (Glasgow Coma Scale = 9) and hypothermia. He was taking metformin 1g bid, bromocriptine 5mg id, hydrocortisone 15mg id, levothyroxine 50mcgid and octreotide 5mg/month. On presentation, his vital signs included a temperature of 35.1°C, blood pressure of 116/105 mmHg and heart rate of 25-30 bpm, which failed to respond to atropine or isoprenaline infusion. A temporary pacemaker was placed. Laboratory data revealed a low serum free thyroxine (T4) concentration (0,70ng/dL). The patient was diagnosed with myxedema coma and was started on intravenous hydrocortisone and levothyroxine. Over the next 24 hours, his neurological status and laboratory data improved (Glasgow Coma Scale= 12, T4 = 1,19ng/dL). However, the patient developed aspiration pneumonia with respiratory failure and died 4 days after admission.

Discussion

For the majority of patients with acromegaly, transsphenoidal surgery is recommended as the initial therapy with a very low rate of postoperative complications such as diabetes insipidus or pan hypopituitarism. Although rare, myxedema coma can occur as the culmination of severe longstanding hypothyroidism or be precipitated by an acute event in a poorly controlled patient. Careful assessment of risk and rapid action are essential for limiting morbidity and mortality. Older patients with cardiac complications, reduced consciousness or sepsis have a worse prognosis.

#1152 - Case Report

CONVULSIVE CRISIS IN PATIENT WITH DEPRESSIVE SYNDROME REACTIVE TO ONCOLOGICAL PATHOLOGY

Maria Manuel Costa, Joana Rodrigues

Hospital de São Sebastião, Oliveira De Azemeis, Portugal

Introduction

Vitamin D deficiency is currently very rare in developed countries, but its prevalence has been increasing globally due to a number of factors including the use of sunscreen, increased body mass index, decreased consumption of dairy products and population-ageing. This deficit can cause changes in the metabolism of calcium and phosphorus, with hypocalcemia, hypophosphatemia and an increase in the parathyroid hormone. It as many consequences,

among which osteoporosis with an increased risk of fractures is the most prevalent. Convulsive seizures associated with severe hypocalcemia may be an isolated presentation of the deficit, but this is a very rare occurrence. The treatment includes supplementation, as well as correction of eating habits and daily sun exposure.

Case description

We report the case of a 71-year-old woman with personal history of endometrial malignant tumor without evidence of metastasis, already submitted to surgical procedure and proposed for chemotherapy and radiotherapy, depressive syndrome related to the tumor, second degree obesity, and hypertension.

The patient enters the emergency room because of vomiting with 4 days of evolution, symptom not related to feeding or recent introduction of new drugs. She presented anorexia, since the diagnosis of the tumor associated to adynamism and diminution of the solar exposition.

During her stay in the emergency room she had a convulsive crisis, with about 1 min of duration and a spontaneous recovery. The study carried out showed hypocalcemia and severe hypophosphatemia with normal magnesium. During hospitalization severe vitamin D deficiency with elevated parathyroid hormone was noted. After supplementation with calcium, phosphorus and vitamin D, a normalization of the ionic deficits was observed. During the entire hospitalization period she had no further seizures. After a joint evaluation with the assistant oncologist, it was considered that the deficits had no relation to the oncological pathology of the patient, assuming changes in a probable context of nutritional deficit and reduction of sun exposure.

Discussion

With this case, the authors intend to present a rare cause of seizure in a patient with important cancerous disease and difficulty in dealing emotionally with it. This case is also intended to stress the importance of evaluating the patient as a whole, and physicians should never neglect the psychological component associated with the pathologies, namely, the oncological ones.

#1156 - Case Report

HEMYCHOREA-HEMIBALLIST ASSOCIATED WITH HYPERGLYCAEMIA

Maria Maia, Ana Gonçalves, Adriana Watts Soares, João Espírito Santo, Ismênia Oliveira, Rita Simões, José Lomelino Araújo

Hospital Beatriz Ângelo, Lisboa, Portugal

Introduction

Hyperosmolar hyperglycaemic non-ketotic (HHNK) syndrome is a clinical syndrome characterized by severe hyperglycaemia, hyperosmolarity without ketoacidosis. Fewer cases of the association of hyperglycaemia with chorea/ballism have been published, being the prevalence of this disorder less than 1/100,000. Major risk factors are female gender and older age.

Authors present two cases of hemychorea-hemiballist associated with hyperglycaemia (HHAH).

Case description

Case 1

91-year-old female, caucasian, history of type 2 diabetes (T2D) no insulin needed, auricular fibrillation under apixaban, that presented to the emergency department (ED) with a four-day history of involuntary movements of the left arm. Clinical exam: hemodynamic stability (HDS), neurological exam (NE) with GCS of 15, choreic movements of the left arm and some of the left leg, more proximal, giving pain and discomfort. Investigation: serum glucose (G) 460mg/dL (HbA1c 14%), ketone test negative, no acidosis.

CT-scan revealed no ischemic or haemorrhagic lesion, but a lenticular and right capsular hyperdensity, confirmed by the MRI with a change on the signal of the lenticular right nucleus, (hypersignal in T1 and hyposignal in T2 and FLAIR) characteristic of HHAH.

After hydration and insulin, risperidone 0,5mg was started. Progressively improvement of the symptoms, until they stop before discharge.

Case 2

60-year-old male, caucasian, history of arterial hypertension, dyslipidaemia, T2D insulin needed, presented to the ED due to involuntary movements of all the right part of the body with a month of progression. Clinical exam: HDS, NE with ballistic and choreiform movements of the right arm and leg. Investigation: G 350mg/dL (HbA1c 12.3%), ketone test negative, no acidosis. CT-SCAN with an hyperdensity on the left globus pallidus. No MRI was performed. Hydration and insulin were started and valproate, lorazepam and haloperidol. Little improvement of the symptoms was seen.

Discussion

HHAH is a rare syndrome characterized by lesions in the basal ganglia, contralateral to the affected side, secondary to hyperglycemia, physiopathologic process not yet clear. With the control of the glycemia the symptoms tend to get better as it could be seen in the first case. The second case, due to time of evolution and difficult control of glycemia, was more difficult to solve.

These two cases show us one more complication of the diabetes that can be confused with a stroke or other neurological entities, being essential the metabolic control.

#1168 - Case Report

HYPOTHYROIDISM AND ASSOCIATED ACUTE KIDNEY INJURY

Jovina Summer Goh, Chaozer Er, Clarissa Hui Wen Aw, Nicholas Cheong

Woodlands Health Campus, Singapore, Singapore

Introduction

Effects of the thyroid hormone throughout the body are pervasive. Hypothyroidism is commonly known to be associated

with multiple physiological manifestations such as lethargy, weakness, cold intolerance and poor appetite. Lesser known are its effects on kidney physiology and a resultant reduction in glomerular filtration. We present an uncommon case of severe hypothyroidism resulting in acute kidney injury.

Case description

A 54-year-old Chinese gentleman presented to the emergency department with generalised anasarca and weight gain of 4kg over the past 1 month. The patient had a significant past medical history of Graves' hyperthyroidism and underwent radioiodine ablation therapy 6 months prior to admission. He however defaulted subsequent appointments with the endocrinologist. Further history taking revealed that the patient had continued to take carbimazole post radioiodine ablation. Thyroid function tests revealed a TSH (Thyroid stimulating hormone) of 75.2 mIU/L (0.27 - 4.2 mIU/L) and a free thyroxine of 1pmol/L (12-22pmol/L). He was also noted to have mild acute kidney injury (AKI) - his creatinine was 121umol/L (67-112 umol/L), elevated from a previous baseline of 52-76 umol/L. Intravenous hydration over the next three days did not result in any significant improvement of his AKI - serum creatinine remained elevated at 129 umol/L.

Further investigation did not reveal any significant contributing cause of the AKI- the patient did not have any exposure to nephrotoxins; Urinalysis revealed a normal urine protein/creatinine ratio of 0.07 (normal range:< 0.2) and a normal urine albumin/creatinine ratio of < 30ug/mg; Urine microscopy examination was clear of any white, red or cast cells and ultrasonography of the kidneys and ureters were normal.

After being started on thyroxine 75 micrograms daily, his symptoms improved markedly and a repeat thyroid panel three weeks later showed significant improvement: TSH 22.6 mIU/L and free thyroxine 12.2pmol/L. A repeat serum creatinine showed a return to baseline - 85 umol/L.

Discussion

The exact mechanism of how hypothyroidism causes reduction in glomerular filtration has yet to be clearly understood but has been attributed partly to the effect of the thyroid hormone on sodium homeostasis, cardiac output and vascular resistance. The findings in this case study are best explained by the association of hypothyroidism and acute kidney injury. We thus hope to highlight hypothyroidism as a cause to be considered in cases with unexplained AKI.

#1171 - Abstract

UNFOLDING THE LINK BETWEEN DIABETES AND CANCER: A RETROSPECTIVE STUDY

Jorge Vaz Lourenço, João Pina Cabral, Joana Coelho

Centro Hospitalar Universitário de Coimbra, Coimbra, Portugal

Background

The link between cancer and diabetes mellitus (DM) is an emerging

and rapidly growing field of study. Accumulating molecular and clinical evidence supports this link and implicates cellular-based mechanisms at the interface of the two diseases. Hyperglycaemia and hyperinsulinaemia are both potential carcinogenic factors, by inducing DNA damage through increased oxidative stress and stimulation of insulin receptor and insulin-like growth factor-1, respectively.

Methods

We collected our data from electronic medical records of enlisting patients that were seen by an Oncologist for the first time during the first semester of 2017 and selected those with DM criteria (HbA1c >6.5% or fasting blood glucose level >126mg/dl). Then, we performed a retrospective study regarding age, gender, type of cancer diagnosed and their profile of DM (disease duration, HbA1c and vascular complications).

Results

We examined 1037 medical records and found a total of 127 patients with type 2 diabetes, 57,5% males (n=73) and 42,5% females (n=54) with a mean age of 67,9 years. The mean duration of DM was 3,9 years and mean HbA1c was 7,05%. There were 13 patients with vascular complications, namely retinopathy (n=8), nephropathy (n=12), neuropathy (n=2), myocardial infarction (n=9) and stroke (n=4). According to the organ systems affected by primary tumors, we found that 29,1% of patients had a GI tract tumor - esophagus (n=5), stomach (n=9), colon (n=20) and liver (n=3); 20,5% had gynecologic tumors - breast (n=20), uterus (n=4), ovary (n=2); 18,9% had hematologic tumors - lymphoma (n=14), myeloma (n=10); 14,2% had urinary tract tumors - bladder (n=8), kidney (n=4), prostate (n=6); finally, 3,9% (n=5) were diagnosed with malignant melanoma.

Conclusion

The GI tract tumors and gynecologic tumors were the most prevalent in diabetic patients and the majority had no vascular complications at the time of tumor diagnosis. Whether DM confers the same excess risk of cancer, overall and by site, in women and men is still unknown. Further studies are needed to clarify the mechanisms underlying the sex differences in the diabetes-cancer mutual influence.

#1221 - Abstract

ANALYSIS OF PATIENTS HOSPITALIZED FOR HYPOGLYCEMIA AT TWO TERTIARY CARE HOSPITALS

Marina Fayos¹, Tania Ramos², David García¹, Luis Gibert¹, Nuria Puente¹, Pablo González¹, Gonzalo Martínez De Las Cuevas¹

¹ Hospital Universitario Marqués de Valdecilla, Santander, Spain

² Complejo Asistencial Universitario de León, León, Spain

Background

Hypoglycemia is one of the main reasons for admission due to

acute complications of diabetes. The aim of this study is to analyze and compare patients hospitalized due to hypoglycemia at two tertiary care hospitals in Spain.

Methods

This is a descriptive retrospective study of patients admitted for hypoglycemia at Marqués de Valdecilla University Hospital of Santander (HUMV) and at Complejo Asistencial Universitario of León (CAULE), between January 2013 and December 2015. Clinical characteristics, hypoglycemic treatment, and readmissions in the first three months were analyzed.

Results

We analyzed 116 patients: 48 in León and 68 in Santander. At CAULE, 59% were women, with a mean age of 71 (SD 19) and an average stay of 7 days (SD 5). At HUMV 54% were men, with a mean age of 77 (SD 12) and an average stay of 14 days (SD 12). At CAULE, 92% were admitted to Internal Medicine Service, compared to 94% at HUMV. At CAULE, 63% of patients were TP2DM, while at HUMV they were 93%.

At CAULE, the average Charlson score was 4.8 (SD2.4), and the mean HbA1c 7.7% (SD 1.4). At HUMV, the average Charlson score was 6.7 (SD 3.2) and the mean HbA1c was 7.5% (SD 1.5).

Regarding treatment, at CAULE 50% of patients were on insulin, mainly mixtures; while 65% were on insulin at HUMV, mainly mixtures and glargine. At CAULE, 25% took OAD, mostly sulfonylureas. 25% used insulin combination with OAD. At HUMV, 22% used OAD, mainly biguanides, and 13% used a combined treatment.

After discharge, at CAULE the hypoglycemic drug was modified to 50%, to 16% the dose was reduced, to 16% the medication was withdrawn and there was no change in 18%. At HUMV, the drug was changed to 35%, it was reduced to 38%, to 6% was removed, and there was no changes in 22%.

At CAULE, 31% of patients were readmitted after 3 months, 3% due to hypoglycemia. At HUMV, 34% were readmitted, 26% due to hypoglycemia.

Conclusion

- Patient's profile admitted to CAULE was a younger woman, with less comorbidity and fewer days of stay, while HUMV's profile was an older man, with higher comorbidity and longer income.
- At CAULE, ADOs were more used than at HUMV, both in monotherapy and combined.
- At CAULE, the tendency was to modify the hypoglycemic treatment, since it was more frequent the use of mixtures and sulfonylureas.
- At HUMV, the dose tended to be decreased, as most of patients were on glargine.
- There were more readmissions for hypoglycemia at HUMV than at CAULE, being that the profile was a more fragile and older patient.

#1224 - Abstract

EVALUATION OF PATIENTS ADMITTED FOR HYPOGLYCEMIA AT A TERTIARY CARE HOSPITAL

Marina Fayos, Nuria Puente, Pablo González, Luis Gibert, David García, Gonzalo Martínez De Las Cuevas

Hospital Universitario Marqués de Valdecilla, Santander, Spain

Background

Hypoglycemia is one of the main reasons for hospitalization due to acute complications of diabetes. The aim of our study is to analyze the causes of admission due to hypoglycemia and the clinical characteristics of the patient.

Methods

This was a descriptive retrospective study of hospitalized patients with hypoglycemia, at Marqués de Valdecilla University Hospital between January 2013 and December 2017. We analyzed: the cause of admission, clinical characteristics, functional status (Profound Index and functionality scale of the red cross), treatment at discharge and evolution.

Results

Among 116 patients analyzed, 54% were women, mean age 78 (SD 12). The median length of hospitalization was 13 days (SD 12). 96% were admitted to Internal Medicine Service and the rest to Endocrine, Oncology and Hematology Services. 93% of patients were T2DM and 7% T1DM.

Comorbidity was high, with an average Charlson score of 7 (SD 3), Profound score of 7 (SD 5) and an average Red Cross disability score of 2 (SD 1). The average HbA1c was 7.6% (SD 1.7).

Most frequently recorded underlying diseases were: renal insufficiency (47%), heart failure (42%), and peripheral artery disease (28%). The main reasons for admission were: hypoglycaemia (44%), respiratory infection (18%), heart failure (12%) and diarrhea (6%).

79% of patients were on insulin as a diabetes treatment regime, mainly glargine (26%) and mixtures (24%). 41% used OAD, mostly biguanides (19%) and inhibitors of DPP4 (15%). 23% used a combination of insulin with OAD. At discharge, the treatment dose was reduced to 37%, the hypoglycemic drug was changed to 29%, the medication was completely withdrawn to 10%, and there was no change in the rest of the patients.

The overall in-hospital mortality was 24%, and 37% were readmitted in the next 3 months, after an average of 29 days (SD 21). 14% of readmissions were due to hypoglycemia.

Conclusion

- T2DM is the main cause of diabetes in patients admitted for hypoglycemia in our hospital.
- The profile of the patient admitted for hypoglycemia was a woman around 78, with high comorbidity and functional disability.
- The main treatments associated with hypoglycemia were

glargine and mixtures.

- At discharge, the treatment tended to be decreased instead of being modified.
- There was a high rate of readmissions and mortality in patients hospitalized for hypoglycemia, due to the fragility and high comorbidity of these patients.

#1250 - Abstract

CORRELATIONS OF GLYCEMIC CONTROL, PHYSICAL FUNCTION, MOOD AND PERSONALITY TRAIT IN TYPE 2 DIABETIC WOMEN

Raziye Nesrin Demirtas¹, Nur Kebapci², Belgin Efe²

¹ Eskisehir Osmangazi University Medical School, Department of Physical Medicine and Rehabilitation, Eskisehir, Turkey

² Eskisehir Osmangazi University Medical School, Department of Endocrinology, Eskisehir, Turkey

Background

The aim of the study was to investigate the correlations of glycemic control, physical function, mood and personality trait in type 2 diabetic women (T2DW).

Methods

The demographic and medical data of 25 T2DW were recorded. They completed the self reported physical function (PF) and mental health (MH) components of the Short Form-36 Health Survey (SF-36), Beck Depression Inventory (BDI) and Hacettepe Personality Inventory (HPI) which included Personal Cohesion (PC), Social Cohesion (SC), General Cohesion (GC) subscales. The glycated hemoglobin (HbA1c) as an index of glycemic control was measured.

Results

In T2DW whose HbA1c level >7% indicating poorer control of blood glucose levels: PF score of SF-36 was less ($p=.018$) than those whose HbA1c level <7%, but there weren't differences for MH of SF-36, BDI scores and personality trait ($p>0.05$). In T2DW whose BDI scores >17: MH ($p=.000$), PF ($p=.042$) scores of SF-36 and PC, SC, GC scores ($p=.000$) of HPI were less than those whose BDI scores <17. There weren't associations between BDI score, age, body mass index and diabetes duration ($p>.05$).

Conclusion

The results of this study suggested that glycemic control was correlated to PF and mood were especially affected with personality trait and PF in T2DW.

#1258 - Case Report

PRIMARY LOCALIZED AMYLOIDOSIS OF THE RENAL PELVIS AND URETER PRESENTING AS ACUTE PYELONEPHRITIS AND MIMICKING UROTHELIAL CARCINOMA

Rita J. Rodrigues, Paula Gonçalves Costa, Marta Costa Gonçalves, Ricardo Macau, Alcina Ponte

Hospital of Santo André - Hospital Center of Leiria, Leiria, Portugal

Introduction

Amyloidosis encompasses several conditions characterized by amyloid deposition in different tissues and organs and it can either be systemic or localized. Localized amyloidosis of the urinary tract is uncommon and the involvement of the renal pelvis and ureter is rare.

Case description

A 56-year-old man with an history of symptomatic nephrolithiasis was referred to the Emergency Department due to severe left back pain and haematuria for the last 3 days. On physical examination, he was febrile and had left costovertebral angle tenderness. Laboratory examination showed an increase in inflammatory markers – leucocytosis ($21 \times 10^9/L$), neutrophilia and C-reactive protein of 144 mg/dL. Ultrasonographic examination revealed foci of calyceal lithiasis and left renal pelvis dilation with an echogenic content without evident cone shadow. He was then submitted to an urographic tomography that described: a diffuse and irregular parietal thickening of the left renal calyces and pelvis which continued along the ureter; numerous irregular and thick calcifications; and a discrete dilation of the ureter. The patient was admitted to the Urology Department considering the possibility of urothelial carcinoma, where he was treated with antibiotic therapy for acute pyelonephritis with clinical and analytical improvement and underwent diagnostic ureterorenoscopy that revealed a bulky mass with multiple surface calcifications that occupied the lumen of the left renal pelvis. The renal pelvis lavage cytology excluded the presence of neoplastic cells. The anatomopathological study of the mass's biopsies revealed apple-green birefringence of Congo red stained amyloid deposits. The patient was then referred to Internal Medicine consultation where systemic amyloidosis was excluded after several exams done without any signs of other organs' involvement, concluding that he had primary localized amyloidosis. He currently maintains surveillance in Nephrology consultation, with normal renal function and without proteinuria.

Discussion

Although the cause of localized amyloidosis of the urinary tract is unknown, local monoclonal plasma cell infiltrates and local amyloid synthesis have been suggested as causes. It may present as renal calculi as focal lesions calcify; in the ureter, it may mimic a malignant tumour in its clinical presentation and imaging aspect, sometimes leading to nephroureterectomy. Therefore, it should be considered and confirmed by biopsy and histological examination thus avoiding unnecessary surgery.

#1288 - Abstract

THE FATIGUE AND ITS RELATIONS WITH GLUCOSE CONTROL, PHYSICAL ACTIVITY AND QUALITY OF LIFE IN TYPE 2 DIABETIC WOMENRaziye Nesrin Demirtas¹, Nur Kebapci², Belgin Efe²¹ Eskisehir Osmangazi University Medical School, Department of Physical Medicine and Rehabilitation, Eskisehir, Turkey² Eskisehir Osmangazi University Medical School, Department of Endocrinology, Eskisehir, Turkey**Background**

The fatigue is a common symptom of diabetes mellitus. The aim of this study was investigated the fatigue and its relations with glucose control, physical activity and quality of life in women with Type 2 Diabetes Mellitus (T2DM).

Methods

A total of 55 consequent women with T2DM aged 42 to 78 years (mean age 60.43±8.62) were eligible to participate in this cross-sectional study. Their clinical and laboratory data were recorded. The glucose control was established by HgA1c level. The fatigue was assessed with energy/fatigue (E/F) component of the Short Form-36 Health Survey (SF-36). The Nottingham Health Profile (NHP) for quality of life and 2-minute walking test (2MWT) and timed Up and Go Test (TUG) for physical activity were applied.

Results

The E/F score of SF-36 were negatively correlated to diabetes duration ($p < 0.01$), HgA1c ($p < 0.05$), comorbidity number ($p < 0.05$), TUG ($p < 0.01$) scores, all components of NHP ($p < 0.001$ - $p < 0.000$) and positively correlated with 2MWT ($p < 0.000$).

Conclusion

The findings suggested that fatigue were related to glucose control, physical activity and quality of life in women with T2DM. The effective interventions such as providing glucose control and improving physical activity and quality of life can help to reduce the fatigue in women with T2DM.

THE FAULT IS NOT OF THE HEART

Ana Figueiredo Albuquerque, Flávia Santos, Maria João Palavras, Juliana Silva, Helena Carrondo, Célio Fernandes

Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

Hypothyroidism is a common endocrine disorder resulting from deficiency of thyroid hormone. Normally, thyroid hormones prevent overexpression of glycosaminoglycans, so, the lack of the thyroid hormone could cause accumulation of matrix glycosaminoglycan's in the interstitial spaces of many tissues provoking myxedema.

Case description

We present a case of an 85-years-old male with past medical history of heart failure, chronic obstructive pulmonary disease, diabetes mellitus, hypertension and obesity. He was medicated with metformin, lorazepam, olmesartan, allopurinol, furosemide and amiodarone.

The patient presented in the Emergency Room with dyspnea, productive cough and easy fatigability. The clinical examination revealed apathy, pulmonary rales on auscultation, and an edema the periorbital region and lower limbs.

The blood analysis showed an elevation of the inflammatory parameters, macrocytic anemia (Hb 8.7 g/dL; VCM 108.0 fL; HCM 38.7 pg), an elevation of both creatinine (3.26 mg/dL) and creatine kinase 612 U/L as well as a discrete hyponatremia (131 mmol/L). In the blood gas analysis presented with partial respiratory failure. The chest X-Ray revealed bilateral pleural effusion. He was admitted to regular ward of Internal Medicine with the diagnosis of respiratory infection and acute heart failure.

The echocardiogram revealed a normal systolic function, with a ventricular ejection fraction of 72%. The thyroid study revealed marked elevation of thyroid-stimulating hormone (TSH) concentration 89.1 yUI/mL and decrease of T4 concentration 2.5 pmol/L. The thyroid echography was normal.

Amiodarone was discontinued and it was started replacement therapy with thyroid hormone, with clinical improvement.

Discussion

The symptoms of hypothyroidism, that may range from mild to severe, include cold intolerance, decreased sweating, weight gain, fatigue, obstructive sleep apnea, congestive heart failure symptoms and decreased mental function. By this means, differential diagnosis and clinical management of hypothyroidism can be challenging. Amiodarone is associated with thyroid dysfunction (both hypo- and hyperthyroidism), which is due to its high iodine content and its direct toxic effect on the thyroid.

The authors intend to demonstrate the importance of the physicians to considerate this disease as a hypothesis when observing patients with a nonspecific or atypical course.

BEHIND THE SCARF

Álvaro Alejandro De Oña, Victor Mato Jimeno, Cristina Ausín García, Noemí Brox Torrecilla, Carmen Cuenca Carvajal, María Victoria Villalba García

Hospital General Universitario Gregorio Marañón, Madrid, Spain

Clinical summary

We present the case of a 62 years old female who reported asthenia and a goiter, presented at least since 2003 (Figure 1). We performed laboratory analysis which showed severe macrocytic regenerative anemia (Hb of 5,3 g/dL), bilirrubina of 3,2 mg/dL, GGT of 89 U/L, LDH of 1119 U/L and suppressed TSH. Chest radiography demonstrated multiple masses in both lungs. We performed a CT

showing hepatic metastasis, and a ultrasonography followed by a fine-needle aspiration (FNA) which was compatible with papillary thyroid cancer. We performed a hepatic FNA which confirmed metastasis.

Due to clinical worsening of patient and after tumor board meeting, palliative management was decided.

Figure #1358.

AN UNNOTICED MANIFESTATION OF PITUITARY ADENOMA

Mónica Silva, Miguel Barbosa, João Gramaça, Fernanda Martins, Filomena Carneiro, Fátima Campante
Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Clinical summary

A 84 year-old-woman presented with nausea, vomiting and acute diarrhoea evolving for two weeks. Initial evaluation showed unspecific discomfort at abdominal palpation. Laboratory studies showed a normal level of myoglobin, hepatic enzymes, cholestasis markers, TSH and FT4. However, levels of morning cortisol and ACTH were both low (1.1 ug/dL and <5.0 pg/mL respectively) and increased serum levels of prolactin (57.34 ng/mL). Brain MRI revealed an expansive inner and suprasellar lesion compressing the hypothalamus and the optic chiasm. No signs of visual loss were found. A diagnosis of pituitary macroadenoma with secondary adrenal insufficiency was made, and the patient underwent hydrocortisone treatment, normalizing cortisol and ACTH levels, and reverting the gastrointestinal symptoms.

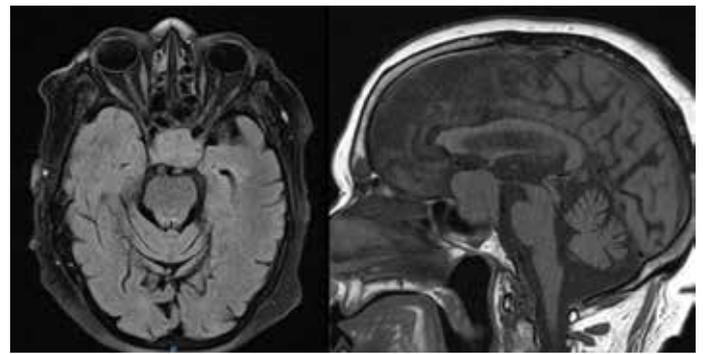

Figure #1360. Pituitary macroadenoma.

HYPERPROCALCINEMIA AND SEVERE KETOACIDOSIS IN A CHILD WITH TYPE 1 DIABETES MELLITUS IN TREATMENT WITH INSULIN PUMP

Ignacio Iniesta-Pino Alcázar, Elena Del Carmen Martínez Cánovas, Lia Ferraro, Maria Del Carmen Hernández Murciano, Carlos Báguena Pérez-Crespo, Gabriel Puche Palao, Vicente David De La Rosa Valero, Ana Martín Cascón, Francisco Javier Hernández Felices, Mónica Martínez Martínez, Isabel Pellicer Espinosa, María Del Carmen Gutiérrez Sánchez
Hospital General Universitario Reina Sofía, Murcia, Spain

Introduction

Procalcitonin (PCT) is a helpful marker of systemic inflammatory response to an infection. It is strongly indicative for sepsis of bacterial aetiology. Mild PCT elevations are also detected in many other diseases.

Case description

14-year-old child diagnosed with mellitus diabetes type I, carrier of insulin bomb, Hashimoto's chronic thyroiditis in the hypothyroid phase, with family history of diabetes and thyroiditis. Chronic treatment with levothyroxine 25 and insulin pump.

He presents a poor metabolic control (glycosylated hemoglobin: 8.4%), although his diabetological training is good (autonomous management of the insulin pump, self-performing catheter replacements, dietary knowledge and control of carbohydrate intake by the rations method).

The patient has nausea, vomiting and malaise. He only refers insulin pump catheter replacement the previous day.

The physical examination (cardiac and pulmonary auscultation, abdomen and extremities) and the vital signs were anodyne (apyretic, blood pressure of 90/40 mm Hg, 95 beats/minute, 16 breaths/minute, oxygen saturation of 99%). Only the oropharyngeal exploration shows tongue with erosion zones and discrete hyperemia and he does not present adenopathies.

In the blood analysis, the following was detected: glucose 581 mg/dl, urea 62 mg/dl, creatinine 1.66 mg/dl, sodium 133 mmol/L, potassium 5.1 mmol/L, procalcitonin 20.41 ng/mL, leukocytes 39,000 ul (neutrophils 84%), platelets 394,000. In the venous

gasometry it was observed: pH 7.11, pO₂ 30 mmHg, pCO₂ 42 mmHg, HCO₃ 12.8 mmol/l, excess of bases -16 mmol/L and lactic acid of 7.6 mmol/L. The rest was normal (Hemoglobin, coagulation and chest X-ray). In urine glucose and positive ketone bodies.

Diabetic ketoacidosis (DKA) management was administered. The patient evolved favorably and remained asymptomatic. Although the blood analysis suggested an infection as trigger, he didn't have an infectious focus or other suggestive data.

Discussion

PCT is a helpful marker indicative for sepsis of bacterial etiology. Mild PCT elevations are also detected in other diseases such as viral infections, myocardial infarction, burns and multiple trauma. Although DKA is not described as a major cause of procalcitonin elevation or false positive test, there are scientific papers that describe this association. During severe DKA there is a secretion of proinflammatory cytokines capable of releasing PCT independently of endotoxins.

#1380 - Case Report

A RARE MALIGNANT CAUSE OF HYPOGLYCAEMIA

Daniela Meireles¹, Diana Carvalho¹, Paulo Almeida¹, Joel Pinto¹, Maria João Amaral², Ana Rafaela Araújo¹

¹ CHBV - Aveiro, Aveiro, Portugal

² CHUC - Coimbra, Coimbra, Portugal

Introduction

Neuroendocrine neoplasms of the pancreas are uncommon and represent 1–2% of all clinically apparent pancreatic neoplasms. Neuroendocrine carcinomas (NECs), or high-grade, poorly-differentiated NETs, are the most aggressive subtype. Tumors arising from neuroendocrine cells are rare and can cause typical symptoms of carcinoid syndrome. Only those patients in whom Whipple's triade is documented require evaluation of hypoglycemia.

Case description

An 80-year-old woman was admitted in the Emergency Department (ED) with a two-months history of morning episodes of temporo-spatial disorientation, aggressive behaviour, asthenia, polyphagia and nocturnal diaphoresis. These symptoms occurred mainly in the fasting state relieved with food ingestion. The patient had a history of atrial fibrillation, toxic multinodular goiter, hypertension and dyslipidemia. In ED, the blood glucose level was 38 mg/dl, with a normal brain computed tomography (CT). Hypertonic glucose (30%) was administered and a 5% glucose infusion was maintained thereafter. The patient was hospitalized for etiological study. Glucose infusion withdrawal resulted in an episode of symptomatic hypoglycaemia (37 mg/dL), with elevated levels of insulin (26.9 mUI/L) and normal levels of C-peptide (6.08 ng/mL). Chromogranin A was 225 ng/mL. FSH, LH estradiol, cortisol, prolactin and ACTH were within normal values.

Thoracoabdominopelvic CT revealed an enlarged body and tail of the pancreas with oval formation of 80 mm with heterogeneous enhancement extended to the splenic cord with involvement of the respective hilar vessels and to the splenic parenchyma, without any other distant metastasis. A ⁶⁸Ga-DOTA-NOC positron-emission tomography CT was highly suggestive of neuroendocrine tumor of the pancreas. A left pancreatectomy, splenectomy and atypical block resection of the gastric fundus was performed. The anatomopathological results were compatible with three large cell neuroendocrine carcinomas of the pancreas (NEC). There was complete remission of the hypoglycemic episodes.

Discussion

What, in the beginning, seemed like an insulinoma, turned out to be a functional insulin producing high-grade NEC of the pancreas, presenting with symptoms of hypoglycemia. For NEC, the overall 5-year survival of the patients is 17%. Our patient did not have any further episodes of hypoglycaemia after surgery. The rarity of this case is even greater because nearly all grade 3 NET are nonsecretory.

#1394 - Case Report

TACHYCARDIA - CONSIDER ME

Virginia Visconti, Andre Fernandes, Adriana Watts, Ismenia Oliveira, Fernando Goncalves, Jose Lomelino Araujo, Maria Maia Hospital Beatriz Angelo, Loures, Portugal

Introduction

Atrial fibrillation is the most frequent chronic arrhythmia, affecting 1-2% of the population. Often, due to its paroxysmal potential, it may be underdiagnosed and undertreated.

Case description

The authors present the case of a 50-year-old patient with a history of essential hypertension, type 2 diabetes and anxiety. Several episodes of palpitations and atypical anterior thoracalgia over the past years, without diagnosis to date.

Admitted to the emergency room for palpitations, fatigue after moderate exertion and anterior thoracalgia (located with one finger and increased with digital pressure), without irradiation, nausea, vomiting, lipothymia. Without orthopnea, cough, fever, urinary or intestinal complaints. Reference to episodes of agoraphobia. The patient was anxious, uncooperative, dehydrated, with discrete crackling at the right base. Apyretic, hypertensive, with a heart rate of 140 beats per minute, with arrhythmic heart sounds.

Electrocardiogram showed atrial fibrillation with a rapid ventricular response of 138 beats per minute, which was controlled with 5 mg of bisoprolol. Analytically, microcytic, hypochromic anemia, without elevation of acute phase parameters and negative cardiac biomarkers. Thyroid stimulating hormone (TSH) <0.01 mU/L, with free thyroxine level (fT4) of 43.8 ng/dl.

She began methimazole, with good tolerance and results. After

one month, the patient was asymptomatic, calmer and more cooperative, with TSH <0.01, FT4 19, Free Triiodothyronine (FT3) 5.6, microsomal anti-peroxidase antibody 609 and anti-TSH receptor antibody 4.53, confirming the presumptive diagnosis of Graves disease.

Discussion

Patients with hyperthyroidism may suffer from a wide range of symptoms, including anxiety, palpitations, irritability, heat intolerance, muscle weakness, among others. Patients often resort to emergency services with similar symptoms, so we mustn't forget this etiology during the diagnostic process.

#1401 - Abstract

MYOPATHY AND PCSK9 INHIBITORS THERAPY

Marta Carmen Esles Bolado, [Cristina Limia Vita](#), Lucia Paz Fajardo, Andrea Gonzalez Pascual, Marta Minguez Picasso
Hospital Sierrallana, Torrelavega, Spain

Background

The adverse effect more frequent with statin use are muscular symptoms (SAMS) to a greater or lesser degree, being rhabdomyolysis the most unusual and serious one¹. Its appearance entails one of the indications of PCSK9 inhibitors therapy² (iPCSK9). A recent meta-analysis confirms its safety in patients diagnosed of HFH (Heterozygotic familiar hypercholesterolemia) and SAMS³ and, also, in patients with primary myopathies^{4,5}. For that reason, we decided to examine this aspect in our patients.

Objective

Verifying the evolution of symptoms and CPK concentration in patients diagnosed of primary myopathy who are under iPCSK9 treatment.

Methods

We looked over patients diagnosed of primary myopathy who are receiving iPCSK9 in our hospital (where 165.000 patients are attended to and 260 beds are available). We establish that a patient presents primary myopathy when plasmatic concentration of CPK are higher than 180 u/L before starting treatment with lipid-lowering drugs and if another cause of secondary myopathy were excluded.

We collected demographic and clinical variables and LDLc concentration as well as CPK concentration before and after beginning iPCSK9 therapy.

Results

Of a total of 49 patients under iPCSK9 treatment, 5 meet criteria for primary myopathy. 60% of them are women and average age is 71 years. All of them are diagnosed of ischemic cardiopathy, one patient was diagnosed of muscular dystrophy and another one of inflammatory myopathy by muscular biopsy. This whole group

of patients were given evolocumab, 140 mg every 14 days, as treatment.

Average LDLc presented by our patients at the beginning of the treatment was 165 mg/dl and 59 mg/dl afterwards (meaning 68% of reduction). Prior to iPCSK9 treatment, CPK average was 3006 u/L, being 810 u/L subsequent to it.

Conclusion

Myopathy associated to statins use (SAMS) is an usual complication, being described in 7-29% of patients. An added problem consists in unmasking a primary myopathy, metabolic or congenital, because of the use of statins. In different published consensus about management of SAMS, the attitude in patients with primary myopathy remains unclear. With the introduction of PCSK9 inhibitors as therapy, several cases of this type of patient treated safely have been described. Our data confirm this aspect about iPCSK9 safety as well as their efficacy.

#1404 - Case Report

ADDISON'S DISEASE IN SCHMIDT SYNDROME

[Maria João Guerra Lopes Palavras](#), Ana Luísa Albuquerque, Catia Santos, Maria João Vieira, João Santos, Filipa Alçada
Hospital de Santo André, Leiria, Portugal

Introduction

Autoimmune polyendocrine syndromes comprise a diverse group of clinical entities involving functional impairment of multiple endocrine glands due to loss of immune tolerance.

Autoimmune polyendocrine syndrome type II (AIPS-II), also known as Schmidt syndrome, is a rare autoimmune disorder in which there is a steep drop in production of several essential hormones by the glands that secrete them. When first described, this disorder was thought to manifest by adrenal insufficiency (Addison's disease) and thyroid insufficiency (Hashimoto's thyroiditis) alone. However, as more patients were studied, the scope of the syndrome was expanded to include other disorders as type 1 diabetes mellitus and parathyroid gland disease. Dysfunction of the endocrine glands is usually accompanied by signs of malnutrition due to a dramatic decrease in intestinal absorption of nutrients.

Case description

The authors present the case of a 26 year-old male who was admitted by asthenia and palpitations. He was diagnosed with type 1 diabetes mellitus at age 12 and celiac disease at age 16. There was a hyperpigmentation on his lips and neck. In the emergency department, blood tests revealed hyperkalemia and hyponatremia. In a more extensive work up a decreased secretion of cortisol and aldosterone was found, as well as an increase in renin production. 21-hydroxylase antibody was negative. Corticosteroid treatment was started, considering the hypothesis of Addison's disease, which contributed to persistent, but eventually controlled, hyperglycemia.

Discussion

The etiology of AIPS-II is not fully known, but it is thought to result from abnormal immune responses. This syndrome, unlike AIPS-I, occurs in adults, with a peak incidence at age 30, and it tends to be more frequent in women than in men.

DEXAMETHASONE ON DEMAND... LOOK AT THE CONSEQUENCES!

Carolina Carrilho Palma, Joana Patrício, Ricardo Pereira, Inês Costa Santos, João Tavares, Ana Catarina Emídio, Beatriz Navarro, Hugo Casimiro, Joana Carreira, Mário Parreira, Ermelinda Pedroso
Centro Hospitalar de Setúbal, Hospital de São Bernardo, Internal Medicine Department, Setúbal, Portugal

Clinical summary

Iatrogenic Cushing's syndrome is rarely seen nowadays, as physicians are aware of the multiple consequences of chronic systemic glucocorticoid therapy. However, it is believed to remain underestimated. A 42 year old male with bronchial asthma was treated with dexamethasone for an acute exacerbation and kept the treatment chronically. He was admitted for general weakness, uncontrollable pain in his right hip joint. He presented a moon face, together with dorsocervical fat pad, abdominal purple striae and bruises. Abdominal CT scanning confirmed atrophy of adrenal cortex, compatible with Iatrogenic Cushing's syndrome and CT scanning of the hip joint showed lytic lesions and cortical rupture of the right femoral head suggesting avascular necrosis, known as a major complication of this disease.

Figure #1414. Iatrogenic Cushing showing a moon face, a dorsocervical fatpad and purple abdominal stria.

#1422 - Case Report

ADDISONIAN CRISIS – A RARE DISEASE ENTITY

Ana Isabel Rodrigues, Rita Martins Fernandes, Domingos Sousa, Hugo Calderon, Cristina Granja
Centro Hospitalar e Universitário do Algarve - Hospital de Faro, Faro, Portugal

Introduction

Addison's disease is a rare disease with a prevalence of 110-140 cases/1,000,000 people in Western Europe, in which there is an inadequate secretion of the adrenocortical hormones - cortisol, aldosterone and androgens.

Case description

A 40-year-old man presented to the emergency department with a 3-day history of dizziness and confusion. He denied any past

medical history or regular medical treatment and reported a flu-like illness in the last week, with fever and productive cough.

On physical exam he was confused, feverish, dehydrated, pale, asthenic, with hyperpigmentation of the oral mucosa. He was hypotensive (mean arterial pressure <65 mmHg), refractory to fluid resuscitation. All other systems were essentially normal.

Laboratory results showed hyponatremia (114 mmol/l), hyperkalemia (5.3 mmol/l) and hypoglycemia (62 mg/dl).

Brain computerized tomography scan showed no ischemic or hemorrhagic changes.

After consulting hospital records it was verified that the patient was diagnosed with Addison's disease 5 years ago, daily medicated with hydrocortisone 17.5 mg id and fludrocortisone 0.075mg id. Asking the patient, he said that he had self-suspended the medication at the onset of the flu-like illness. The most likely hypothesis was Addisonian crisis triggered by the flu.

He started treatment with hydrocortisone 100 mg 3 id, fludrocortisone 0.1mg id and ionic correction. Due to cardiovascular dysfunction that required aminergic support, he was admitted to the Intermediate Care Unit, with progressive weaning of corticosteroid therapy and a favourable evolution.

Discussion

Acute adrenal insufficiency or Addisonian crisis is a rare endocrine emergency in which the prognosis depends on suspicion and timely intervention. In this clinical case, the delay in treatment was due to the difficulty in collecting the clinical history due to the patient's state of consciousness, which made the diagnosis difficult. The goal of treatment is to achieve glucocorticoid and mineralocorticoid levels in healthy individuals, in similar circumstances, as well as symptomatic support

#1438 - Case Report

A RARE CASE OF A THYROID RUNNING OUT OF BATTERIES

Rui Files Flores, Joana Rita Lopes, Maurício Peixoto, Guilherme Alpedrinha, Sofia Caridade
Hospital of Braga, Braga, Portugal

Introduction

Myxedema coma is one of many possible causes for acute changes in consciousness and is described as a serious life-threatening hypothyroidism that slows the body metabolism and can culminate in death. The most frequent clinical presentations involve neurological manifestations, such as lethargy and coma. Other clinical findings include extreme bradycardia and hypothermia that require early diagnosis and treatment.

Case description

An 80-year-old woman, independent, was brought to the emergency department after being found unconscious. Past medical history is noted for hypertension, dyslipidaemia and sleep disorder. She had an accidental fall less than a month previous to this episode, which resulted in a fracture of the orbit and lamina papyracea. Usually medicated with esomeprazol, simvastatine, lisinopril and bromazepam. At admission, she was conscious but with slowed speech and movements. Physical examination was noted for hypothermia, poorly perfused extremities, bradycardia and discrete peripheral edema. ECG confirmed bradycardia with Osbourne waves and T wave inversion in all precordial leads, except for V1. Arterial blood gas showed lactate levels of 3.8 mmol/L. Blood analysis showed elevated myoglobin and creatine kinase; thyroid stimulating hormone level of 69 U/mL and free T4 level of 0.42 ng/dL. Brain CT scan excluded vascular lesions. Diagnosis of Mixedema Coma was assumed and the patient received hydrocortisone followed by levothyroxine. During the first days of hospitalization, corticosteroid and thyroid supplementation were both maintained (100mg three times a day and 50µg od, respectively). After exclusion of adrenal insufficiency, hydrocortisone was withdrawn. Clinical

evolution was favorable and levothyroxine was titrated according to TSH levels taken weekly. During hospitalization, seizures were noted and confirmed by EEG. Levetiracetam 500 mg twice daily was initiated with good response.

Discussion

Myxedema Coma is a rare manifestation of severe hypothyroidism that is associated with high mortality rate if left untreated. Some of its diagnostic criteria combine acute changes in consciousness and hypothermia, alongside elevation of TSH and suppressed T4 levels. Other clinical findings are bradycardia, rhabdomyolysis, hyponatremia, hypoglycaemia and hypoventilation. Initial treatment with steroids and thyroid hormone should begin as soon as possible. Support treatment for managing systemic complications should not be underestimated.

ENLARGING NECK MASS IN THE ELDERLY

Diogo Drummond Borges, Filipa Lourenço, Heidi Gruner, António Panarra

Serviço de Medicina Interna 72, Hospital Curry Cabral, Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

Clinical summary

87-year-old male went to the ER with complaints of headache, dysphagia, weight loss and cervical swelling. He denied dyspnea, dysphonia or nocturnal sweating. Physical examination revealed a heterogeneous hard elastic nodule on the right thyroid lobe over 4cm, and a smaller one on the left lobe with the same characteristics, with fixed right jugular adenopathy. Known medical history of type 2 diabetes, hypertension, chronic gastritis with Dieulafoy's lesion. Thyroid ultrasound revealed a large solid nodule, probable adenopathy with invasion and thrombosis of the left jugular vein. He underwent fine needle aspiration compatible with anaplastic thyroid carcinoma. Full body CT scan revealed loco regional invasion with vascular, lymphatic compromise and pulmonary metastasis, staged as T4N1bM1.

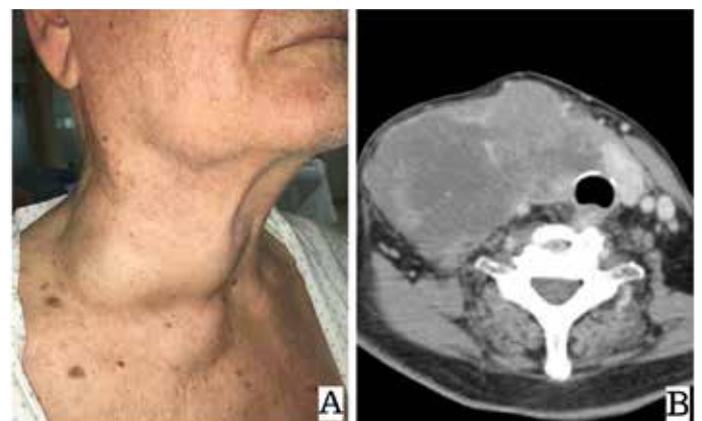

Figure #1444. A - Neck mass; B - Computed tomography (CT) findings of anaplastic thyroid carcinoma, with loco regional invasion, vascular and lymphatic compromise.

#1449 - Abstract

NONALCOHOLIC FATTY LIVER DISEASE AND THE CARDIOVASCULAR RISK IN DIABETIC PATIENTS

Elena Cristina Rezi

Lucian Blaga University, Medical Faculty, Sibiu, Romania

Background

Non-alcoholic fatty liver disease (NAFLD) can be considered a feature of metabolic syndrome. Some studies suggest that the metabolic syndrome predicts incident cardiovascular disease (CVD), so it is possible to hypothesize that NAFLD patients might have a greater CVD risk.

Methods

We have performed a retrospective observational study in order to see if there is any significant difference between the risks of CVD (assessed by using the UKPDS risk engine) at the type 2 diabetic patients with NAFLD, comparing with those without NAFLD. We have studied a group of 80 type 2 diabetic patients who were hospitalized in the Diabetes and Nutrition disease Department of the Clinical County Hospital from Sibiu, Romania, during a period of three months.

Results

From the whole group, 23 patients (28.75%) were diagnosed with NAFLD. The average age of the patients with NAFLD was higher than of those without NAFLD (66.91 ± 7.59 years, comparing with 60.29 ± 9.15 , with $p=0.0015$). The risks of developing CVD at those without NAFLD comparing with those with NAFLD were: for coronary heart disease 21.3% comparing with 33.02% ($p=0.0071$), for fatal coronary heart disease 15.3% comparing with 26.81% ($p=0.0031$), for stroke 7.6% comparing with 15.91% ($p=0.0001$) and for fatal stroke 1.3% comparing with 2.86% ($p=0.0004$). A linear correlation was found between the Forns index of liver fibrosis and the risk of developing CVD ($r=0.21$ for coronary heart disease, $r=0.199$ for fatal coronary heart disease, $r=0.334$ for stroke and $r=0.325$ for fatal stroke). The level of liver cytolysis did not correlate with the risk of CVD, in the NAFLD group.

Conclusion

The diabetic patients with non-alcoholic fatty liver disease have a higher risk of developing cardiovascular diseases than those without the liver pathology. There is a linear correlation between the degree of liver fibrosis and the risk of cardiovascular diseases. Our findings support the hypothesis that non-alcoholic fatty liver disease is associated with a moderately increased risk for future cardiovascular events among type 2 diabetic individuals, independent of the degree of liver cytolysis.

#1482 - Abstract

DYSTHYROIDISM AND SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

Wafa Baya, Imen Ben Hassine, Jihed Anoun, Fatma Ben Fredj Ismail, Monia Karmani, Amel Rezgui, Chedia Laouani Kechrid
Internal Medicine Department, Sahloul University Department, Sousse, Tunisia

Background

Thyroid dysfunction is more common in lupus patients than in general population. The aim of our study is to evaluate the frequency of dysthyroidism in lupus patients.

Methods

This is a retrospective descriptive study carried out in the Internal Medicine Department of Sahloul University Hospital in Sousse, based on the records of lupus patients.

Results

Among the 127 lupus patients hospitalized at least once in the department, thyroid dysfunction was observed in 11 patients. They were all women. The mean age was 53 years [26 - 79 years]. The mean duration of SLE was 11.5 years. Articular, cutaneous and hematological involvements were mostly observed. Our patients have been treated with synthetic antimalarials associated with corticosteroids in the majority of cases.

All cases of thyroid dysfunction were hypothyroidism. Hypothyroidism was subclinical in 4 cases. Asthenia and weight gain were the most frequent manifestations. A goiter was found in two patients. Hashimoto's thyroiditis was diagnosed in four cases. Hypothyroidism was discovered after SLE diagnosis in one case. Among these patients, only one case of Schmidt syndrome was found.

The patients were on substitution treatment when indicated, with good evolution.

Conclusion

Any lupus patient must benefit from thyroid exploration given the frequency of subclinical hypothyroidism association and Hashimoto's thyroiditis.

#1496 - Case Report

UREA IN THE TREATMENT OF SIADH

Marta Arriaga Rocha, Joana Maurício, Martim Trovão Bastos, Susana Bastos Heitor
Hospital Prof.Doutor Fernando Fonseca, Amadora, Portugal

Introduction

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) results from the non-osmotic release of vasopressin. The secretion of this hormone induces water retention with maintenance of normal total sodium levels, which results in the

dilution of solutes and consequent euvoletic hyponatremia and hypoosmolality. Although SIADH is associated with multiple conditions, one-third is idiopathic. Therapy involves water restriction and an increase in solute intake (0.25-0.50 g/kg/day of urea) or a combination of loop diuretics and sodium chloride may be considered.

Case description

An 83-year-old man diagnosed with hypertension, dyslipidemia and smoking 45 pack-years, treated with losartan and atorvastatin, was hospitalized due to altered state of consciousness. At admission he presented with hyponatremia of 126 mmol/L. Objective examination had no signs of dehydration or water overload. Among the aetiological investigations during hospitalization were: creatinine 0.58 mg/dL, urea 0.58 mg/dL, uric acid 2.2 mg/dL, plasma osmolality 258 mEq/L, urinary osmolality 499 mOsmol/kg, urinary sodium 125 mmol/L. Euvoletic hypotonic hyponatremia was admitted and treatment with 0.9% sodium chloride (NaCl), water restriction and furosemide 40 mg oral was initiated. Assuming SIADH or endocrinological pathology as a diagnostic hypothesis, he performed thyroid function tests with normal values, serum cortisol dosage with borderline value (4.43mcg/dL), ACTH 29.57 pg/ml, still performing synacthen test with cortisol 0': 5; 30': 18.5; 60': 20mcg/dL. Thoracic, abdominal, pelvic and brain CT scan did not show alterations. Analytical profile was within reference value. In the absence of response to the established measures, with worsening hyponatremia (119 mmol/L), 40 mL of 20% NaCl was added to the 500 mL of 0.9% NaCl, with improvement of serum sodium levels (133 mmol/L). However, after interrupting fluid therapy, the hyponatraemia worsened. The implementation of therapy with 30 g/day of Urea restored the ionic balance and maintenance of serum sodium values in the order of 134 mmol/L. The patient was discharged keeping urea therapy until further evaluation in the outpatient clinic.

Discussion

SIADH causes high morbidity and its main therapeutics have varying efficacy and tolerability. Urea appears as an effective, safe and relatively well-tolerated alternative for the treatment of euvoletic hypotonic hyponatremia, which can be used on an outpatient basis and with lower costs when compared to vasopressin antagonists.

#1522 - Case Report

GAIT DISORDERS- DIFICULT DIAGNOSIS IN A DIABETIC PATIENT

Rita Dos Santos Marques

Centro Hospitalar do Oeste, Torres Vedras, Portugal

Introduction

The diabetic neuropathy is a frequent complication of Diabetes mellitus. In Diabetes mellitus type 1, the distal polyneuropathy usually becomes symptomatic, after years of prolonged

hyperglycemia. In majority it manifests with sensitive and motor symptoms, such as ataxia. Ataxia is an incapacity to maintain a normal posture and a coordinated movement.

Case description

Male, 65 years old, with diagnosed diabetes mellitus type 1 (30 years ago), dyslipidemia, essential hypertension and urinary incontinence. Chronically medicated with Insuline and Ramipril. He comes to emergency room with headache, vomits and hyperglycemia. Physical exam: prostrate but responsive to verbal stimulus with ocular opening, pale e dehydrated, acetone breath. Arterial sample: pH 7.16, bicarbonate 12 mmol/L; lactate 1.6 mmol/L; glucose 320 mg/dl; anion gap 20.1 mmol/L; ketone bodies 7.8 mg/dL.

Hospitalized with diabetic ketoacidosis, without sign of infection. During hospitalization there is maintenance of confusion, bilateral muscular weakness of lower limbs and ataxic gait. Brain CT: "supratentorial ventricular dilation, with reduce sulcal permeability, some degree of hydrocephalus with Evan's ration of 0.42. EEG: chronic loss of motor units of the distal muscles, related to sensitive and motor polyneuropathy in patient with chronic diabetes mellitus, without signs of demyelinating disease such as amyotrophic lateral sclerosis. There was improvement in metabolic status and mental confusion. Neurologist's examination: " oriented in person and space but not in time; Without dysarthria, neither diplopia or nystagmus; fast and irregular postural tremor. Hypopalasthesia from feet to ankles; Proprioception errors fin feet and hand fingers. Nose-finger test: dysmetria with closed eyes. Positive Romberg test. Irregular gait mostly with closed eyes". He was discharged with booked Neurology's consultation, for follow-up.

Discussion

This case report highlights the difficulty to have a definitive diagnosis in a diabetic patient, with bad metabolic control and a long-term evolution. The clinical features (ataxic gait, urinary incontinence, cognitive disorders), and brain CT findings, may suggest normal pressure hydrocephalus. Spontaneous resolution of the mental confusion status, exclude that diagnosis, and assume that gait disorder may be related to diabetic neuropathy. A definitive conclusion just be possible with natural disease progression and a good follow-up of the patient.

#1547 - Case Report

GABA (IN) THE GUT

Maria João Palavras, Ana Albuquerque, Flávia Santos, Filipa Alçada

933613792, Leiria, Portugal

Introduction

Pregabalin, a gamma-aminobutyric acid (GABA) analogue used to treat neuropathic pain and fibromyalgia, is mostly used for the treatment of pain related to nerve injury or inflammation, but it has also been used as an adjunctive therapy for partial onset seizures.

Case description

The authors describe the case of a 61 year-old woman with severe demyelinating sensorimotor polyneuropathy, admitted to the hospital following acute exacerbation of chronic obstructive pulmonary disease. Two days later, she suffered three episodes of generalized tonic-clonic seizure. The cause for these seizures was not identified. The electroencephalogram suggested a grade 3 metabolic encephalopathy with no epileptogenic activity. After speaking with the patient's sisters, an abuse of pregabalin ingestion at home was identified, at least 800mg per day. Since this medication was not administered during the hospital stay and the patient never complained about uncontrolled pain, the most probable cause for the seizure was assumed to be pregabalin withdrawal.

Discussion

The case focused on a patient who developed seizures after a sudden discontinuation of a relatively large dose of pregabalin, which is very uncommon in a patient with no previous history of epilepsy. The reason for the overuse of pregabalin in this patient is unknown, since she denied any additional benefits, as well as the abuse itself. The authors believe a thorough psychological examination should take place before starting chronic pain relief medications, since further studies are needed to clarify which ones will cause withdrawal seizures or addiction psychosis.

#1566 - Case Report

COR PULMONALE SECONDARY TO SEVERE PULMONARY HYPERTENSION AS THE FIRST MANIFESTATION OF GRAVES' DISEASE

Sandra D. Santos¹, Ana Guiomar, Ana Cristina Martins¹, João Rua¹, Pedro Ribeiro¹, Armando Carvalho^{1,2}

¹ Serviço de Medicina Interna, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

² Clínica Universitária de Medicina Interna, FMUC, Coimbra, Portugal

Introduction

Pulmonary hypertension (PH) is a severe, multifactorial, multi-causal clinical syndrome that compromises physical capacity and causes great morbidity. It consists of an increase in pulmonary arterial pressure by a progressive increase in pulmonary vascular resistance, which tends to evolve with right ventricular failure and premature death of the patient.

Case description

A 88-year-old woman, with history of CKD stage IIIa, atrial fibrillation, heart failure and hypertension, was evaluated at the Hospital because of dyspnea and edema of the lower limbs. She was hemodynamically (HD) stable, afebrile, with absence of murmur in both pulmonary bases, with hepatomegaly, ascites and marked inferior limbs edema. She had type 1 respiratory insufficiency, atrial fibrillation with rapid ventricular rate, and increased Nt-proBNP (20,000 pg/ml). The patient was diagnosed with severe heart failure and was hospitalized. There was a history of 2 similar hospitalizations

that year, with rapid re-admission after discharge and loss of walking ability. Three days later, she presented acute pulmonary edema and, underwent a transthoracic echocardiogram (ETT), which showed severe PH (PSAP 75 mmHg), right ventricular dysfunction without left structural or functional dysfunction. An AngioCT excluded pulmonary thromboembolism. The PH investigation was initiated, although the right catheterization was refused, including a CT-CTAP that excluded relevant pulmonary pathology and an extended, also negative, autoimmune study. Thyroid function evaluation [TSH <0.008 IU/ml, T4L 3.2 ng/dl (0.8-1.6), T3L 3.7 pg/ml (1.8-4.2), TRABS 1,6 IU/ml (<1.0)] revealed a Graves' disease with thyrotoxicosis. Treatment with propylthiouracil, 100 mg 3id, was started and later replaced with thiamazol due to an allergic reaction. There was a rapid improvement in the clinical and hemodynamic status of the patient, stabilization of the right HF and resolution of the volume overload. A new ETT showed improvement with mild PH (PSAP 50 mmHg). At discharge, the patient was HD stable, with no need for oxygen therapy or relevant limitation of physical activity (NYHA I) and was able to walk autonomously. At one month reevaluation appointment the patient remained stable.

Discussion

The patient had a clear clinical course of right HF due to severe PH, but few clinical signs of hyperthyroidism (increased cardiac output, decreased vascular resistance). Therefore, we assumed that PH was due to stimulation and proliferation of the pulmonary artery vasculature.

#1570 - Case Report

ALKAPTONURIA

Ana Simas, Ricardo Veloso, Maria Menezes, Ana Silveira, Juvenal Morais, Mariela Rodrigues, Joana Mota, Sandra Brum, Fátima Pinto, António Goulart

Hospital da Horta, E.P.E., Horta, Portugal

Introduction

Alkaptonuria is a rare autosomal recessive error in phenylalanine and tyrosine metabolism (affecting 0.0004 to 0.001% of the world's population) that causes an accumulation of homogentisic acid, consequently, increasing urinary excretion. The first signs appear in childhood but the patients only become symptomatic in the fourth decade of life. This disease is characterized by ochronosis arthropathy, cardiovascular, cutaneous and ocular ochronosis, renal lithiasis and black urine. Ochronosis arthropathy is the most disabling manifestation and it can initially affect the large joints and vertebral column.

The authors consider that this case report should be exposed by its rarity, contributing in this way for a better knowledge and characterization of this disease.

Case description

A 72-years-old female with personal antecedents of type 2 diabetes, arterial hypertension, dyslipidemia, incapacitating left

gonartrosis and chronic kidney disease, with multiple references in follow-up visits to “blue disease” in order to justify the “blue” dermic coloration, diagnosed at the age of 50.

The patient arrived to the emergency department with nausea, vomiting and prostration. The physical examination revealed crackles in both lung bases, edema of the lower limbs, cyanosed lips, gray skin color with dark spots on the hands and ears. The urine collection bag presented dark-colored urine.

The clinical picture worsened and the patient died a few hours later due to heart failure.

Given the atypical findings, direct relatives were contacted, confirming similar dermic dark spots in other family members.

A clinical autopsy was performed to clarify a possible hereditary disease. The macroscopic observation revealed dark spots on the eyelids, ears, areas of limb flexion, pleats of hands palms and soles of the feet, ribs with dark color mainly at the cut surface, heart with dark insertion of aortic and mitral valves, and brown shade of aorta. The histology revealed irregular deposits of brown/ochre pigment in the dark areas previously cited and in areas where macroscopic observations looked normal. These features are compatible with ochronosis (alkaptonuria).

Discussion

In this case report the signs and symptoms were typical, however the diagnosis was post-mortem due to the rarity of the disease. This case shows the importance and necessity of a high level of suspicion.

#1603 - Abstract

GESTATIONAL DIABETES OF A MEDIAN PORTUGUESE COMMUNITY HOSPITAL

Juliana Chen Xu, Angela Coelho, Pedro Carvalho E Marques, Sónia Da Costa Fernandes, Teresa Pinto, Ana Maria Maia
CHPVVC, Póvoa De Varzim, Portugal

Background

Gestational diabetes (GD) has lately grown in number (nr), not only because of underdiagnosed cases in the past, today's characteristics of our society (overeating and non-exercising) but also the recent lower cut-off (92 mg/dL of fasting glucose).

In order to analyze the effect that GD has in the community that attends our hospital, we decided to collect GD cases for one year.

Methods

Data was collected during GD consultations since the diagnosis until post-partum evaluation of all the births occurring from 2018 January 1st to December 31st. Therefore, the database is based on those registrations and examined retrospectively. The information gathered was: citizenship, age, academic qualifications, familial history of diabetes, body mass index (BMI), history of previous GD, previous macrosomia, diagnosis with fasting glycemia or oral glucose tolerance test (OGTT), gestational week of diagnosis/1st consultation, nr of waiting weeks, weight

before pregnancy/diagnosis/end of pregnancy, use of insulin or metformin, pregnancy complications, delivery information, newborn information and reevaluation post-partum with OGTT. IBM SPSS Statistics 25 was used for statistical analysis.

Results

We had 84 cases of GD in 2018 from a total of 1055 births, with mean age of 33.93 years.

15.5% had higher education and 8.3% completed high school. 69% had familial history of diabetes. 32.1% were already obese before pregnancy, 33.3% were overweight and 32.1% had normal BMI. 16.7% had previous pregnancies with GD and 4.8% had previous macrosomia. The median delay from diagnosis until the 1st consultation was 8 weeks, with minimum 1week and maximum 30 weeks of waiting. 61.9% of the pregnant were controlled with diet and exercise, 15.5% had only insulin therapy, 10.7% had just metformin and 11.9% had both insulin and metformin during pregnancy. Only 6% of the newborns weighted ≥ 4000 g from which 40% were from mothers controlled only by diet. On post-partum reevaluation, we had one case of diabetes, 2 impaired glucose tolerance and a case of impaired fasting glucose.

Conclusion

The familial history of diabetes and previous BMI are great risk factors for the development of GD. However, it is possible to control glycemia only with appropriate diet and exercise.

It has come to our attention that our latency period is too long. The reasons for such are still under evaluation and it may be due to delay in referral/scheduling consultations, so measures have been taken to speed up the patients follow up.

#1617 - Abstract

THE RELATIONSHIP BETWEEN STRESS LEVELS AND METABOLIC RISK FACTORS IN NORMAL AND PROFESSIONAL MUSICIAN POPULATIONS

Yavuz Masrabacı, Melisa Askim Paker
Güven Cayyolu Healthy Living Campus, Ankara, Turkey

Background

The aim was to reveal the relation between different stress levels and metabolic abnormalities in normal population, and to compare this relation in normal and musicians populations.

Methods

Samples were consisted of 46 professional musicians and 21 participants from normal population. Recent Life Events Scale was applied to participants who attended to Güven Cayyolu Healthy Living Campus-Checkup Program. Mann-Whitney U Test, χ^2 Test and independent samples t-tests (Bootstrapping run) were run to reveal differences in fasting blood glucose, insulin resistance and TOTAL/HDL cholesterol among gender and different stress levels in normal population, and one-way between subjects ANOVA

tests (Bootstrapping run) were run to compare these variables among normal and musicians.

Results

In normal population, males had significantly higher TOTAL/HDL cholesterol ratio than females, same as musicians whilst in musicians, different stress levels were founded to significantly differ for fasting blood glucose level. Male musicians had found to have significantly lower TOTAL/HDL cholesterol ratio and fasting blood glucose than males in normal population. There was no significant difference in metabolic abnormalities among stress levels in normal population.

Conclusion

In normal and musician populations, males had higher cardiovascular disease risks since TOTAL/HDL cholesterol ratio was higher. Performing musical instruments could be thought as a protective factor for TOTAL/HDL cholesterol ratio and fasting blood glucose.

#1625 - Case Report

PREGNANCY-RELATED OSTEOPOROSIS

Ana Chora Sousa, Francisco Dias Claudio, Rita Ribeirinho, Tiago Tribolet Abreu

Hospital do Espírito Santo de Évora, Évora, Portugal

Introduction

Pregnancy-related osteoporosis is a very rare condition characterized by the occurrence of fracture during pregnancy or the puerperium. Its etiology and pathogenesis are unknown. Throughout the last period of pregnancy, calcium mobilization and bone resorption are increased and lactation imposes a further increase. These changes could lead to osteoporosis and fracture in young women.

Case description

A 32-year-old pregnant woman, primiparous, at 32 weeks of pregnancy, was sent to the emergency room after a small-energy fall with trauma of the lower limb. She had no relevant past medical or family history. The radiological evaluation showed a subcapital femur fracture. The patient was submitted to a percutaneous osteosynthesis, without post-op complications. The blood panel showed a vitamin D of 15 ng/mL, with normal serum calcium and phosphorus. At discharge, she was given bisphosphonates, calcium and cholecalciferol. Four weeks later, she delivered the baby by caesarean. The bone mineral density (BMD) T-scores, 3 months after the delivery were -1.6 at femur total and -0.9 at lumbar. The therapy was maintained for 6 months. The BMD T-scores 15 months after the delivery and after 6 months without therapy were -0.8 at femur total and -0.7 at lumbar. After a 2-year follow up there were no new fractures.

Discussion

Our aim is to report this unusual case of pregnancy-related

osteoporosis with a pathological femur fracture during the third trimester of a primiparous woman. The underlying pathological factor is still not clear. However, there are certain risk factors such poor nutrition, low calcium intake, family history, smoking and corticosteroid intake which strongly increase the risk. Our patient did not have any of these risk factors. Antiresorptives are the first line of management in pregnancy-related osteoporosis with fractures. Calcium and vitamin D supplementation increase the levels of calcium in body and calcium absorption, respectively. The optimal duration of bisphosphonate in pregnancy-related osteoporosis remains unsolved. Following the delivery and the above-described therapy, the bone mineral density improved and she did not experience any recurrence.

#1633 - Abstract

THREE YEARS OF MANAGEMENT OF GESTATIONAL DIABETES IN A PORTUGUESE HOSPITAL CENTRE

Giovana Clare Sousa Ennis, Diana Pinho Santos, Cristina Andrade, Adelino Carragoso, Isabel Torres, António Correia Tondela-Viseu, Hospital Centre, Portugal, Viseu, Portugal

Background

Gestational diabetes (GDM) is prevalent and is associated with adverse maternal and foetal outcomes. The authors report the results of a three-year follow-up study of pregnant women with GDM.

Methods

A retrospective study was performed based on medical records of women with gestational diabetes followed in a Portuguese hospital centre with childbirth from 2015 to 2017.

Results

501 pregnant women with GDM were included. Women's ages ranged from 16 to 44 years (mean 32.75). Most were in the 30 to 35 year age group and nearly a third were over 35. In 2017, there was a considerable reduction of overweighted or obese women (51.3%), however more than half still had a body mass index above normal values. The third trimester glycated haemoglobin value was stable throughout these three years, with a mean of 5.15% (± 0.40). Average gestational age at childbirth was 38.58 weeks (± 1.42), and 92.3% of women carried their pregnancy to term. Average new-born's weight was 3,192.88g (± 490.55). The proportion of new-borns weighing more than 4,000kg at birth averaged 4.2%, ranging from 1.8% in 2015 to 4.9% in 2016. The percentage of low birth weight (less than 2,500 g) has been more stable, averaging 8.0%. More than 80% of the women included in our study were reclassified. At the reclassification appointment, more than 90% presented a normal glucose tolerance test. There was a progressive increase in fasting glucose abnormality diagnoses (0.64%, 1.76% and 2.08% in 2015, 2016 and 2017, respectively), whereas diminished glucose tolerance declined

over the period (3.87%, 2.35% and 2.08% in 2015, 2016 and 2017, respectively). 2017 saw the largest proportion of diabetes diagnoses in reclassification appointments (2.58%).

Conclusion

The number of women who delay pregnancy has been growing over the years, as is shown by our study in which almost third of the sample were over 35 years of age. There is a surprising number of young women overweighted or obese, accentuating the increased cardiovascular risk associated with GDM. Nonetheless, pregnancy outcomes were quite satisfactory, as more than 90% of these women carried their pregnancy to term, and the average rate of macrosomia was less than 5%. Post-partum reclassification of the state of tolerance to carbohydrates is essential, as a history of GDM is a risk factor for GDM in a subsequent pregnancy, as well type-2 diabetes and cardiovascular disease.

#1656 - Case Report

HYPERCALCEMIA IN A 75-YEAR-OLD PRESENTING WITH PANCREATITIS AND ITS CONFOUNDING FACTORS

Catarina Ribeiro Pereira

Hospital Prof. Doutor Fernando de Fonseca, EPE, Lisboa, Portugal

Introduction

In the presence of pancreatitis, finding an aetiology can be challenging and has important prognostic implications.

Hypercalcemia is an uncommon yet recognized cause of acute pancreatitis with a reported prevalence between 1,5-8%. In its presence, particularly in the elderly, secondary malignancy should be excluded.

Case description

A 75-year-old male with previous medical history of hypertension, renal lithiasis, hyperuricemia, benign prostatic hyperplasia submitted to parcial prostatectomy in the past and chronic constipation was admitted with vomits and abdominal pain with epigastric location radiating to both flanks. Concomitantly, he referred unquantified weight loss as well as bilateral hip pain with mechanical features in the 6-months previous to admission.

Initial investigation presented an elevation of inflammatory parameters, hyperamylasaemia 1087 U/L and hypercalcemia of 12.9 mg/dL. The abdominal ultrasound documented a distended gall bladder without evident of biliary lithiasis or biliary tract distention. Abdominal CT-scan demonstrated pancreatic inflammation and additionally three bone lesions with lithic features in the pelvic region.

Additional studies directed to hypercalcaemia revealed an elevated parathormone level of 357pg/mL and thyroid ultrasound identified a nodule with mixed features.

Bone scintigraphy presented six additional bone lesions of osteoblastic nature, further supporting the neoplasm hypothesis. Given past medical history, a free prostatic antigen was solicited

25 ng/mL and the patient underwent prostatic biopsy with no identification of tumour cells.

The patient underwent PET tomography that identified FDG avidity in the pancreatic head and further characterized bone lesions as possible implants. No tumor was found on an eco-guided biopsy performed later. Two hip lesions were biopsied surgically and pathology identified "brown tumour" with extensive osteoclastic activity and no evidence of tumour cells. Furthermore, an adenoma was found and confirmed on parathyroid scintigraphy, confirming the diagnosis of primary hyperparathyroidism. The patient awaits surgery on support therapy with bisphosphonates.

Discussion

This case demonstrates the interdisciplinarity that defines, and norms, Internal Medicine, and the importance of the classical syndromic presentations. Therefore, in an era where cancer diagnosis is more frequent and actively sought in medical wards, an unbiased knowledge of the classic metabolic multisystemic syndromes should remain present.

#1669 - Abstract

EFFECTS OF PRE-PREGNANCY BODY MASS INDEX AND GESTATIONAL WEIGHT GAIN ON RISK OF MACROSOMIA IN WOMEN WITH GESTATIONAL DIABETES MELLITUS

Diana Pinho Santos, Giovana Ennis, Adelino Carragoso, Cristina Andrade, Isabel Torres, António Correia

Centro Hospitalar Tondela-Viseu, Viseu, Portugal

Background

Gestational Diabetes (GD) is associated with numerous complications for both mother and fetus. Pre-pregnancy Body Mass Index (BMI) and Gestational Weight Gain (GWG) have been associated with newborn's weight. We proposed to investigate: (1) associations between pre-pregnancy BMI, total GWG and excessive GWG with macrosomia; (2) differences between excessive and no excessive GWG groups in pre-pregnancy BMI variable.

Methods

This observational retrospective study included 459 pregnant women with GD followed in a Portuguese Hospital with childbirth from 2015 to 2017. BMI was categorized according to WHO criteria. Total GWG was calculated using the weight at the last appointment before delivery and the pre-pregnancy weight. GWG was categorized according to Institute of Medicine recommendations. Macrosomia was defined as birth weight ≥ 4000 g. Association between pre-pregnancy BMI, total GWG and excessive GWG with macrosomia were computed using a Chi-square (X^2) test. Differences between excessive and no excessive GWG groups in pre-pregnancy BMI variable was computed using student's t-test. Statistics were performed in IBM-SPSS 23 and the level of significance was established in 5%.

Results

Pre-pregnancy BMI mean was $27.0 \pm 6.0 \text{ kg/m}^2$; 2.6% of women were underweight, 42.9% had normal weight, 27.7% were overweight and 26.8% were obese. The mean birth weight was $3216.5 \pm 478.7 \text{ g}$ and macrosomia occurred in 4.1% of newborn. 4.4% of overweight and obese women delivered a macrosomic infant, and 4.1% of women with normal weight had a macrosomic infant. Significant association was found between pre-pregnancy BMI and macrosomia ($X^2=9.054$, $p<0.05$). The mean total GWG was $8.5 \pm 5.7 \text{ kg}$ in the whole population. No significant associations were found between total GWG ($X^2=50.420$, $p>0.05$) and macrosomia. Only 32.0% of women had an adequate GWG and 17.2% had an excessive GWG. Women with excessive GWG had more macrosomic infants compared with women with no excessive GWG (7.5% vs 3.4%), but no significant association was found between excessive GWG ($X^2=2.757$, $p>0.05$) and macrosomia. Women with excessive GWG had a higher mean pre-pregnancy BMI ($28.8 \pm 4.6 \text{ kg/m}^2$) than women without excessive GWG ($26.7 \pm 6.2 \text{ kg/m}^2$) ($t=-3.474$, $p<0.05$).

Conclusion

Pre-pregnancy BMI is predictive of the risk of macrosomia and women with excessive GWG had a higher pre-pregnancy BMI. This information should be considered when designing more efficient strategies to control weight before the women's pregnancy.

#1679 - Case Report

(A RARE CASE OF) METHADONE-INDUCED HYPOGLYCEMIA

Maria Inês Vicente^{1,2}, Alexandre N. Fernandes¹, Tânia Strecht¹, Ana Paula Antunes¹, Carolina Sequeira¹, Marta Custódio¹, Ana Gorgulho¹, Jana Zelinová¹

¹ Hospital de Cascais, Cascais, Portugal

² IPO Lisboa, Lisboa, Portugal

Introduction

Methadone is the main pharmacologic agent used in the treatment of opioid addiction. Although uncommon, hypoglycemia has been observed in patients receiving this drug and the effect is believed to be dose-related. Some studies point out that the risk is increased for doses exceeding 40 mg orally per day. Several authors recommend blood glucose monitoring during methadone use and titration.

Case description

We present the case of a 48-year-old woman with medical history of HIV1/HCV coinfection for 20 years and irregular antiretroviral therapy use, alcoholic and viral chronic hepatic disease (CHD), current smoker and previous IV drug user, on methadone 80 mg daily and recently under cotrimoxazole prophylaxis (CD4 count 2 cells/ μL). She was admitted to the emergency room for symptomatic hypoglycemia (35 mg/dL), which became partially refractory to dietary measures and glucose infusion. Serum insulin

was normal (14 $\mu\text{UI/mL}$), as were serum peptide-C (6.4 ng/mL), β -hydroxybutyrate (0.03 mmol/L), ACTH (20.5 pg/mL) and morning cortisol (18.2 mcg/dL). She also had anemia, thrombocytopenia, mild hyponatremia, prolonged INR, hypoalbuminemia and altered hepatic enzymes, all presumed to be related to CHD. Abdominal CT showed features of CHD. Episodes of hypoglycemia started before she initiated cotrimoxazole (1 month earlier). Based on rare cases of hypoglycemia associated with this drug it was suspended, but hypoglycemia persisted. It only ceased after methadone dose reduction to 70 mg/day. The patient was discharged home and so far (8 months later) hypoglycemia never recurred.

Discussion

Methadone-induced hypoglycemia has been mainly described in association with rapid dose escalation. Our patient was already on methadone for several years, however, hypoglycemia only resolved after dose reduction and no other apparent explanation was found. This case reminds us about the clinical importance of knowing drug side-effects in our daily practice and that methadone use should be included in the differential diagnosis of new onset hypoglycemia.

#1695 - Case Report

ANTIBODY-INDUCED GRAVES' ORBITOPATHY

Fabiana Gouveia¹, Isabel Taveira², Hipólito Nzwalo²

¹ Hospital Central do Funchal, Funchal, Portugal

² Unidade Local de Saúde do Litoral Alentejano, Funchal, Portugal

Introduction

Ocular manifestations, in particular, exophthalmos, are a frequent complication of Graves' Disease (GD). The occurrence of ophthalmopathy preceding the clinical manifestations of the DG is rare.

Case description

Woman, 49 years old, with a history of hypertension, type 2 diabetes mellitus, obesity, and dyslipidemia, with a history of progressive onset in one week of holocranial headache and monocular blurred vision on the right. At the emergency department, hemorrhagic exudate and conjunctival hyperemia of the right eye were present. The initial investigation (ocular fluorescein angiography, angio-resonance, cerebral and ocular Magnetic Resonance Imaging (MRI)) was negative. He did not present systemic symptoms or constitutional complaints. Repetitive study for systemic, autoimmune diseases including anti-thyroid antibodies was negative. During three years, the clinical condition remained stable, until the onset of aggravation, with asymmetrical involvement, with evident proptosis, hyperemia and slight pain to the ocular mobilization. Orbital MRI showed exophthalmos and dimensional increase of the extrinsic muscles of the eye (inferior rectus, medial and superior rectus bilaterally). With the exception of holocranial headache, there were no additional complaints.

The analytical study revealed the presence of low TSH (0.14 uIU/mL), T4 (11.55 ug/dl), slightly increased anti-thyroid peroxidase antibodies consistent with GD diagnosis.

Discussion

This case highlights the diagnostic difficulties arising from an atypical manifestation of a well-described disease. The isolated attainment of the eye in the GD is due to the particular affinity of the GD antibodies to the ocular tissues, probably in a phase of reduced activity of the disease.

#1696 - Abstract

THE EFFECT OF DAILY VERSUS WEEKLY LEVOTHYROXINE - REPLACEMENT ON THYROID FUNCTION TEST IN HYPOTHYROID PATIENTS AT A TERTIARY CARE CENTRE

Pratibha Singh^{1,2}, Avinash Chandra Srivastava^{1,2}

¹ Dr. Ram Manohar Lohiya Institute of Medical Sciences, Lucknow, India

² Dr. Ram Manohar Lohiya Hospital, Lucknow, India

Background

Hypothyroidism is the most common thyroid disorder and affects women more frequently than men, and incidence increases with age. Its clinical presentation ranges from asymptomatic to severe, with myxedema coma as a severe complication.

In spite of being easily treatable using a daily dose of levothyroxine (LT4),

many patients remain hypothyroid due to malabsorption syndromes, pancreatic and liver disorders, drug interactions, autoimmune gastritis, polymorphisms in type 2 deiodinase, high fiber diet and, more frequently, noncompliance to LT4 therapy.

Noncompliance is attributed to the limitations and inconveniences imposed by therapy:

1. the need to take the medication while fasting;
2. the need to wait approximately 30 minutes for the next meal;
3. the need to take the medication on a daily basis.
4. the need to avoid other medications that may interfere with absorption.

Methods

The mean treatment dose of oral thyroxine is 1.6 µg/kg/day. The results achieved with this dose are adequate and reproducible. This will be a randomised crossover experimental study in which 100 hypothyroid patients on a stable LT4 dose will be divided into 2 groups of 50 each.

In group I, patients will given daily therapy for 8 weeks and then shifted to weekly therapy for the next 8 weeks. In group II, patients will be given LT4 once a week for 8 weeks and then switched to daily therapy for the next 8 weeks.

Inclusion Criteria:

1. All patients will be bio-chemically euthyroid on stable doses of LT4 for at least 3 months before recruitment into the study.

2. AGE GROUP: 25 - 55 years
3. Both males and females but in a fixed proportion of 1:9
4. Purely voluntary participation

Exclusion Criteria:

1. Population not under euthyroid conditions.
2. Pregnant women and Postpartum females
3. Population with comorbidities like IHD, DM, CAD, immunodeficiency state, chronic illness.
4. BMI > 30 kg/m²
5. Population > 60 years
6. Secondary and Tertiary Hypothyroidism

Ethical considerations

1. Transparency on goals and methods of experiment to be shared with patient
2. No additional cost to participating patients
3. Participants' information will be processed in confidence

Results

1. TFT ((euthyroid level) (0.5-4.0 mU/L)
2. quality of life (QoL) with SF-36
3. Hyperthyroidism symptom scale (HSS) score will be compared in each group at 0, 8, and 16 weeks.

Conclusion

Demonstrate that a weekly dose of levothyroxine is sufficient to manage hypothyroidism and show improved TFT, QoL (using SF-36 as a generic measure) and HSS.

#1701 - Abstract

GESTATIONAL DIABETES IN A PORTUGUESE HOSPITAL CENTRE IN 2017

Giovana Clare Sousa Ennis, Diana Pinho Santos, Cristina Andrade, Adelino Carragoso, Isabel Torres, António Correia
Tondela-Viseu Hospital Centre, Viseu, Portugal

Background

Gestational diabetes mellitus (GDM) is prevalent and is associated with a high risk of perinatal morbidity and mortality.

Methods

A retrospective study was performed, based on medical records of women attending gestational diabetes appointments in a Portuguese hospital centre with childbirth in 2017, compared to the national data.

Results

A total of 185 pregnant women with GDM were included, with ages ranging from 16 to 44 (average 33 years). 29.2% were over 35 years old, lower than national average (45%). 18.4% had a previous history of GDM. More GDM women were diagnosed in the first trimester (51.9%) than in the second trimester (42.2%); the

inverse occurred at national level (36.0% and 56% respectively). 1.1% were diagnosed only in the third trimester. Most women (58.4%) waited 3 to 6 weeks for their first appointment, and only 10.3% had their first appointment in less than 3 weeks. These results are inferior to national data (27.4% with first appointment in less than 3 weeks). More women achieved glycaemic control without pharmacological therapy than in the national whole (67% vs. 64.4%). Only 13.6% of women who needed pharmacological therapy were medicated with metformin, compared to 22% nationally, while 15.7% were treated with insulin and 3.7% with both, compared to 17.9% and 6.9% respectively in the national data. There was a similar rate of complications in our sample compared to the national whole: chronic hypertension 4.9% vs 5%; gestational hypertension 3.8 vs. 4%; pre-eclampsia 2.7% vs. 3%; hydramnios 0.5% vs. 1.9%; foetal death 0.5% vs. 0.37%. Average gestational age at birth was 38,57 weeks, and 88.1% of women carried their pregnancy to term. 4.9% of new-borns weighed more than 4,000 g, compared to the national average (3.8%), and 7.03% weighed less than 2,500 g (9.2% at national level). 83.8% of women were reclassified, more than nationally (65%). Most (92.9%) presented a normal glucose tolerance test, 2.6% were diagnosed with diabetes, 0.6% had a fasting glucose anomaly, and 3.9% displayed a lower glucose tolerance, differently from the national whole (91%, 1%, 2% and 6%, respectively).

Conclusion

The hospital centre compares very well with the whole national. However, it needs to shorten the time between the diagnosis of GDM and the first appointment, as studies have shown that appropriate management of gestational diabetes reduces complications such as macrosomia and pre-eclampsia.

#1714 - Abstract

EVALUATION OF THE INFERENCE OF PERIODONTAL DISEASE TREATMENT ON HEALTH UTILIZATION AND DISEASE PROGRESS IN DIABETIC PATIENTS

Chi-Jeng Hsieh¹, Wender Lin²

¹ Oriental Institute of Technology, New Taipei City, Taiwan

² Chang Jung Christian University, Tainan City, Taiwan

Background

Diabetes and periodontal disease (PD) are common diseases in health care services. Previous studies showed diabetic patients with periodontal treatment have lower blood glucose. Few studies explored health care expenditure associated with diabetes after periodontal treatment. Besides, few studies used total population database to explore this topic. This study aimed at evaluating the impact of scaling and PD treatment on the consequent health care expenditure associated with diabetic care.

Methods

We used NHI claims data to identify diabetic patients in 2014

and 2015. NHI claims data contained diagnostic codes, procedure codes such as examination, treatment, operation, medication, and expenditure information. Diabetic patients who had PD diagnosis in 2014 were assigned to three groups. The PD group was those who had PD treatment in 2014 or 2015. The scaling group was those who had scaling treatment and didn't have PD treatment in 2014 or 2015. The non-treatment group was those who did not have PD or scaling treatment utilization in 2014 and 2015. We used propensity score matching method to select the control cases. Health expenditure associated with diabetes was defined as ambulatory care and inpatient expenditure incurred by patients with diabetes in primary or secondary diagnostic codes. Multivariate regression was conducted to compare the differences of diabetes-associated health expenditure between these three groups. Logistic regression was used to evaluate the probability of dialysis treatment of these three groups in three years period.

Results

After propensity score matching, every groups had 4,460 cases. The diabetes-associated health expenditures of non-treatment, scaling and PD groups in 2015 were 37,627, 32,646 and 31,332 New Taiwan Dollar (1 U.S. D=30.46 NTD), respectively. After adjusted for demographic characteristics, Diabetes Complications Severity Index, and hospital region and level, the diabetes-associated health expenditures of scaling group was lower than those of non-treatment group by 4,914 NTD, and this expenditures of PD group was lower than those of non-treatment group by 6,245 NTD. The probability of dialysis treatment of these three groups in three years period had no significant difference.

Conclusion

We found that scaling and PD program could reduce the diabetes-associated health expenditure. The health authorities should consider to providing more incentives to increase scaling or PD treatment when physicians treat patients with diabetes.

#1730 - Abstract

ENDOCRINOPATHIES AND SYSTEMIC LUPUS ERYTHEMATOSUS

Wafa Baya, Imen Ben Hassine, Jihed Anoun, Fatma Ben Fredj Ismail, Monia Karmani, Amel Rezgui, Chedia Laouani Kechrid
Internal Medicine Department, Sahloul University Hospital, Sousse, Tunisia

Background

Systemic Lupus Erythematosus (SLE) is an autoimmune connective tissue pathology. Its association with an endocrinopathy is frequent. This endocrinopathy may be secondary to an autoimmune process or an adverse effect of corticosteroid therapy.

Methods

This is a descriptive retrospective study carried out in the Internal Medicine Department including lupus patients.

Results

We collected 21 out of 127 lupus patients (16.5%). The average age was 51.3 years old. The average duration of disease evolution was 11 years. Articular, cutaneous and hematological involvements were mostly observed. Our patients were treated with synthetic anti-malarials in all cases associated in some cases with corticosteroids, immunosuppressive therapy.

Dysthyroidism was the most common endocrinopathy. We found 11 cases of hypothyroidism and no case of hyperthyroidism. It was Hashimoto's thyroiditis in 4 cases. Hypothyroidism was discovered after one year of SLE evolution in one case.

Eight cases of diabetes were noted including 7 cases of cortisone-induced diabetes which occurred in less than one year.

Adrenal insufficiency was found in 4 patients. It was secondary to the corticosteroids abrupt stoppage in 3 cases and post-tuberculosis in 2 cases. Only one case of Schmidt syndrome was found.

Patients received substitution therapies and /or oral anti-diabetic drugs.

Conclusion

The association of an endocrinopathy with an SLE is not rare, in particular a hypothyroidism imposing its systematic screening.

#1732 - Case Report

A CASE OF HYPERPARATHYROIDISM

Ivo Castro, Adelaide Figueiredo, Maria Cristina Esteves

Hospital Distrital de Santarém, Santarém, Portugal

Introduction

Primary hyperparathyroidism is an uncommon disorder and occurs when the parathyroid hormone is secreted excessively, resulting in high levels of calcium.

Case description

We report a case of an 80-year-old woman with a history of hypertension and type 2 diabetes mellitus that was admitted to the hospital with loss of appetite, nausea, polydipsia, polyuria, confusion, muscle weakness and hypercalcemia (16 mg/dL). A more completed analytical serum study was conducted and revealed severe vitamin D deficiency (8.80 ng/mL) and elevated parathyroid hormone (736.80 pg/mL). During the time that patient was hospitalized we did several reevaluations of calcium level and perform image studies, specifically neck and thyroid ultrasonography and Technetium-99m scintigraphy. The results were compatible with the presence of parathyroid tissue hyperfunctional projected to the left lobe of the thyroid gland. While the surgery was programmed the patient need to be hospitalized twice to control symptoms due to the high levels of calcium that was corrected with diuretics and bisphosphonates. After the parathyroidectomy performed, the histology result of hyperplasia of the left superior parathyroid was established and the levels of calcium and parathormone return to normal ranges.

Discussion

This is a rare case of severe hypercalcemia duo to primary hyperparathyroidism.

YOU ARE JUST ANXIOUS...

Carolina Reis Ferreira, Cláudia Costa, Dora Gomes, Inês Batista Mesquita, José Borges Martins, António Correia

Centro Hospitalar Tondela-Viseu, Viseu, Portugal

Introduction

The prevalence of hyperthyroidism ranges from 0.2% to 1.3% in iodine-sufficient countries. The prevalence of thyroid disease in Portugal is high. Graves' disease is the most common cause of hyperthyroidism, mostly in young women. Symptoms of this condition are anxiety, insomnia, emotional lability, muscle weakness, tremor, palpitations, heat intolerance, increased perspiration and weight loss, despite a normal or increased appetite. Some patient's diseases can lead to a misdiagnosis, namely psychiatric or neurologic conditions. It is also known that some stress life-events can trigger Grave's disease development.

Case description

A 34-year-old woman, with major depression, under mirtazapine and diazepam, visited her primary care physician because of palpitations, chest pain episodes, easy fatigue, insomnia, and tremor of the upper limbs, for several months. She also presented weight loss (25 kg in 10 months) and increased number of daily dejections. The clinical condition was presumed to be an exacerbation of her depression, so the psychiatric medication was adjusted. There was no improvement; the patient remained anxious, with upper limb tremor and complained about dysphagia. Her blood pressure was 130/95mmHg and her heart-rate was 119bpm. On physical examination a goiter was noticed. Because of this, she was sent to an internal medicine outpatient clinic. Analytic study: TSH=0.005µIU/mL (normal range 0.350-5.500µIU/mL) and free T4>100ng/dL (normal range 0.90-1.80ng/dL); anti-thyroglobulin (AT) >4000U/mL (positive if >100U/mL), anti-thyroid peroxidase (TPO)=204U/mL (positive if >60U/mL) and anti-TSH receptor antibody (TRABs) >30IU/L (positive if >1.5IU/L). Thyroid ultrasonography: exuberantly enlarged thyroid (right lobe 18x24x65 and left lobe 15x16x57) with heterogeneous echo-structure, without nodules. At this point she was started on tiamazol 5mg 3 times daily and propranolol 20mg 3 times daily with adjustments in each clinical evaluation. In her last visit, the patient was not euthyroid yet.

Discussion

This case report illustrates the delay in the diagnosis of hyperthyroidism that may occur when the patient presents co-morbidities with similar symptoms. The patient remained hyperthyroid for almost then months, because her clinical picture was thought to be a depression worsening with anxiety.

MADELUNG'S DISEASE

Maria Inês Santos, Marisa Brochado, Helena Vieira Dias
Hospital Distrital de Santarém, Santarém, Portugal

Clinical summary

Madelung's disease is a rare disorder of the lipid metabolism, of unknown cause, characterized by massive deposits of fatty tumors (lipoma) located symmetrically around the neck, and on

the shoulders, upper arms and upper trunk. These abnormal fat deposits may grow rapidly over the course of months or more slowly over a period of years. The rest of the body may be lean in contrast to the affected parts. The fatty deposits do not indicate malignancy but may cause deformities, loss of mobility and pain due to peripheral nerve compression (peripheral neuropathy). Prevalence is highest in men, of Mediterranean ancestry, with ages between 30 to 70 years old and 60 to 90% of the cases have an history of alcohol abuse.

Figure #1798. Madelung's disease - 79 year-old male with long term developing lipomas around the neck and shoulders.

HYPERFERRITINEMIA: DO WE ALWAYS GET THE DIAGNOSIS?

Carlos Báguena Pérez-Crespo, Francisco Javier Hernández Felices, Gabriel Puche Palao, María Del Carmen Hernández Murciano, Ignacio Iniesta-Pino Alcázar, Elena Del Carmen Martínez Cánovas, Vicente David De La Rosa Valero, Ana Martín Cascón, Lia Ferraro, Mónica Martínez Martínez
Hospital General Universitario Reina Sofía, Murcia, Spain

Introduction

Patients with elevated levels of ferritin are a diagnostic problem, given that hyperferritinemia, in addition to iron overload, can be the presence of a variety of disease such as anemia, liver diseases or inflammatory syndromes.

Case description

A 61-year-old man with metabolic syndrome (hypertension, diabetes and dyslipidemia together with obesity) remitted from Endocrinology due to elevated ferritin levels. The patient was totally asymptomatic, and in the anamnesis he denied alcohol consumption as well as other toxins. The analyte only preserved elevated levels of ferritin (821) with normal levels of transferrin. Hepatic, renal and hemogram function were normal, and markers of inflammation were

negative. An abdominal ultrasound showed a completely normal liver, and a genetic test of hemochromatosis was performed, which was negative for the HFE C282Y gene, so finally it was diagnosed with hyperferritinemia secondary to metabolic syndrome.

Discussion

For years the association between metabolic syndrome and hyperferritinemia has been described as the main cause of it in the western world. It is a diagnosis of discarding, to which it is necessary to arrive after having rejected the rest of possible secondary causes.

DIAGNOSTIC CHALLENGES IN THYROTOKIC PERIODIC PARALYSIS: A CASE REPORT

Lazaros Sideras, Vasiliki Tsoutsouli, Georgios Christantonou, Christina Chrysanthi Theocharidou, Dimitrios Kampranis, Armonia Chatzigeorgiou, Konstantinos Gkogkos
Internal Medicine Clinic of G.Papanikolaou General Hospital, Thessaloniki, Greece

Introduction

Thyrototoxic Periodic Paralysis (TPP) is a rare endocrine disorder

occurring predominantly in men of Asian origin but it has also been reported increasingly in western countries mainly due to immigration. TPP is a potentially life-threatening complication of hyperthyroidism, characterized by muscle paralysis and hypokalemia resulted from massive intracellular shift of potassium. We describe the following case to call attention to an important cause of acute paralysis of endocrine origin.

Case description

A 42-year-old Iraqi female immigrant was admitted from a rural hospital to the emergency neurology department as potential acute stroke. The patient complained of sudden onset weakness of proximal and distant limb muscles manifested as complete inability to walk. Brain Computed Tomography scan was normal. The patient had history of hyperthyroidism treated with carbimazole 10mg and reported weight loss, palpitations, tremors and heat intolerance. Neurological examination revealed diminished deep tendon reflexes with decreased muscle power in both lower limbs, no sensory deficit and intact cranial nerves. Systemic examination was normal. Laboratory studies revealed hypokalemia ($K^+=2,9$ mmol/L) with low urinary potassium excretion and electrocardiographic alternations. The patient was admitted to the neurology department and further evaluation revealed symmetrical low amplitude electrical compound muscle action potential on electromyography. Immediate therapy with potassium chloride supplementation improved the symptoms within 4 hours, without rebound hyperkalemia. Thyroid function tests revealed $TSH < 0,001$ U/mL with FT3 8,64 pg/mL and FT4 3,04 ng/dL. Thyroid ultrasound was consistent with Graves' disease. Treatment was initiated with carbimazole 40mg and propranolol 80 mg. The patient was discharged after 8 days with complete recovery of muscle strength.

Discussion

It is important to consider the diagnosis of TPP in patients of Asian origin presenting with acute paralysis. The inability to evaluate thyroid function on the emergency department led to a misdiagnosis of stroke. Thyroid function should be tested on a routine basis. Emergency therapy with potassium chloride supplements, nonselective β -blockers and antithyroid drugs can prevent life threatening complications.

CONFUSED? TAKE A LITTLE SODIUM

Joana Rita Lopes, Maurício Peixoto, Rui Files Flores, Sofia Caridade, Guilherme Alpedrinha
Hospital of Braga, Braga, Portugal

Introduction

Hyponatremia may manifest with neurological symptoms, such as the acute confusional state. It may be associated with hypovolemia, euvolemia or hypervolemia, so a good clinical history and physical examination are needed to make this distinction, since the etiology of hyponatremia varies according to the category.

Case description

A 57-year-old female, with a history of hyperthyroidism due to multinodular goiter and dyslipidemia, underwent total thyroidectomy and was discharged one week later with 100 mcg of levothyroxine, calcium, and calcitriol. She presented dysphonia as the only complication which was treated with corticotherapy during hospitalization still.

She came to the ER 3 days after discharging due to confusion and incoherent speech with no other symptoms. The physical examination was normal except for high blood pressure and neurological examination was normal except for temporal disorientation and occasional incoherent speech. She was submitted to brain CT, brain MRI, electroencephalography and lumbar puncture that excluded central nervous system disease. Analytically with hyponatremia (124 mEq) and elevated TSH (7.7 mU/L). She was admitted to the Internal Medicine service to study the presented confusional state associated with hyponatremia. During hospitalization tests revealed normal free T4, elevated TSH (peak 13.7 mU/L), normal aldosterone, cortisol and ACTH levels, decreased serum osmolarity. Urinary sodium was 154 mmol/L. Hyponatremia was progressively corrected with saline solution during hospitalization associated with decreasing of the number and duration of confusional episodes. She was discharged with sustained and symptom-free eunatremia, medicated with levothyroxine 137 mcg daily.

Discussion

In the presented case, the patient has an altered state of consciousness due to acute hyponatremia. Thus, it was necessary to find the cause for this hyponatremia. Since the metabolic study was normal, apart from increased TSH, we can contextualize hyponatremia in a post-surgical setting accompanied, eventually, by hypothyroidism.

#1871 - Abstract

POLYMORPHISM ID OF ANGIOTENSIN CONVERTING ENZYME, ARTERIAL HYPERTENSION AND LOSS OF BONE MASS

¹ ISAMB, Genetic Laboratory, FMUL, Lisboa, Portugal

² Institute for Scientific Research Bento Rocha Cabral, Lisboa, Portugal

³ CIPER, FMH-UL, Lisboa, Portugal

⁴ Service of Endocrinology, Diabetes and Metabolism, H.S.Maria - CHLN, Lisboa, Portugal

⁵ Endocrinology, Diabetes and Metabolism, Lisbon Clinic, Lda, Lisboa, Portugal

Background

The association of bone mass loss and hypertension is a controversial subject. There are few studies on the influence of the renin angiotensin system on blood pressure regulation in osteoporosis. The objective of the study was to study the

association of the ACE functional polymorphism of the angiotensin converting enzyme (ACE) and its serum activity with arterial hypertension (HBP) in individuals with normal or reduced bone mineral density (osteopenia and osteoporosis).

Methods

A sample of 650 individuals both genders (90.6% Fem) was studied, with a mean age of 55.2 ± 13.3 years old and BMI = 28.5 ± 4.9 kg/m². Of these, 218 were hypertensive according to the guidelines (www.sphta.org.pt/). Bone mineral density (BMD-g/cm²) was assessed by DEXA (DualEnergy X-ray Absorptiometry) at the lumbar spine, femoral neck, and distal end of the radius, with 400 individuals with reduced BMD (osteoporosis or osteopenia) and 250 with normal BMD. The enzymatic activity of ACE (IU/ml) was determined in serum by spectrophotometry in 389 individuals (15.63 ± 10.36). The genetic polymorphism ACE I/D by PCR in 562 individuals. The three possible genotypes for ECA I/D (II, ID and DD), the dominant model (II + ID vs DD) and the recessive model (II vs ID + DD) were considered. The program SPSS 24.0 for Windows was used. Statistical significance was considered for $p < 0.05$.

Results

There was an increase in the frequency of genotype II and ID in patients with reduced BMD and hypertension. Individuals with reduced BMD and I allele (II and ID) have a risk of 1,885-fold for the development of hypertension in relation to DD, OR = 1.885; 95% CI [1.177-3.018] $p = 0.008$. There was a decrease in the enzymatic activity of ACE in individuals with reduced BMD and hypertension, median [min-max] (n): without HBP - 14.8 [2.1-64.3] (188); with HBP -11.1 [3.7-47.7] (70), $p = 0.006$. The ACE polymorphism was related to its enzymatic activity, presenting the lowest activity, the genotypes II and ID (median [min-max] (n)) regardless of BMD: normal BMD ECA II vs ID vs DD - 6.8 [4.4-12.6] (8) vs 9.9 [1.1-32.6] (57) vs 12.1 [1.5-72.8] (39) $p = 0.002$; reduced BMD ECA II vs ID vs DD - 8.5 [4.6-47.7] (25) vs 13.2 [3.7-42.7] (73) vs 17.3 [3.7-64.3] (99) $p = 0.005$.

Conclusion

In individuals with reduced bone mass, the ACE I/D polymorphism and the lower activity of this enzyme may confer susceptibility to hypertension. Future studies may assess the association of BMD with antihypertensive therapy based on ACE inhibitors.

#1893 - Case Report

WHEN A RARE DIAGNOSIS IS IN FRONT OF YOUR EYES

Andreia Vanessa Novais Teixeira^{1,2}, Mariana Matos Pinto¹, Paulo Maia¹, Fernando Rua¹

¹ Centro Hospitalar Universitário do Porto, Porto, Portugal

² Hospital Santa Luzia de Elvas, Elvas, Portugal

Introduction

Altered state of consciousness is a common cause of medical emergency and the most frequent etiologies are cardio and

cerebrovascular diseases. Coma induced by metabolic alterations must be considered in differential diagnosis.

Case description

59-year-old man, found unconscious at home and had known pathological history of schizophrenia, chronic respiratory disease, gastritis, smoking and obesity.

At the arrival of the emergency team at his home, the patient presented a Glasgow score of 3/15, myotic, isoreactive and isochoric pupils, bradipneic, hypotensive and hypoxic. Patient needed orotracheal intubation and presented great amount of secretions and enteric content that was aspirated. His relatives referred labial commissure deviation the day before.

At the emergency room was mechanically ventilated with FiO₂ 100% with saturation of 91%, hypotensive, sinus bradycardia, sedated (RASS-5), hypothermic, and presented severe edemas and scaly skin. The more relevant in the complementary diagnosis exams included: arterial gasometry with respiratory acidosis and hyperlactacidemia (4.1mmol/L); CT CE normal; CT thorax: bilateral pleural effusion with chronicity signs, without pericardial effusion; Echocardiogram: right heart and inferior vena cava dilatation, and severe biventricular systolic dysfunction; pleural fluid thoracentesis compatible with exudative effusion.

After excluding frequent causes of coma compatible with clinical findings such as stroke, alterations of acid-base, myocardial infarction, the most probable diagnosis hypothesis was myxedema coma. The myxedema coma score was 120 points (> 60 points its very suggestive of the diagnosis). Analytical study was completed with thyroidal function: TSH 87,9 uIU/mL (N 0,3-3,18); T4L < 0,039 ng/dL (N 1,01-1,65); T3L 0,43 pg/mL (N 2,66-4,33). The cause of the hypothyroidism was Hashimoto's disease (Antiperoxidase antibodies: 154,9 UI/mL (> 34 positive), and the trigger factor was respiratory infection.

The patient started treatment with levothyroxine and hydrocortisone with clinical and analytical favorable evolution.

Discussion

Myxedema coma is a rare disorder and if not promptly diagnosed and treated, the mortality rate can be more than 50%, and even with immediate recognition and medical intervention the mortality rate could be as high as 25%. In this case report the medical history and clinical findings were primordial to the successful diagnosis and treatment of myxedema coma.

MONOFOCAL PAGET'S DISEASE OF BONE IN THE HIP: A LONG JOURNEY TO DIAGNOSIS

Lídia Caley, Telma Elias, Cristina Lopes, Fátima Pimenta
Hospital Center of Médio Tejo, Abrantes, Portugal

Introduction

Paget's disease of bone is a metabolic disorder, in which there is an increased and disorganized bone remodelling. Although radiological imaging can be straightforward for diagnostic,

monofocal involvement of a bone may raise doubts that sometimes require invasive procedures, such as bone biopsy.

Case description

We present the case of a 78-year-old Caucasian woman who was admitted to the emergency department for falling, which resulted in a severe pain in her right hip and motor impairment of the limb. She referred having hip pain for 3 months, along with episodes of diarrhea and weight loss.

On examination, she was underweight, presented bilateral protruding eyeballs and bilateral foot drop. She complained with pain on the right hip with mobilization, but did not present any bruising or swelling of the limb.

Laboratory tests revealed normocytic normochromic anemia. Hip X-ray showed bone resorption in the head of the femur and the acetabulum. CT revealed an enhanced image of the femoral head, with bone destruction and lesion of soft tissue, involving the surface of the acetabulum. MRI evidenced the presence of bulky liquid collection in the trochanteric region of the femur, with suspicious of an infection or inflammatory process. PET-scan showed a musculoskeletal mass suggestive of malignancy. Due to the uncertainty of the diagnosis, it was decided to perform a biopsy. The result excluded malignancy and was consistent with non-specific inflammation.

All these findings, along with subsequent elevation of alkaline phosphatase and the presence of elevated urinary hydroxyprolin, established the diagnosis of Paget's Disease of Bone as a final diagnostic. Treatment with zoledronic acid resulted in a clinical and laboratory improvement.

Discussion

The fact that the patient fell, had chronic diarrhea and weight loss, along with the presence of a focal x-ray image of bone rarefaction of the hip, made considerate several diagnostic hypotheses. This led to the patient being observed by several specialists who took time to execute many exams performed such as imaging, ultrasound, endoscopy and laboratory tests that did not clarify the case. The bone biopsy was essential to exclude malignancy or infectious etiology, allowing to establish of monofocal Paget's disease of bone as final diagnostic.

In the presented case the fact that there was a previous trauma and the suspicion of neoplasm lesion, as a result of some tests, made the journey to diagnosis difficult and lengthy.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1 MASQUERADING AS REFRACTORY EPILEPSY: A CASE REPORT

Vasiliki Tsoutsouli, Lazaros Sideras, Dimos Foutsitsakis, Georgios Papadimos, Georgios Christantoniou, Dimitrios Kazineris, Zacharo Sachla

Internal Medicine Clinic of G.Papanikolaou General Hospital, Thessaloniki, Greece

Introduction

Multiple Endocrine Neoplasia type 1 (MEN1) is a rare endocrine tumor syndrome characterized by tumors of the parathyroid glands, endocrine gastroenteropancreatic tract and anterior pituitary. Hypercalcaemia due to parathyroid tumors is usually the first manifestation. Pancreatic islet tumors occur less frequently, among them gastrinomas and insulinomas are the most prevalent. We report a sporadic case of insulinoma in MEN1 presented as refractory epilepsy.

Case description

A 23 year old male patient under antiepileptic medication was admitted to the emergency department for refractory epilepsy. Electroencephalography revealed temporal lobe epileptiform discharges. Following meticulous observation recurrent hypoglycemia was detected during the seizures. Laboratory investigation revealed hypoglycemia and hypercalcemia. Fasting C-peptide levels were inappropriately normal. Although serum glucose reached remarkably low levels, the patient did not manifest any symptoms of hypoglycemia, other than, eventually, seizures. Thus, there was a strong suspicion of multiple endocrinopathy. Abdominal magnetic resonance imaging (MRI) showed rapidly enhancing tumor in the pancreatic body. Somatostatin receptor scintigraphy results were normal. Cervical ultrasound and sestamibi parathyroid scintigraphy revealed a single parathyroid adenoma. The pituitary gland appeared normal in MRI. Consequently, the diagnosis of MEN-1 with pancreatic insulinoma and primary hyperparathyroidism was established. The patient was immediately referred to a specialized surgical department for surgical resection of the insulinoma. Insulin and glucose levels remained normal for 6 months of follow-up postoperatively. He reported no episodes of seizures while the antiepileptic medication was discontinued. The patient is under surveillance for the parathyroid adenoma in a specialized oncology department.

Discussion

MEN1 can pose a diagnostic challenge even to the experienced clinician. Misdiagnosis of insulinoma as psychiatric illness or epilepsy is common and might lead to disastrous consequences.

#1915 - Case Report

A NOT SO SUBCLINICAL CASE OF SUBCLINICAL HYPOTHYROIDISM

Isabel Vilas-Boas¹, Marta Vilaça², Elaine Aires², Denise Magalhães², Helena Greenfield², Filipe Teixeira Andrade²

¹ Instituto Português de Oncologia do Porto, Porto, Portugal

² Hospital Pedro Hispano, Matosinhos, Portugal

Introduction

Hypothyroidism is a prevalent condition and is an important cause of pericardial effusion. More rarely, it may also be associated with large-volume pericardial effusions and pericarditis. Although

controversial, subclinical hypothyroidism (SH) is also reported to be associated with some of the manifestations observed in hypothyroidism, such as increased cardiovascular risk and there are also reported cases of pericardial effusion in patients with SH.

Case description

The authors present the case of a 67-year-old man who was admitted to the emergency department with complaints of pleuritic chest pain, fever, anorexia and dyspnea. Chemistry laboratory tests revealed increased inflammatory parameters and hypoxemic respiratory failure. An electrocardiogram revealed sinus tachycardia and an ST elevation of 1-2mm ST in the inferior leads. Thoracic computed tomography and transthoracic echocardiography showed a large pericardial effusion (28 mm). A diagnosis of acute pericarditis with associated pleural effusion was assumed and ibuprofen and colchicine were started. Due to hemodynamic instability, a new echocardiogram was performed and showed a partial collapse of the right atrium and ventricle. Pericardiocentesis was performed with a 70 mL outlet and subsequent clinical improvement. The effusion was an exudate with polymorphonuclear cell predominance. Microbiological studies were negative for bacteria, viruses, fungi and mycobacteria, and there was no evidence of malignant cells. The etiological study performed revealed subclinical hypothyroidism (TSH of 15.7 uIU/mL and free T4 of 0.92 ng/dL) and positivity for anti-TPO and anti-thyroglobulin antibodies. Thyroid echography was compatible with thyroiditis and Hashimoto's thyroiditis was diagnosed. The patient started thyroid hormone supplementation with 50 ug levothyroxine and, to date, 4 months after the onset of symptoms, there was no recurrence of the condition. Despite normal T4 and T3 levels, it was assumed that the subclinical hypothyroidism was the cause of the pericardial effusion and pericarditis in this patient.

Discussion

The effects of subclinical hypothyroidism are variable and depend on the degree of TSH elevation and on the duration of hypothyroidism. This case intends to demonstrate that, although defined as "subclinical", SH may be a cause of large pericardial effusions and that it is important to initiate levothyroxine supplementation to control the endocrine dysfunction.

#1936 - Abstract

NUTRITIONAL STATUS AND CLINICAL OUTCOME

Ana Filipa Batista, Joana Antunes, Filipa Domingues, Margarida Gaudêncio, Sónia Campelo Pereira, Amélia Pereira
Hospital Distrital da Figueira da Foz, Coimbra, Portugal

Background

In the setting of the acute hospital care, malnutrition or the risk of malnutrition are very frequent, with an estimate incidence of up to 60%. Although they are established independent predictors of prolonged hospitalization and increased mortality, the practice of individualized nutritional assessment is rarely if ever

addressed. We conducted a study to assess the prevalence of malnutrition and nutritional risk at hospital admission and its association with clinical outcome.

Methods

This is a prospective study of hospitalized patients evaluated within the first 48 hours of admission, by NRS (Nutritional Risk Screening), MNA (Mini Nutritional Assessment) and Charlson Comorbidity Index questionnaires. The variables recorded included demographic, anthropometric, hospitalization and clinical data. Patients were separated based on their homogeneous diagnostic groups and subgroups of severity and mortality. We excluded patients receiving enteric or parenteral feeding.

Results

Out of 403 patients hospitalized during the study period (January to April of 2018), a total of 121 patients were included (30%); 52% were women, with a mean age of 76.91±13.03 years. The mean Charlson Comorbidity Index was 5.97±2.36. According to mean body mass index (BMI) classification for people aged 65 years and older, 17.9% of the patients were underweight. The MNA classified 21% of the patients as malnourished and 57% at risk of malnutrition. The patients aged over 85 years were at most risk of malnutrition (NRS≥3) and had the lowest scores in the MNA. There were no differences between BMI and nutritional risk, but there was a positive correlation between the first and better nutritional status. The main reason for hospitalization was infection (42%). The length of stay, with a median of 10.96 days, had no significant difference between the estimate time determined by the severity and mortality rates in the corresponding diagnostic group and did not correlate either with the risk of malnutrition or the nutritional status. Among the patients that died, 60% were malnourished.

Conclusion

In our study, a combined percentage of 77.68% of patients were either malnourished or at risk of malnutrition. Even though the nutritional status did not influence the length of stay, it was associated with a higher mortality rate. Malnutrition and poor food intake, unlike age or comorbidities, are both modifiable risk factors, so it even more accentuates the importance of implementing a nutrition care process.

#1979 - Case Report

PLASMA EXCHANGE IN THYROID STORM – A CASE OF AGRANULOCYTOSIS

Leonor Boavida¹, Joana Carvalho¹, Afonso Santos¹, Fabiana Pimentel¹, Micaela Caixeiro¹, João Mendes¹, Isabel Serra¹, Teresa Brandão¹, Paulo Freitas²

¹ Professor Doutor Fernando Fonseca Hospital, Lisbon, Portugal

² Professor Doutor Fernando Fonseca Hospital, Lisboa, Portugal

Introduction

Hyperthyroidism, in particular, Graves' disease, can be associated with various hematologic abnormalities. Agranulocytosis

contraindicates the use of thionamides, therefore, in a severe presentation, as in thyroid storm, plasma exchange therapy can become the only therapeutic option.

Case description

A 45-year-old woman with past history of Graves' Disease diagnosed at 14 treated with anti-thyroid drugs with remission, presented with gradual onset of asthenia, weight loss and high pyrexia over 3 months. On physical examination she was febrile, tachycardic, with thyroid gland enlargement. Laboratory findings included a high free triiodothyronine (FT3) level of 22 pg/dL (2.3–4.4 pg/dL), free thyroxine (FT4) level over 7.7 ng/dL (0.9–1.7 ng/dL), and a low thyroid stimulation hormone (TSH) concentration of less than 0.005 μ IU/mL (0.27–4.2.0 μ IU/mL, with serum TRAb positivity at a concentration of 36.5 IU/L (under 1.75 IU/L). In addition, complete blood count showed pancytopenia, in particular leukopenia of $0.7 \times 10^3/\mu\text{L}$ ($4.0\text{--}11.0 \times 10^3/\mu\text{L}$). The patient was diagnosed with a thyroid storm associated with Graves' Disease recurrence, with a Burch-Wartofsky score of 45 out of 140, and severe hematologic abnormalities contraindicating thionamides given their potential of leukopenia worsening. She was admitted to the Intensive Care Unit and therapeutic plasma exchange was started. The patient underwent four exchanges in addition to steroids, propranolol and cholestyramine with partial correction of thyroid function but marked improvement in blood cell counts and neutrophil count recuperation. Thiamazole and potassium iodide-iodine were then started with thyroid hormones' normalization and without further hematologic deterioration, thus enabling radical surgical treatment after 2 weeks. The patient is currently asymptomatic.

Discussion

Thyroid storm has an excessively high mortality rate of 30% making its prompt recognition and treatment of utmost importance. Plasma exchange therapy is a relatively safe option that can and should be used, especially if conventional medical treatments are ineffective or contraindicated as is the case with agranulocytosis. Rapid blood cell count improvement with plasma exchange therapy corroborates the potential humoral autoimmune mechanisms behind hematologic abnormalities associated with hyperthyroidism, particularly in Graves' Disease.

#1982 - Case Report

SEVERE HYPOCALCEMIA INDUCED BY ZOLEDRONIC ACID - CASE REPORT

Sofia Calaça, Iolanda Oliveira, Francisco Rebocho, Diogo Canudo Diogo Canudo, Diana Coutinho
Hospital Espírito Santo de Évora, Évora, Portugal

Introduction

Intravenous bisphosphonate are usually safe and are used in the management of metastatic and metabolic bone diseases, hypocalcemia cancer-related, osteoporosis and Paget's bone disease.

Although infrequently, hypocalcemia may occur and is usually asymptomatic, however could lead if untreated to life-threatening situations.

Case description

A 79-year-old male, still employed came to the emergency department with a 3 week course of fatigue, loss of appetite, lethargy, gait difficulty and desorientation for a few hours. One week before the onset of symptoms he was treated with zoledronic acid 5 mg/100 ml due to Paget's bone disease.

At hospital admission the patient presented with altered level of consciousness and progressive mental deterioration. Chvostek's and Trousseau's signs were not tested. Laboratory tests revealed a serum creatinine of 2.39 mg/dl (for a baseline of 0.68 mg/dl) and an ionized calcium of 0.54 mmol/L. On electrocardiography, corrected QT interval was prolonged (521 msec). Later, serum 25-hydroxyvitamin D showed immeasurable levels and parathyroid hormone level was 270 pmol/L. Three months earlier he presented a serum calcium value at the lower limit of normality and a PTH within the normal range. Vitamin D was not measured. The patient was diagnosed with severe hypocalcemia induced by zoledronic acid, severe vitamin D deficiency and secondary hyperparathyroidism.

In spite of vigorous and continuous supplying of intravenous and oral calcium and vitamin D, ionized calcium concentration had a very slow improvement with a level of 0.95 mmol/L in 7 weeks after hospital admission. The patient presented a slow and almost insignificant clinical improvement with several nosocomial infectious interurrences, namely pneumonia (in the context of vomit aspiration), urinary infection and clostridium difficile-induced diarrhea.

Unfortunately, he never recovered his prior status and was discharged after 49 days to a convalescence unit with significant neurological compromise and loss of autonomy.

Discussion

This case emphasizes the importance of evaluating renal dysfunction, vitamin D, calcium and PTH levels, prior bisphosphonate treatment. Although vitamin D and calcium supply it's not mandatory it's highly recommended.

#1986 - Case Report

EMPTY SELLA SYNDROME- A RARE CAUSE OF HYPONATREMIA

Maria Inês Ribeiro, Melanie Ferreira
Hospital Garcia de Orta, Almada, Portugal

Introduction

Hyponatremia is a frequent diagnosis found in the internal medicine ward. Determining the etiology of hyponatremia is fundamental to guide treatment and prognosis. The differential diagnosis is wide-ranging, often complicated by overlapping causes of hyponatremia. Secondary hyperthyroidism due to

hypopituitarism is a rare cause of hyponatremia. Empty sella syndrome is a rare cause of hypopituitarism. It is a radiological finding characterized by enlargement of sella turcica, that is not entirely filled with pituitary tissue, but with cerebrospinal fluid. It can be diagnosed by Magnetic Resonance Imaging (MRI) or computed tomography. Treatment is warranted in the presence of hormone deficiency and directed to affected hormones.

Case description

We present a case of a 59 years old woman, with a known history of arterial hypertension and ischemic cardiomyopathy, submitted to coronary artery bypass 1 month before, was admitted with new onset of altered mental status. On evaluation, she had a symptomatic hypotonic hyponatremia, with serum sodium levels 114 mmol/L, serum osmolarity 233 mOsm/L (excluded pseudohyponatremia), and right-side pleural effusion. Initially, we attributed the hyponatremia to a hypervolemic status due to recent cardiac surgery. However, with the maintenance of severe hyponatremia, even with water restriction and diuretic therapy, further investigation was ordered. It revealed a normal thyroid stimulating hormone, low total thyroxine and low free triiodothyronine, suggesting secondary hypothyroidism. Other hormonal analysis and the synacthen test were normal. Finally, an MRI was performed, which was compatible with empty sella. Hormone replacement therapy with levothyroxine was initiated, with resolution of hyponatremia and symptoms.

Discussion

Empty sella after coronary artery bypass has been reported in the literature previously. It is a rare complication, but can be fatal or cause permanent neurological or endocrine damage in absence of proper treatment. The physician should be aware of hyponatremia, altered mental status or visual changes after cardiac surgery as presenting features. Early diagnosis and treatment minimize morbidity and mortality from this complication.

#2013 - Case Report

HYPERGLYCEMIC HYPEROSMOLAR SYNDROME WITH NEUROLOGICAL MANIFESTATIONS - INAUGURAL EVENT OF DIABETES MELLITUS TYPE 2

Tatiana Gonçalves, Jorge Leitão, Lélita Santos, Armando Carvalho
Internal Medicine Department A - Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Hyperglycemic Hyperosmolar Syndrome (HHS) is a entity with high mortality and exact incidence is not known. Most cases occur in patients diagnosed with Type 2 Diabetes Mellitus, with their initial presentation being 30-40%. HHS can be associated with neurological involvement ranging from seizures, involuntary movements to irreversible focal neurological deficits.

Case description

We report the case of a 78-year-old patient, with no relevant personal history. He entered the emergency department of the hospital, ventilated and intubated, with a history of seizures and myoclonus on the left with 1 day of evolution. Patient was dehydrated and the study showed high glycemia (900 mg/dl), hyperosmolarity, acute renal failure and hyperkalemia. Cranioencephalic Computed Tomography (CT-EC) was normal. Electroencephalogram (EEG) was compatible with metabolic encephalopathy and lumbar puncture (PL) presented hyperglycorrachia. It was concluded that SHH was associated with urinary tract infection by *Klebsiella pneumoniae*. It progressed initially with neurological improvement and glycemic profile, but on the 5th day of hospitalization, the myoclonus was restored to the left and the EEG was compatible with the right focal stage, interpreted as hemichorea-hemiballismu. She was treated with fluid replacement, targeted antibiotics and anticonvulsants. There was progressive degradation of the state of consciousness, without neurological recovery and evolution to total dependence.

Discussion

This case reports HHS with neurological sequelae. Hemichorea-hemiballismus is a rare but dramatic complication of nonketotic hyperglycemia in patients with uncontrolled diabetes. The authors believe that this case report is relevant because of its rarity and the exuberance of the clinical presentation.

UNDERCOVER HYPOTHYROIDISM

Eduarda Carias, Roberto Marques, Rosario Blanco Saez, Rafaela Pereira, André Fragoso, Ana Paula Silva, Pedro Leão Neves
Centro Hospitalar Universitário do Algarve - Hospital de Faro, Faro, Portugal

Introduction

Some causes of nephrotic syndrome and intrinsic kidney diseases are associated with autoimmune thyroid disease. Although there is no data, it's reasonable to test thyroid function when in presence of kidney injury or nephrotic syndrome.

Case description

A 69-year-old man with past medical history of a tracheostomy due to neoplasm in larynx, treated with chemo and radiotherapy (RT) in 2010, hypertension, medicated with an ACEi and hemorrhagic stroke. In the last 2 weeks he has had an history of myalgia limited to lower limbs, paresthesia in fingers and diarrhea 3 times per day for 4 days. He wasn't aware of decreased urine output. After blood tests his attending physician sent him to emergency department (ED) with serum creatinine levels of 7 mg/dl and BUN 101 mg/dl (6 months before SCreat 1 mg/dl).

In ED general physical examination: temp 36.5°C, cardiac frequency 72 bpm, blood pressure 95/60 mmHg. He was conscious, calm and capable of presenting medical history, had no periorbital

or peripheric edema and cardiopulmonary auscultation had no alterations. Ultrasound showed normal kidneys and no signs of chronicity, urine summary test: blood 3+ and proteins 2+ and 20% dysmorphic red cells. He was admitted in nephrology department to study for a rapid progressive glomerulonephritis.

Remaining study showed normocytic anemia, CRP 127 mg/l, albumin 2.4 g/dl, 4.7 g/24hour proteinuria, PR3-ANCA 148 UA/ml (<15), normal C3 and C4 levels. We also evaluated thyroid function: TSH>100 uIU/mL (0.35-4.94), T4<0,40 ng/dl (0.52-3.88) and Thyroid peroxidase 85 UI/ml (<50). After evaluation by an Endocrinologist he started low doses of levothyroxin. We questioned patient and his family about other symptoms of hypothyroidism: lethargy, irritability, bradycardia, obesity and edema, which were all denied.

At last we admitted ANCA PR3 renal limited vasculitis, started metilprednisolone pulses, then cyclophosphamide cycle. He didn't recover renal function. Nowadays he is integrated in hospital day care of hemodialysis where he does regular sessions.

Discussion

The association between thyroid disease and ANCA vasculitis may reflect a propensity for autoimmune disease. It was remarkable that in this case the patient had no symptoms, however thyroid function levels were extremely altered with serum T4 levels very low, that could lead to severe hypothyroidism.

In this case the patient had history of previous thyroid injury with radiation therapy, so we admitted insidious hypothyroidism on account of RT.

#2062 - Case Report

PRIMARY HYPERPARATHYROIDISM - A CASE REPORT

Isabel Borges, Madalena Meneses, Bernardo Pereira, Luis Dias

Hospital do Divino Espírito Santo, Ponta Delgada EPE, Ponta Delgada, Portugal

Introduction

Hypercalcemia (HyperCa) affects 0.5% to 1% of the general population. Primary hyperparathyroidism (PHPT) causes 70% of outpatient and 20% of inpatient cases of HyperCA. It's prevalence is highest in women (3:1).

Case description

We report a 61 year-old woman, with chronic hepatic disease, coronary artery disease and hypertension, medicated with thiazid diuretic (TD), without personal history of cervical irradiation or family history of thyroid cancer. She was admitted at the Emergency Department (ED), because of multiple episodes of downfalls preceded by dizziness without loss of consciousness or convulsion. She also referred lethargy, weakness, confusion and limb paresthesias. Clinically, there wasn't fever or focal neurological deficits. Laboratory tests (LabT) revealed elevation of creatine kinase and liver enzymes, hyperamonemia, HyperCa,

hypophosphatemia and hypomagnesaemia. Cardiovascular and neurological ethiology was excluded. We admitted the following diagnosis: Rhabdomyolysis and Electrolyte Disturbance (ED), for investigation. At Internal Medicine (IM) ward, we started the study of HyperCa and its differential diagnosis, like neoplastic disease and HPT. LabT revealed persistency of HyperCa, hypophosphatemia, 25(OH)vitD insufficiency, elevated iPTH without renal impairment and 24h urinalysis with polyuria and slight hypercalciuria. After correction of 25(OH)vitD, we verified persistency of electrolyte disturbance and the ratio Cl-/PO4-: >33. We admitted PHPT and she underwent cervical ultrasonography (US) that show a nodular thyroid. She was discharged to ambulatory for follow up. Two weeks later, she was readmitted in the ED, because of obnubilation, dehydration and severe HyperCa. At IM ward, we started calcium mimetic. However it was suspended, due to gastrointestinal side effects and switched to zoledronic acid with good response. Parathyroid four-dimensional computed tomography (CT) and US revealed a nodule at the left lobule of the thyroid gland. A parathyroid sestamibi scan was performed, with findings suggestive of parathyroid adenoma. In accordance with clinical findings, serum calcium and bone densitometry, she was proposed for surgery.

Discussion

The triad consisting of HyperCA, elevated iPTH and hypophosphatemia makes the diagnosis of PHPT likely. A single parathyroid adenoma (85%) is the most frequent cause, followed by four-gland hyperplasia (10%) and parathyroid carcinomas (5%). The only definitive therapy for PHPT is parathyroidectomy.

#2090 - Case Report

INSULIN OVERDOSE - RARE CAUSE OF SUICIDE ATTEMPT

Joana Alves Duarte, Sofia Gomes Brazão, Sara Leitão, Rui Santos, Armando Carvalho

Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

The use of insulin with suicidal ideation is rare. It is usually associated with the administration of high doses, it can be difficult to identify and is often fatal. More frequent in diabetics, it also appears in non-diabetics. The hypoglycemic effect of insulin depends on the dose, individual susceptibility, absorption factors and coadministration of other substances. The speed of diagnosis and the intensive treatment are fundamental for a complete recovery of the patient.

Case description

A 54-year-old female was admitted to the emergency department in coma, with hypoglycaemia maintained even after administration of 12 g of glucose. Without a history of diabetes, with major depression (followed in Psychiatry appointment) and a history of abdominal surgery complicated by abdominal lip dystrophy, with

altered sensitivity. Already had several suicide attempts with oral antidiabetics and insulin – her husband’s usual therapy. It was found in coma, with evidence of multiple pricks in the abdomen and several Insuman Comb 25® empty pens (± 2400 IU). At admission in the hospital GCS 12, sweating, cold extremities and cyanosed lips, BP 109/70 mmHg, HR 108bpm and SpO₂ 90%. Blood glucose 33 mg/dL, kalemia 2.75 mmol/L, blood alcohol concentration 1,12 g/L and positive urinary benzodiazepines. Arterial gasimetry with pO₂ 66mmHg, pCO₂ 36mmHg and lactates 5.5 mmol/L. Under continuous monitoring, she was treated with hypertonic glucose in perfusion, glucagon in bolus and correction of hydroelectrolytic imbalance. After 6 days, the blood glucose values normalized and the patient recovered, being able to be transferred to the psychiatric hospital.

Discussion

Although rare, insulin poisoning with suicidal ideation was easy to establish because of the circumstances in which it was found. The use of premixed insulin and the use of other substances (alcohol and benzodiazepines) combined with abdominal lip dystrophy may have contributed to the administration of such a high dose and the need for such long-term surveillance. In the absence of an action protocol, continuous monitoring and administration of glucose and glucagon are the key to optimizing treatment and prognosis.

#2101 - Case Report

PLEURAL EFFUSION IN A YOUNG PATIENT - BEYOND THE MAJOR CAUSES: CASE REPORT

Marta Quaresma, Patricia Varela Ramos, Ana Isabel Oliveira, Sofia Cruz, Zara Soares, Jose Barata

Hospital Vila Franca Xira, Vila Franca Xira, Portugal

Introduction

Pleural effusion (PE) is common finding in daily practice and can be a diagnostic challenge since it may occur in pleuropulmonary or systemic diseases. The cause of a PE may remain unclear after initial research in up to 25 percent of patients.

Case description

The authors report the case of a 28-year-old male referred to the Emergency Department due to persistent PE. He complained of increased fatigue in the last few weeks. No other symptoms were referred and the patient’s personal history, usual medication or epidemiologic context were not relevant. Physical examination was normal apart from bilaterally decreased pulmonary murmur. Additional study was conducted revealing leukocytosis 10000/ UI, with 30% lymphocytosis, c-reactive protein of 1.88 mg/dl, increased D-dimers 2024 ng/mL and Erythrocyte sedimentation rate 31. Highlighting negative autoimmunity markers. Echocardiogram, Thoracic CT angiography, thoracoabdominal CT with no relevant changes, besides persistent PE.

Pleural fluid analysis revealed exudate characteristics, ANA

negative; Cytological examination and pleural biopsies were negative for neoplastic cells. Bacteriological examination was negative.

Three months after the first evaluation, the clinical, analytical and radiological manifestations persisted. An additional PET-CT showed no evidence of pathological hypermetabolic images.

With no etiological diagnosis after the initial study of the most frequent causes of PE, and taking into consideration the patient’s age and associated symptomatology, a further analytical study was performed with neuroendocrine markers revealing a marked increase in somatostatin (> 400 pmol / L) and increased 5-hydroxyindoleacetic acid (5-HIAA) in urine.

At this point, considering the possibility of a somatostatinoma, abdominal MRI followed by a Dotanoc PET study were performed. These did not detect any abnormal tissue or abnormal expression of somatostatin receptors suggestive of metabolically active neoplastic tissue.

Knowing that somatostatinoma is a neuroendocrine tumor of indolent growth, with 5 to 10 years between analytical alterations and identification of the tumoral location, the patient was referred to be followed by Endocrinology.

Discussion

This case illustrates the challenges of the etiological diagnosis of PE, particularly in young patients, highlighting the importance of detailed research towards persistent PE, and the fundamental role of Internal Medicine in integrating every detail in the absence of evident etiology.

#2104 - Case Report

PAGET’S DISEASE - CASE REPORT

David Paiva, Sandra Barbosa, Jorge Cotter

Hospital Senhora da Oliveira, Guimaraes, Portugal

Introduction

Paget’s disease (PD), also called osteitis deformante, is characterized by an osteoclastic hyperactivity with consequent bone resorption, accompanied by a compensatory osteoblastic response. This disease rarely has a symptomatic clinic (5%), which can affect one or several bones, the pelvis and sacrum are the most prevalent. Diagnosis is essentially radiological, but some laboratory alterations help the accomplishment of the same.

Case description

Man 72 years old, smoker with history of multiple bone fractures. Painful complaints, with 1 month of evolution, in the lumbar region, with irradiation to the lower limbs and decrease of the associated muscular strength. Assistant physician treated with deflazacorte witch resulted in clinical improvement. Computed tomography (CT) of the lumbar spine was performed, which revealed areas of lytic lesions and/or greater bone resorption in the posterior iliac region suggesting Paget’s disease. All of the study that was done, thyroid ultrasound, upper and lower digestive endoscopy and

abdominopelvic CT without any changes of relief. Analytically, increased alkaline phosphatase (160 U/L) and hydroxyproline 42 mg/24h (normal value:<42). Calcium, phosphorus and parathyroid hormone without alterations. Calcium in urine 24h was normal. Bone scintigraphy: outbreaks of abnormal osteoclastic hyperactivity in L4-L5 in the left iliac, sacral and pubic bone. The patient initiated infusion of zoledronic acid and had hospital discharge with calcium, vitamin D and supplemented with B vitamins. Oriented for internal medicine consultation, and three months later he presented significant clinical improvement, without pain and return to his normal life.

Discussion

It is important to exclude secondary causes (neoplasias, multiple myeloma) for bone lytic lesions. Treatment is indicated for symptomatic control, reduction of hypercalciuria, reduction of the number of complications and suppress high levels of bone resorption. Bisphosphonates are the agents approved for treatment of PD.

#2121 - Case Report

DELIRIUM SECONDARY TO HYPOTHYROIDISM

José Abreu Fernandes, João Borges Rosa, Nelson Pedro, Lèlita Santos, Armando Carvalho

Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Confusional state and delirium are common neurologic dysfunctions in elderly patients specially those who have multiple morbidities and it may complicate their evaluation and management. Besides the attention and cognitive impairment, delirium can be accompanied by psychomotor and autonomic overactivity.

Although its pathophysiology is not well explained it is established to be associated with an underlying organic condition.

Case description

An 80 years-old male, autonomous for daily life activities (Katz functional scale of 6), antecedents of hypothyroidism due to thyroidectomy, essential arterial hypertension, and glaucoma was admitted to the emergency room for behavioral alterations and complex visual hallucinations for the past 2 weeks. The physical examination did not have any alterations, but the neurological examination showed dysarthria. Head CT revealed no recent vascular or expansive lesion. Lumbar puncture did not show any bacterial growth in the direct or cultural exam, biochemistry showed mild proteinorachia with normal glucose and without pleocytosis, and the multiple test for viruses and bacteria were all negative. HIV and screening for sifilis were negative. Thyroid function test revealed thyroid dysfunction, thyreo-stimulating hormone of 80 uUI/mL and free T4 was <0,4 mg/dL, while in previous study the patient had had normal values.

The patient was admitted to the Internal Medicine ward with thyroid hormone reposition and supportive care, and when asked he mentioned to have withdrawn all medication for the past few weeks.

Two days later, the patient resumed his past cognitive status without hallucinations. Hyperactive delirium secondary to hypothyroidism due to lack of medication compliance was assumed and the patient was reevaluated 1 month later with normal thyroid function.

Discussion

We report a case of a behavioral alteration and complex visual hallucinations potentially secondary to a hypothyroidism due to lack of medication compliance. Although cognitive impairment is common in overt hypothyroidism it is uncommon to see neuropsychologic symptoms like disorientation or psychosis.

It is emphasized the relevance of thyroid testing in elderly patients with neurologic dysfunction as well as the importance of pharmacology compliance vigilance in risk patients.

#2125 - Case Report

HYPOPITUITARISM ASSOCIATED WITH HYPOGLYCEMIA: CASE REPORT

Mario Angelo Cenedesi Junior^{1,2}, Fabiana Santos Felipe³

¹ Senhor Bom Jesus Hospital, Monte Azul Paulista, Brazil

² University of Sao Paulo, Ribeirao Preto, Brazil

³ Central Family Health Unit, Pitangueiras, Brazil

Introduction

The occurrence of hypoglycemia associated with hypopituitarism is a rare event in adult patients and a little more frequent in children with similar pituitary dysfunction. In patients with adrenal insufficiency, hypoglycemia is more prevalent in those whose cortisol deficiency is secondary to ACTH deficiency than in those with primary adrenal disease. This is probably due to the fact that, in the first condition, there are simultaneous deficiencies of GH and cortisol.

Case description

A 27-year-old man with a history of recurrent episodes of loss of consciousness. Attendance at all times, with superficial coma, with capillary glycemia less than 50 mg/dL, with improvement of the condition to hypertonic glucose correction. It refers to nocturnal enuresis for more than 5 years, daily. Bearer of short stature (1,60 cm), without beard, face and voice infantilizados, with appearance of characters secondary to the 17 years. Patient presenting daily nocturnal enuresis. The physical examination evidences genitalia with grade IV piloting (Tanner scale), elongated penis, with evident balanopreputial groove, with topical testes, of about 02cm each. Absence of postural hypotension and others. Laboratory tests: blood count, electrolytes and renal function without abnormalities. Endocrinological evaluation: ACTH: less than 5 pg/mL (NV <60pg/mL); Cortisol: <1 ug/dL (NV 7-31 ug/dL); Insulin: <1 uUI/mL (NV

2.6-24.9 uIU/mL); GH: <1ng/dL (NV 55-25 2ng/dL); TSH: 9.03 uIU/mL (NV 0.4-4.3 uIU/mL); Free T4: 0.5ng/dL (VN 0.6-1.5ng/dL LH: 8.5UI/L (NV 1.4-9.2 UI/L); FSH: 6.8IU/L (NV 1-12 IU/L); Cortisol suppression test after dexamethasone: 0.31ug/dL (NV <2 ug/dL); Total testosterone 1046ng/dL (NV 241-627ng/dL); Prolactin/DHEA/Androstenedione: not performed due to lack of laboratory possibility. Computed tomography (CT) of the abdomen and skull does not show any changes.

Discussion

Hypoglycaemia caused by deficiency of counterregulatory hormones is not a common clinical condition in adults with hypopituitarism, except when hypopituitarism is associated with diabetes treated with insulin or oral hypoglycemic agents (which is not the case with this patient). Hypoglycemia episodes disappeared after treatment with glucocorticoids. This demonstrated a cause and effect relationship between hypocortisolism and hypoglycemia.

Excluding other causes, after studying the hormones and axes, we assume that pituitary function impairment was caused by an autoimmune process, causing hypophysitis.

The patient is still being followed up.

#2128 - Case Report

PRIMARY HYPERALDOSTERONISM PRESENTING WITH HAEMORRHAGIC STROKE IN A YOUNG ADULT

Rita J. Rodrigues, Paula Gonçalves Costa, Marta Costa Gonçalves, Patrícia Gomes Pereira, Alcina Ponte

Hospital of Santo André - Hospital Center of Leiria, Leiria, Portugal

Introduction

There is an increased risk of cerebrovascular events in primary hyperaldosteronism (PH). Nevertheless, acute neurologic event as presenting feature of PH is uncommon. We present a case of stroke in young adult to highlight the need for secondary hypertension management workup in these patients.

Case description

A 39-year-old female presented to the emergency department with left hemiplegia, minor facial paralysis, left extinction and a blood pressure of 205/105 mmHg. She had previous history of unstudied uncontrolled hypertension since her first pregnancy at 29-years-old and was under antihypertensive therapy. Computed tomography (CT) scan of the brain showed an acute right lenticulo-capsular 5cm-long hematoma with involvement of the corona radiata, which had no surgical indication. She was admitted with diagnosis of haemorrhagic stroke. Laboratory exams revealed hypokalaemia (2.8mmol/L), normal thyroid stimulating hormone and raised T4, raised parathyroid hormone, normal serum calcium, low vitamin D and high cholesterol levels. During inpatient care, her clinical evolution was favourable. Etiologic study of stroke was negative except for uncontrolled hypertension. Further

investigation revealed normal catecholamines, high aldosterone (>20ng/dL) and increased aldosterone-to-renin ratio confirmed by sodium-loading test results. Abdominal CT scan showed a right suprarenal hypodense nodule suggesting adrenal adenoma. Parathyroid scintigraphy excluded adenoma. The patient was diagnosed with primary hyperaldosteronism caused by a functioning unilateral adrenal adenoma and is now waiting for surgical intervention while under medical treatment that includes a mineralocorticoid receptor antagonist. Hyperparathyroidism was considered secondary to vitamin D deficiency.

Discussion

In this case, the patient had secondary hypertension for 10 years without a known cause. The diagnostic approach to resistant hypertension should include screening for a secondary cause, including PH because it is one of the most common causes with a prevalence of 5-15%. An early diagnosis and subsequent treatment not only improves blood pressure control, but also acts to diminish cardiovascular morbidity and mortality.

#2133 - Case Report

HYPERPARATHYROIDISM - JAW TUMOR SYNDROME - CDC73 GERMLINE MUTATION

Isabel Borges, Bernardo Pereira, Rui Cesar

Hospital Do Divino Espírito Santo, Ponta Delgada EPE, Ponta Delgada, Portugal

Introduction

Primary hyperparathyroidism (pHTP), the main finding of hyperparathyroidism-jaw tumor (HPT-JT) syndrome, occurs in up to 95% of affected individuals. It is a rare autosomal dominant syndrome, linked to germline inactivating mutations in the tumour suppressor gene CDC73 (1q31.2 chromosome). Onset is typically in late adolescence or early adulthood.

Case description

We report a 59-year-old woman, with history of complicated and symptomatic nephrolithiasis during youth, with the need of extracorporeal shock wave lithotripsy and double-J stent implantation, benign uterine tumor and jaw tumor, intervened in 1999 and 2002. In the last three years, she was investigated at hospital's appointment, because of renal impairment stage 3. Hypertension and recurrent nephrolithiasis were the two major risk factors identified. Laboratory tests (LabT), during its investigation revealed mild hypercalcemia, elevation of parathyroid hormone, 25(OH)vitD deficiency, normal serum phosphorus levels, urinary calcium/creatinine >0.02 and no evidence of lithogenic risk profile on 24hour urinalysis. Clinical findings and LabT was suggestive of HTP. There weren't cervical compressive symptoms, palpable nodules and family history of HTP or neoplastic disease. According to the findings, HPT-JT syndrome was a plausible diagnosis. Indeed, the patient underwent cervical ultrasonography (US), without evidence of suspected

parathyroid nodules. A parathyroid sestamibi scan was performed and was negative. However, cervical CT-scan combined with "second-look" US examination evidenced a hypoechoic nodular formation at the inferior lobe of the right gland, suggestive of parathyroid adenoma.

Because of pHTP renal complications, a successfully parathyroidectomy of the two right glands was performed. Histologic diagnosis confirmed an adenoma. HPT-JT syndrome diagnosis was made by a positive genetic testing for CDC73 mutation (exon 14).

Discussion

The diagnosis of hereditary pHPT should be confirmed by a genetic testing preceded by the appropriate genetic counselling. CDC73 germline mutation may offer a predisposition to neoplastic progression with parathyroid carcinoma found in 21.6%. The optimal surgical approach has not yet been established and remains controversial. Because of the risk of recurrent or new disease, a regular lifelong serum testing for biochemical evidence of pHPT is recommended.

#2142 - Case Report

A RARE CASE OF ACQUIRED CHOREA

Guilherme Assis¹, Daniela Viana¹, Joana Rua¹, Luís Marques Loureiro², Romeu Pires¹, Paula Vaz Marques¹

¹ Hospital São Pedro de Vila Real, Vila Real, Portugal

² Hospital Distrital de Chaves, Chaves, Portugal

Introduction

Chorea is defined as an involuntary, non-stereotyped, random and continuous flow of movements that most commonly affects distal limbs and face. The classification comprises primary (idiopathic, hereditary) and secondary (acquired) etiologies. Causes for acquired chorea include metabolic/endocrine, infectious, drugs, toxins, neurologic, vascular and malignancy. The differential diagnosis relies on age, mode of onset, and other accompanying features.

Case description

A 60 years-old man presented in the emergency room with psychomotor agitation and hypersalivation. Physical examination revealed tachycardia, generalized chorea and previously known tetraparesis with crural predominance, anterocollis and dystonic posture of the left lower limb. No new-onset motor deficit was noted. No recent history of fever, neuroleptic administration or tonic-clonic seizures was documented. Relevant background included congenital cognitive deficit and epilepsy with ongoing treatment with valproic acid (800 mg per day). Family history included multiple stillborn siblings and a sister with identical intellectual phenotype. Initial blood and urinary analysis displayed no significant results. Valproic acid levels were normal. Cerebral CT showed no relevant findings. EKG revealed sinus tachycardia. Haloperidol and heart rate control drugs merely had partial

response. He later conducted extended tests: syphilis and HIV were negative, ANA testing was negative, but endocrine testing revealed free T4 58.60 pmol/L (normal level, 8.24 - 21) and TSH <0,01 mIU/L (normal level, 0.27 - 4.20). We assumed the diagnosis of thyrotoxicosis and instituted treatment with beta-blocker and methimazole. After normalization of the thyroid function tests, the neurological condition of the patient returned to its previous basal state.

Discussion

Although the patient has relevant neurological background, hereditary chorea usually develops insidiously, whilst acute onset is characteristic of acquired etiology. In this case, recognizing a secondary or reversible cause was relevant, as some conditions might be reversed. This patient manifested chorea in the context of hyperthyroidism. The effective correction of the level of thyroid hormones and concomitant abolishment of the neurological condition, while other causes were excluded, is sufficient to establish the diagnosis of hyperthyroidism-induced chorea.

#2145 - Case Report

AN ATYPICAL CASE OF POLYGLANDULAR AUTOIMMUNE SYNDROME TYPE III

Pedro Martins Dos Santos, Pedro Gomes Santos, Lucy Alves, Pedro Mendonça, Sérgio Gonçalves, António Veiga E Moura
Centro Hospitalar Universitário do Algarve - Faro, Faro, Portugal

Introduction

Polyglandular autoimmune syndrome (PAS) is defined as the functional disorder of at least two abnormal endocrine glands based on autoimmune mechanisms, that can also be associated with nonendocrine Autoimmune Diseases. PAS type III is one of the four types of PAS, and includes autoimmune thyroid disorders associated with other Autoimmune Diseases (ADs) and is not accompanied by Addison disease or Hypoparathyroidism. The authors describe the case of a middle-aged woman with a rare presentation of a PAS type III.

Case description

A 53-year-old woman is referenced to an Internal Medicine appointment after a short hospitalization due to a macrocytic anemia with vitamin B12 (vB12) deficiency. The patient had history of Hypothyroidism and Anemia irregularly medicated with vB12 and folate. There were no significant alterations in the physical examination, except for xanthelasmas in the upper eyelids. Laboratory results presented positive anti-gastric parietal cell antibodies (Ab) and negative anti-intrinsic factor Ab, which associated with vB12 deficiency were suggestive of Pernicious Anemia (PA). Immunology tests were also suggestive of Autoimmune Thyroiditis (AT) (Anti-Thyroglobulin Ab >3000 IU/mL and anti-thyroid peroxidase Ab 951 IU / mL). The findings of positive anti-mitochondrial Ab and anti-nuclear Ab with anti-SP100 Ab and anti-gp210 Ab, associated with the xanthelasmas in

the upper eyelids and absence of laboratory alterations of hepatic enzymes, revealed a subclinical Primary Biliary Cholangitis (PBC). About 11 months after discharge, the patient presented ptosis of the right eye and periods of dysarthria and dysphagia. Based on a suspected diagnosis of Myasthenia Gravis (MG), she underwent electromyography that revealed dysfunction of the post-synaptic membrane of the motor plate and is now awaiting the detection of specific MG Ab to confirm the diagnosis.

Discussion

Patients with ADs have a higher risk of developing other ADs, which makes it important to be alert to the possible sequential development of other autoimmune events in patients with PAS. In this case, a woman with PA and AT, developed a subclinical PBC and is in the early stages of a possible MG. As there is a possibility of developing other ADs, a strict follow-up is needed. An early detection of newer ADs in patients with PAS by screening for autoantibodies is a controversial issue but may help in introducing early treatment of other AD that may arise, before irreversible changes develop.

#2148 - Case Report

HEREDITARY HEMOCHROMATOSIS: AN INCIDENTAL DIAGNOSIS

Marta Mendes Lopes, Catarina Lameiras, Afonso Santos, Énia Ornelas, Maria Do Céu Dória

Professor Doutor Fernando Fonseca Hospital, Amadora, Portugal

Introduction

Hereditary hemochromatosis is the most frequent autosomal recessive genetic disease in the Caucasian population. It consists of excess iron deposition in tissues due to increased intestinal iron absorption, resulting in multiorgan dysfunction (liver, heart and endocrine glands). In 80% of cases it is caused by mutations in the HFE gene (H63D and C282Y being the most frequent), however, in some rarer cases it can be due to mutations in other genes involved in the regulation of iron metabolism – HFE-negative hemochromatosis.

Case description

We present a 76-year-old Caucasian male, with arterial hypertension and a recent hospital admission due to an ischemic stroke caused by ipsilateral carotid stenosis. During his hospital stay, due to a haemoglobin level of 12,5 g/dl, an iron study was requested, revealing an serum iron of 123 µg/dl, transferrin saturation of 60% and hyperferritinemia of 7949 ng/ml, hence making the diagnosis of hereditary hemochromatosis. The genetic testing proved to be negative for HFE gene most frequent mutations, therefore being most likely a HFE-negative hemochromatosis with the results from the remaining genetic study still in course.

The patient has been asymptomatic since the diagnosis. Due to a slight increase in liver enzymes (AST 42 U/L e ALT 70 U/L) and

although the abdominal ultrasound was normal, an abdominal MRI was ordered which revealed severe iron overload in the liver (232 µmol/g) as well as mild overload in the spleen (64 µmol/g). Moreover, the patient has no signs or symptoms of congestive heart failure and has a normal transthoracic echocardiogram. His thyroid function is normal, his fasting blood sugar levels are also under normal values and he has no signs of arthropathy or skin lesions. He is currently undergoing regular phlebotomies in the Day Hospital and is being followed-up in conjunction with the Immunotherapy Department.

Discussion

This case illustrates an incidental diagnosis of a rarer form of hemochromatosis. Although the patient is asymptomatic, he already presents signs of end-organ damage, namely, liver iron overload, being therefore at a greater risk of developing cirrhosis and hepatocellular carcinoma. We can thus conclude that early detection of this disorder and treatment initiation can delay and prevent end-organ damage, leading to lower morbidity and mortality.

#2155 - Case Report

WHEN BEHAVIOR CHANGE AND CARDIOVASCULAR RISK HAVE THE SAME CAUSE

Raquel Bastos Plácido¹, Ana Rafaela Araújo², Daniela Meireles², Diana Carvalho²

¹ USF Beira Ria - ACeS do Baixo Vouga, Gafanha Da Nazaré, Portugal

² Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

Introduction

The Symptomatology of the Cushing's Syndrome is related to the exposure to high corticoid levels, bearing in mind that the severity is directly related to the intensity and duration of the Hypercortisolism. There's a wide spectrum of non-pathognomonic manifestations, some of them being common among the population, as for example glucose intolerance, obesity and arterial hypertension.

Case description

The authors present the case of a male patient, 57 years old, with a history of bipolar disorder, admitted to the emergency department in November 2018 for behavior change, showing alternation between periods of agitation and prostration. He had resumed therapy with lithium a few months before because of mood swings. Observed by Psychiatry he was being admitted for intoxication by lithium, in patient with concomitant hypernatremia.

However, clinical features remained the same despite the normalization of lithium levels, and a computerized cranioencephalic CT scan was requested that raised suspicion of pituitary lesion.

He was hospitalized for a study, with symptoms and signs

reviewed: food refusal and muscle weakness, despite weight gain, with recent diagnosis of hypertension and diabetes mellitus. The objective examination included obesity of the trunk and neck, full moon and bitemporal hemianopia.

Hypothesized state of hypercortisolism, confirmed in the analytical study (significant elevation of serum and urinary cortisol levels and serum ACTH levels). Had also reduced levels of TSH and thyroid hormones, with no other changes in the pituitary base.

EC magnetic resonance imaging confirmed that it was an invasive pituitary macroadenoma, with involvement of adjacent structures. Was submitted to transsphenoidal removal, with normalization of urinary and serum cortisol levels in a post-surgical study.

In this patient the behavioral changes were the cardinal manifestation, initially attributed to the underlying psychiatric illness and drug iatrogeny.

CS is associated with a significant increase in cardiovascular risk, as happened in this case, which made us suspect that hypercortisolism was confirmed.

Discussion

HBP, DM and obesity may improve after treatment, but often do not normalize. This suggests that they continue to be at increased risk, even after the disease being controlled, thereby benefiting from targeted and intensive therapy.

We reinforce the need for integration of signs and symptoms in the management of the differential diagnosis of confusional syndrome.

#2157 - Case Report

POLYURIA: A CASE OF CENTRAL DIABETES INSIPIDUS

Ana Luís Ferreira, Gabriela Pereira, Laura Castro, Magda Fernandes, Jorge Cotter

Hospital da Senhora da Oliveira - Guimarães, Guimarães, Portugal

Introduction

Central diabetes insipidus is a rare disorder caused by absent or reduced concentrations of antidiuretic hormone (ADH). Approximately thirty to fifty percent of cases are idiopathic. Differential diagnosis includes nephrogenic diabetes insipidus and primary polydipsia.

Case description

Healthy, forty-nine year-old woman complains of polyuria and polydipsia with one month of evolution and a daily water input of six liters. No history of trauma or neurosurgery. Abdominal ecography without evidence of urinary obstruction. MRI imaging showed a slight thickening of the pituitary stalk, with no evidence of space occupying lesions. Intravenous desmopressin was administered after water restriction with a one hundred and sixty percent increase in urine osmolarity, consistent with central diabetes insipidus. Oral treatment with desmopressin tablets, 0.1 mg twice daily, was introduced and the patient achieved clinical stability by the time of discharge.

Discussion

Water balance relies on a precise and flexible regulation, allowing adaptation to various circumstances of deprivation or abundance. The thirst mechanism is essential to achieve homeostasis. This is a rare case that highlights the importance of the hypothalamic-pituitary system and its interaction with multiple organs, particularly the kidney.

#2171 - Abstract

EVALUATING HOW THE WEEKENDS AND WARM SEASONS AFFECT THE INCIDENCE OF SEVERE HYPOGLYCEMIA AND DIABETIC KETOACIDOSIS IN A PORTUGUESE HOSPITAL

Liliana R Santos, Carlos Lemos, Rita Medeiros, Ana Paula Vilas

CHLN, Lisboa, Portugal

Background

Severe hypoglycemia (SH) and diabetic ketoacidosis (DKA) are among the main endocrinological disorders that cause Emergency Department (ED) visits. Although diabetes management has improved significantly over the years, this has not led to a decline in SH and DKA incidence. The primary outcome is to assess the effects of environmental factors, such as seasonality and weekends/weekdays, on SH and DKA incidence. This effect has never been studied in the Portuguese population.

Methods

Retrospective population observational study capturing all episodes of SH and KD between 2014 and 2018 in a tertiary care University Hospital. SH was defined as a symptomatic low glucose blood level (<60 mg/dL) that required intravenous glucose. DKA was defined as the association of hyperglycaemia (>250 mg/dL), acidosis and ketonaemia/Ketonaemia.

Results

Between 2014 and 2018, 48157 glucose blood levels were determined at the ED. A total of 474 episodes of SH were registered, 345 on weekdays and 129 on weekends. When the data was stratified per year, there was an increase in the admissions on the weekends versus weekdays. In 2014, the frequency of weekend SH admissions was 10.9% per day (15.6%/day in the week group), compared to 17.4% per day in 2018. Regarding seasons distribution, warm seasons were associated with an increased incidence of SH.

During the same period of time, 4622 patients presented with glucose higher than 250 mg/dL and 344 fulfilled DKA criteria. There were 108 DKA admissions on weekends (15.7%/day) and 236 admissions on week days (13.7%/day). Unlike SH, in the DKA group the lowest incidence happened in the summer (19.1% versus 38,0% during the winter).

Conclusion

For the risk and prognosis of SH and DKA, temporal and season

factors appear to contribute substantially. The enhanced frequency of SH in patients during weekends, in particular in warm seasons, is probably caused by short-term changes in behavior such as increased physical activity or higher alcohol consumption. Supporting these data, some international studies have documented that hemoglobin A1c levels are lower in the warm seasons. Concerning prognosis, a recent North American study concluded that patients admitted to hospital with DKA during weekends had a higher mortality rate than those admitted on weekdays. In conclusion, temporal and season factors may affect diabetes and awareness of this fact may help improve its' management.

#2186 - Abstract

PREVALENCE OF GLYCEMIC CONTROL IN TWO RANDOM DAYS OF AN INTERNAL MEDICINE SERVICE

Sérgio Antunes Da Silva, Domingos Sousa, Catarina Jorge, Margarida Viana, Elena Rios, Sara Aleixo, Diana Reis, Armindo Figueiredo

CHUA - Hospital de Faro, Faro, Portugal

Background

The prevalence of diabetes mellitus (DM) has been steadily increasing over the past few decades, promoted by the global rise in the prevalence of obesity and unhealthy lifestyles. The latest report from the World Health Organization (WHO) estimates a global prevalence of 422 million people living with diabetes in 2014. Patients with diabetes mellitus have highest rates of hospitalization and increased risk of adverse outcomes and mortality.

Objectives

To characterize the population of patients with diabetes mellitus admitted to an Internal Medicine service of a central hospital on two random days in 2019 (6 of March and 3 April 2019) and study the prevalence of glycemic variability.

Methods

Cross-sectional study based on consultation of the clinical files of patients admitted to the Internal Medicine of a Central Hospital. Hyperglycemia in hospitalized patients was defined as blood glucose levels > 180 mg/dL and hypoglycaemia as <80mg/dL.

Results

A total population of 280 patients with a mean age of 79.8 years was considered. The prevalence of diabetes was of 31.4%. Patient included to data collection need to be admitted less than 14 days ago and should be assigned to internal medicine specialist.

So we finally had 51 patients. Blood glucose (mg/dL) <80 1%, 81-180 46.9%; 181-240 26.2%; 241-300 15.8%, >301 9.8%. Only 25% of patients with oral antidiabetic agents persisted during hospital stay. 90% of the patients was under insulin during the hospital stay. A sliding-scale regimen was present on 65.3%.

Conclusion

It has been proved that both hyperglycemia and hypoglycemia are associated with adverse outcomes, including death. A sliding-scale regimen is strongly discouraged.

In the hospital setting, a basal insulin plus premeal short- or rapid-acting insulin (basal-bolus) coverage has been associated with improved glycemic control and lower rates complications compared with the traditional sliding scale regimen

Lastly our study reinforces that the internist should be able to control diabetes at the hospitalized patients accordingly with the standards of diabetes care.

GASTROINTESTINAL AND LIVER DISEASES

#35 - Abstract

SIRS CRITERIA VERSUS QSOFA IN SEVERE ALCOHOLIC HEPATITIS

Paula Reyes Suárez, Onán Pérez Hernández, Emilio González Reimers, María José Sánchez Pérez, Camino Fernández Rodríguez, María Candelaria Martín González, Víctor Vera Delgado
Complejo Hospitalario Universitario de Canarias, San Cristóbal De La Laguna, Spain

Background

Severe alcoholic hepatitis (sAH) is a serious complication in patients with alcoholism and was associated with high mortality. Bacterial translocation is a fundamental pathogenic factor and its intensity is related to severity and prognosis. In a recent study, SIRS criteria were related to LPS levels and surveillance. On the other hand, qSOFA has displaced these criteria in the definition of sepsis. The purpose of this study is to determine if qSOFA has greater clinical utility than SIRS criteria in patients with sAH.

Methods

Sixty-two patients with sAH (Maddrey ≥ 32) were included. We recorded these variables used in usual clinical practice, such as age, sex, liver and renal function parameters. We also determined SIRS criteria and qSOFA components.

Results

Mean age was 52.5 ± 10.7 years. During this period, 24 patients died (38.7%). SIRS criteria ≥ 3 and qSOFA ≥ 2 were related with mortality at 180 days (LR=12.09; $p=0.001$; LR=4.81, $p=0.028$, respectively). Other parameters who had related with surveillance were: male sex (LR=5.73; $p=0.017$), high serum bilirubin (LR=7.62; $p=0.006$), high serum creatinine (LR=5.43; $p=0.020$) and hyponatremia (LR=5.75; $p=0.018$). Cox regression was made and only bilirubin and SIRS criteria were independent prognostic factor.

Conclusion

SIRS criteria appear to have prognostic value in sAH, unlike qSOFA. We found that altered Glasgow (component of qSOFA) was related with delirium tremens, frequent in alcoholics and with almost non-existent mortality relation. Likewise, cirrhotic patients have lower blood pressure (other component), without this implying a worse prognosis. These facts could justify that the qSOFA does not have an independent relation with mortality in sAH.

#36 - Abstract

MALONDIALDEHYDE ASSOCIATED TO MELD IN SEVERE ALCOHOLIC HEPATITIS

Emilio González Reimers, Onán Pérez Hernández, Paula Reyes Suárez, María José Sánchez Pérez, Selena Gala Aguilera García, Lucía Romero Acevedo, Daniel Martínez Martínez
Complejo Hospitalario Universitario de Canarias, San Cristobal De La Laguna, Spain

Background

Severe alcoholic hepatitis (sAH) is a serious complication in patients with alcoholism and was associated with high mortality. Oxidative stress and lipid peroxidation are increased in sAH. In previous study, we found that malondialdehyde (MDA, as lipid peroxidation marker) could be independent prognostic factor. The aim of this research is to demonstrate the utility of MDA in clinical practice. For this, we decided to associate MDA to MELD, a previously validated prognostic score.

Methods

Sixty-two patients with sAH (Maddrey ≥ 32) were included. Serum MDA was determined at admission. In the cited study, MDA was related with 180 days-mortality. We built a new score with MDA and MELD, both corrected by Hazard ratio obtained in this work. The formula was $2 \times \text{MDA} + \text{MELD}$. Kaplan Meier curves and ROC curves was made for new score and its components.

Results

Mean age was 52.5 ± 10.7 years. During this period, 24 patients died (38.7%). High MDA levels were related with mortality (LR=7.89; $p=0.005$), just like MELD (LR=7.17; $p=0.007$). The association of both also had prognostic value (LR=7.89 ; $p=0.005$). ROC curves were constructed. MDA and MELD had a smaller area separately (AUROC=0.79 and 0.72, respectively) than the association of both (AUROC=0.83).

Conclusion

MDA could be useful in clinical valoration of sAH. The association of MDA with the MELD score could improve its predictive value, although it is necessary to perform a confirmatory work with an external cohort.

WHAT IS HIDING BENEATH A LOWER LIMB NODULAR LESION?

Irina Tica¹, Zizi Niculescu¹, Liliana Mocanu², Mihaela-Maria Ghinea¹, Costin Niculescu¹

¹ Faculty of Medicine, Constanta, Romania

² County Clinical Emergency Hospital, Constanta, Romania

Introduction

Pancreatic panniculitis represents a dermatological manifestation mainly due to a pancreatic disorder, but other etiologies are possible. Usually it occurs prior to the clinical manifestation of the underlying disease, and its presence must orientate the investigations especially towards pancreas, liver and neuroendocrine system.

Case description

We report the case of a 47-years-old male patient who presented to emergency unit complaining for 2 weeks persistent pain in the upper abdomen and biliary vomiting. He recognized alcohol abuse. Several days prior to the onset of these symptoms, the patient noticed the occurrence of a nodular inflammatory lesion of 5/3 cm in the anterior middle third of the right calf. Based on clinical aspect and high levels of pancreatic enzymes, acute pancreatitis was diagnosed. Contrast enhanced abdominal CT examination revealed a cystic pancreatic mass and dilated intrahepatic biliary ducts, MRI being recommended. Abdominal MRI revealed a cystic tumor of the pancreatic head and thrombosis of portal vein, rising the suspicion of pancreatic adenocarcinoma. Biopsy was performed from the calf nodular lesion, with the diagnosis of panniculitis.

Discussion

Discussions over the differential diagnosis of the etiology of calf panniculitis, of the cystic pancreatic mass and of patient's evolution are performed, along with a review of the medical literature.

#48 - Abstract

NON ALCOHOLIC FATTY LIVER DISEASE (NAFLD) AND METABOLIC ASSOCIATED DISTURBANCES: THE IMPORTANCE OF DIET AND SPORT

Elena Gologan

University of Medicine and Pharmacy, Iasi, Romania

Background

A prospective study on obese patients with NAFLD, in an outpatient service, (06/2016 - 07/2017), with associated metabolic and tensional disturbances to find if an one year diet would improve the liver function.

Methods

A lot of 47 patients with NAFLD, obese (mean BMI=33.1), mean age 47.8 years, with diabetes mellitus (24), hypertriglyceridemia

(39), hypertension (36) were studied for liver function before and after one year a restrictive diet and sport.

Results

Initially the patients had mean values of: ALT=191.5 IU/l, AST=235.7 IU/l, serum albumin=3.5 g/dl, serum bilirubin=2.1 mg/dl, glycemia=159 mg/dl, triglyceridemia=370 mg/dl, INR=1.2 and a mean value of arterial pressure 165/96 mmHg. The patients were treated only by diet (low calories, low carbohydrates, low saturated fat, rich fibers, moderate rich in low glycemic index carbohydrates, no alcohol) and 7 hours per week sport. After one year the mean values of BMI=25.1, ALT=45.7 IU/l, AST=56.3 IU/l, serum albumin=3.7 g/dl, serum bilirubin=1.1mg/dl, glycemia=109 mg/dl, triglyceridemia=197 mg/dl, INR=1.07 and mean arterial pressure 135/83 mmHg.

Conclusion

The role of diet and sport in NAFLD in order to decrease the BMI is also essential for the improvement of liver function and regulation of associated metabolic disturbances and arterial pressure.

#51 - Case Report

WATERMELON STOMACH - AN UNCOMMON CAUSE OF ANEMIA IN THE ELDERLY

Rahul Unnikrishnan

Rashid Hospital, Dubai, United Arab Emirates

Introduction

Gastric Antral Vascular Ectasia(GAVE), also referred to as 'watermelon stomach' is an uncommon, under reported, yet significant cause of acute or chronic gastrointestinal blood loss in the elderly. It accounts for about 4% of non variceal upper GI bleed and diagnosis is established by demonstration of characteristic watermelon stripes on upper GI endoscopy.

Case description

65-year-old lady, with no known comorbid illnesses, presented with complains of generalised fatigue, loss of appetite, unquantified loss of weight for the last 4 months, She was evaluated locally 2 months ago and was found to be anemic with a Hemoglobin of 10g% and was started on oral iron supplementation, as her iron stores were found to be low, with no significant symptomatic improvement since then. Over the next two months, she had persistent complaints of generalised edema and occasional bouts of diarrhea. She did not have any associated overt bleeding manifestations. Routine evaluation revealed iron deficiency anemia and stool occult blood was positive. This warranted the second line of anemia evaluation. Upper GI Endoscopy thus done revealed Gastric Antral Vascular Ectasia (GAVE). Argon Plasma Coagulation was done, and her occult blood loss ceased. On followup, her hemoglobin levels gradually improved and she continued to be asymptomatic, as her earlier symptoms had largely resolved.

Discussion

GAVE is an uncommon but significant cause of acute or chronic GI blood loss in the elderly. It was first described in 1954 by Rider as “fiery red changes with marked hypertrophic mucosal changes, and scattered profuse bleeding.

#60 - Case Report

DIARRHEA IN YOUNG PEOPLE

Cristina Lojo, M. Angeles Gallardo, Isabel Melguizo, Jose Antonio Mira

Hospital de Valme, Sevilla, Spain

Introduction

Diarrheal diseases are a leading cause of morbidity and mortality worldwide

Case description

A 15-year-old woman with chronic normocytic-normochromic anemia since 2015 was admitted due to asthenia, intermittent hematuria, lower limbs edema and diarrhea with blood of 15 days of evolution. The examination revealed skin pallor, bilateral malleolar edema and low weight with no pubic or axillary hair (Tanner I) with slightly developed breasts (Tanner II). Blood count shows Hb 7.8 g/dl (normo-normo), white series and normal platelets; smear with red series with tendency to rouleaux, hypochromia and poikilocytosis. He presents iron deficiency and folic deficit. In the coagulation study no clot is detected, so fresh plasma and vitamin K are administered. In the biochemistry, total proteins of 3.5 g/dl stand out. Normal immunoglobulins. In urine sediment presence of red blood cells. Stool culture with normal flora and normal abdominal ultrasound.

Therefore silent episode of severe malnutrition with coagulopathy and delayed growth and maturation, until the moment of admission. Given the diagnostic suspicion, Ac antigliadina is requested (these being > 80), a gluten-free diet is initiated and an oral endoscopy is performed, with duodenal second folds and nodular mucosa of a biopsy pattern being observed, all compatible with celiac disease. Excellent evolution with gluten-free diet, staying asymptomatic.

Discussion

Celiac Disease is an immune-mediated systemic disease caused by gluten and related prolamins in genetically susceptible individuals and is characterized by: gluten-dependent clinical manifestations, EC-specific antibodies, HLA haplotypes DQ2 or DQ8 and enteropathy. The prevalence in Europe is 1%, more frequent in women. Symptoms may be atypical or absent and 75% of patients are undiagnosed.

For certainty diagnosis, intestinal biopsy is essential without removing gluten from the diet.

#69 - Case Report

A RARE COLITIS IN A YOUNG GIRL

Ana Beatriz Amaral, Pedro Duarte, Cláudia Rodrigues, Luís Dias

Hospital do Divino Espírito Santo de Ponta Delgada, Ponta Delgada, Portugal

Introduction

Ischemic colitis is the most common form of intestinal ischemia, with heterogeneous presentation, more frequent in the elderly and rare in young people.

Case description

A 22-year-old woman was referred to the emergency department for abdominal colic, more intense in the left lower quadrant, without irradiation, with diarrhoea and haematochezia, after 10 hours of evolution. She denied associated fever, vomiting and urinary symptoms. She had a history of anxiety disorder, migraine and irritable bowel syndrome and was taking an oral contraceptive. On examination she had a blood pressure of 96/67 mmHg, a heart rate of 97 bpm, an abdomen without guarding but painful in the epigastrium and left quadrant, with no signs of peritoneal irritation. Rectal examination showed abundant mucus and blood. She had leucocytosis (12,280/μl) and neutrophilia (81.3%), low CRP, with no change in coagulation, renal or hepatic function. X-ray of the abdomen without changes of relief. A flexible rectosigmoidoscopy revealed a vascular erythema and edema, with mucous desquamation with haemorrhagic suffusions, without ulcers, suggestive of ischemic colitis. An abdomino-pelvic CT showed parietal thickening of the colon, from the splenic angle to the beginning of the sigmoid colon, compatible with colitis of the descending colon. No signs suggestive of obstructive vascular disease. Ciprofloxacin was prescribed, and the patient was hospitalized for study and monitoring. Coprocultures and study of thrombophilias were negative. The histological result confirmed ischemic colitis. Two months later and after suspended oral contraceptive intake the patient was asymptomatic and had normal colonoscopy.

Discussion

Among young people, ischemic colitis is a rare but not impossible condition, which may be idiopathic and occur insidiously. However, in most cases ischemia is self-limiting and leaves no sequelae.

#70 - Case Report

LIFE THREATENING IDIOPATHIC ACUTE LIVER FAILURE IN POSTPARTUM FEMALE: A RARE PRESENTATION OF ACUTE FATTY LIVER OF PREGNANCY

Chavely Valdes Sanchez, Nitasa Sahu, Rohit Jain

Hershey Medical Center, Hershey, United States

Introduction

Acute fatty liver of pregnancy (AFLP) is a rare life-threatening acute liver failure (ALF) (5/100,000 pregnancies), primarily

diagnosed in the late third trimester than in post-partum. This case describes idiopathic AFLP in postpartum period and its diagnosis by Swansea criteria.

Case description

A 26-year-old female, G1P1 presented to ED on postpartum day 5, with complains of epigastric pain, nausea, yellowing of skin and eyes, and diffuse rash of two day duration. Her physical exam demonstrated soft, non-tender, distended abdomen, bilateral 1+ pedal edema, diffuse jaundice and skin rash. Patient was hemodynamically stable. Laboratory workup revealed albumin 2.2, Alk phos 269, ALT 153, AST 132, total bilirubin 12.2, direct bilirubin 9.7, uric acid 8.1, INR 2.1, PTT 21.3, glucose 56, BUN 26, Cr 1.74, Fibrinogen 92, hemoglobin 11.4, WBC 17 000, platelets 171 000, and LDH 661. Abdominal ultrasound (US) showed tiny polypoid extrusion of the liver from the inferior liver margin, normal portal vein and gallbladder. Retroperitoneal US showed increased echogenicity of the liver. Abdominal venous duplex showed no abnormality. Skin biopsy confirmed perivascular and interstitial lymphocytic infiltrate of the dermis, indicative of urticaria. Work up for viral serology and screening for long-chain-3-hydroxyacyl-coenzyme-A dehydrogenase (LCHAD) were negative. Her AFLP improved with no complications due to early diagnosis and optimal management.

Discussion

This case highlights importance of Swansea criteria to exclude other causes of ALF, which mimic AFLD. Physicians should be aware of Swansea criteria, for early diagnosis of AFLD, prevention of complications, and educating patients to avoid recurrence.

#92 - Abstract

CLINICAL AND INVESTIGATIVE PROFILE OF ACUTE VIRAL HEPATITIS: A PROSPECTIVE OBSERVATIONAL STUDY FROM NORTHERN INDIA

Biswadeep Roy, P K Bansal, Vinod Kumar, Veenu Gupta
St. Stephen's Hospital, New Delhi, India

Background

Viral hepatitis, an acute infectious disease of liver with systemic involvement, is a cause for major health care burden in India. It is now equated as a threat comparable to the "big three" communicable diseases – HIV/AIDS, malaria and tuberculosis and may occur in both sporadic form as well as in the form of epidemic outbreaks. The present study was aimed to study clinical and investigative profile of acute viral hepatitis (AVH) and to determine relative frequency of different viral etiologies in AVH. Observations were also made on different types of complications, clinical outcome and certain risk factors that determine the severity of hepatitis.

Methods

A prospective, observational study was conducted in the Department of Medicine St. Stephens Hospital, New Delhi from July 2016 to December 2017. A total of 100 patients aged more than 12 years of either sex with indoor and outdoor patients were included. Based on history, physical examination and results of various investigations, patients of acute viral hepatitis were evaluated with regard to relative frequency of various viral hepatitis markers and prevalence of various complications among them. Prevalence of common risk factors for hepatitis and/or its severity such as alcohol intake, diabetes mellitus, low socio-economic status and older age of patients was determined.

Results

Among 62 males and 38 females patients, mean age was 32.3 years. Mean values of laboratory investigations of haemoglobin (11.89±1.74), total count (6650±3931), platelet count (1.94±0.75 lakhs), total bilirubin (5.23±2.84), direct bilirubin (4.49±2.35), SGOT (1354±1120), SGPT (1451±1040), alkaline phosphatase (303±194.66) and INR (1.43±0.79). Hepatitis E (62%) was the most common etiology followed by Hepatitis A (25%).

Conclusion

Patients with AVH often present not only with well known symptoms, signs and laboratory manifestation of disease but at times can have a variety of complications. Feco-oral mode of transmission together with types of hepatitis such as E and A are much more common than parenteral route like B and C types. By and large clinical and laboratory features of feco-oral and parenteral AVH are similar and majority of AVH patients have good outcome. Diabetes, alcohol intake and increased age of patients are more often associated with severe form of hepatitis. Patients who develop hypoalbuminemia, ascites, shock or AKI have poorer outcome.

#93 - Case Report

ACUTE PANCREATITIS AS AN UNUSUAL PRESENTATION OF BURKITT'S LYMPHOMA

Natália Bystrianska

HEGITO (Division of Hepatology, Banská Bystrica, Slovakia)

Introduction

Burkitt's lymphoma is a highly aggressive B-cell non-Hodgkin lymphoma (B-NHL) accounting to less than 2% of all adult NHL cases. There are three clinical variants, of which the sporadic form is the most common in our area.

Burkitt's lymphoma usually presents as a tumorous mass in the abdominal region (ileocecal region, retroperitoneum). Acute pancreatitis is a very rare initial presentation of BL rarely described in case reports.

Case description

In our case report, we present a patient – a middle-aged man

without any previous severe diseases – admitted on the basis of acute edematous pancreatitis, followed by a progressive deterioration of his health state within a short time frame during a period of hospitalization, manifested by various clinical findings ranging from focal liver lesions, sudden onset of dysphagia to paraplegia of the lower limbs with associated neurological complications. After a thorough examination, it was the bone marrow biopsy that revealed the diagnosis responsible for everything – Burkitt's lymphoma.

Discussion

This case report, therefore, contributes to the conclusion that NHL belongs to the differential diagnosis of pancreatitis and in the case of Burkitt's lymphoma, the early diagnosis with immediate intervention is essential.

#103 - Case Report

OLMESARTAN INDUCED ENTEROPATHY – A CAUSE FOR DIARRHEA AND MALABSORPTION

Miguel Trindade, Leonor Boavida, Joana Carvalho, João Serôdio, Catarina Favas, José Delgado Alves
Hospital Professor Fernando Fonseca, Lisboa, Portugal

Introduction

Drug-induced enteropathy has been described with azathioprine, methotrexate, colchicine and mycophenolate mofetil. Since 2012 it has recently garnered more attention with its association with olmesartan, a commonly prescribed antihypertensive medication. We describe two cases in which olmesartan was accountable for a sprue-like enteropathy.

Case description

Case 1

59 years-old-female presenting with abdominal pain, diarrhea and vomits while on olmesartan treatment for hypertension. Workup for celiac and inflammatory intestinal disease were negative. The colonoscopy showed no macroscopic lesions and the histology revealed focal loss of goblet cells, intraepithelial lymphocytosis, and mixed inflammatory infiltrate. Olmesartan as a precipitant agent was suspected and withdrawn. Follow-up at one year shows clinical remission.

Case 2

84 years-old-male presenting with diarrhea and weight loss while on olmesartan plus amlodipine and olmesartan plus hydrochlorothiazide. No evidence for celiac disease was found. Gastrointestinal endoscopy showed extensive erosive duodenopathy. Gastrin levels were normal. The histology revealed villous atrophy with intraepithelial lymphocytosis and mixed inflammatory infiltrate. Both olmesartan associations were suspended and the patient was discharged with clinical improvement. The patient mistakenly resumed his former antihypertensive medication and diarrhea recurred. Olmesartan

was permanently removed and follow-up at four months shows complete clinical remission.

Discussion

Olmесartan-induced enteropathy causes diarrhea and malabsorption. It features intestinal villous atrophy, particularly in the duodenum, intraepithelial lymphocytosis and subepithelial collagen deposition. There is no specific macroscopic finding or serology. Therefore, the diagnosis is based on clinical and/or histologic improvement after drug suspension. Since being a commonly prescribed drug in the hospital setting, this is a significant differential diagnosis in cases presenting with diarrhea, weight loss, and villous atrophy.

RIGHT PLEURAL EFFUSION AND ABDOMINAL PAIN

María Elena Mansilla Rodríguez, Joaquín González Cantón, Blanca Hidalgo Armayones, Eva Nadejda Gutierrez Cortizo, Manuel Jesús Romero Jiménez
Hospital Infanta Elena, Huelva, Spain

Clinical summary

A 75-year-old man who went to the Emergency Department for abdominal pain and dyspnea. In hepatic MRI (A) and (B) CT images of the abdomen, we can see a subcapsular hematoma coming from a bleeding metastasis as a first possibility and / or primary hepatic tumor. (C) Fine needle aspiration of one nodular lesion established the diagnosis of neuroendocrine tumor. After the autopsy, the pathological anatomy of the hepatic lesions showed abundant necrosis (D, E), evident nucleolus and abundant mitotic figures (C) and, in the stomach (F), we discovered an excretion which confirmed a gastrinoma with hepatic metastasis. Neuroendocrine tumors are presented as radiological syndromes in which the diagnosis and anatomical location of the primary tumor influences its clinical presentation and treatment.

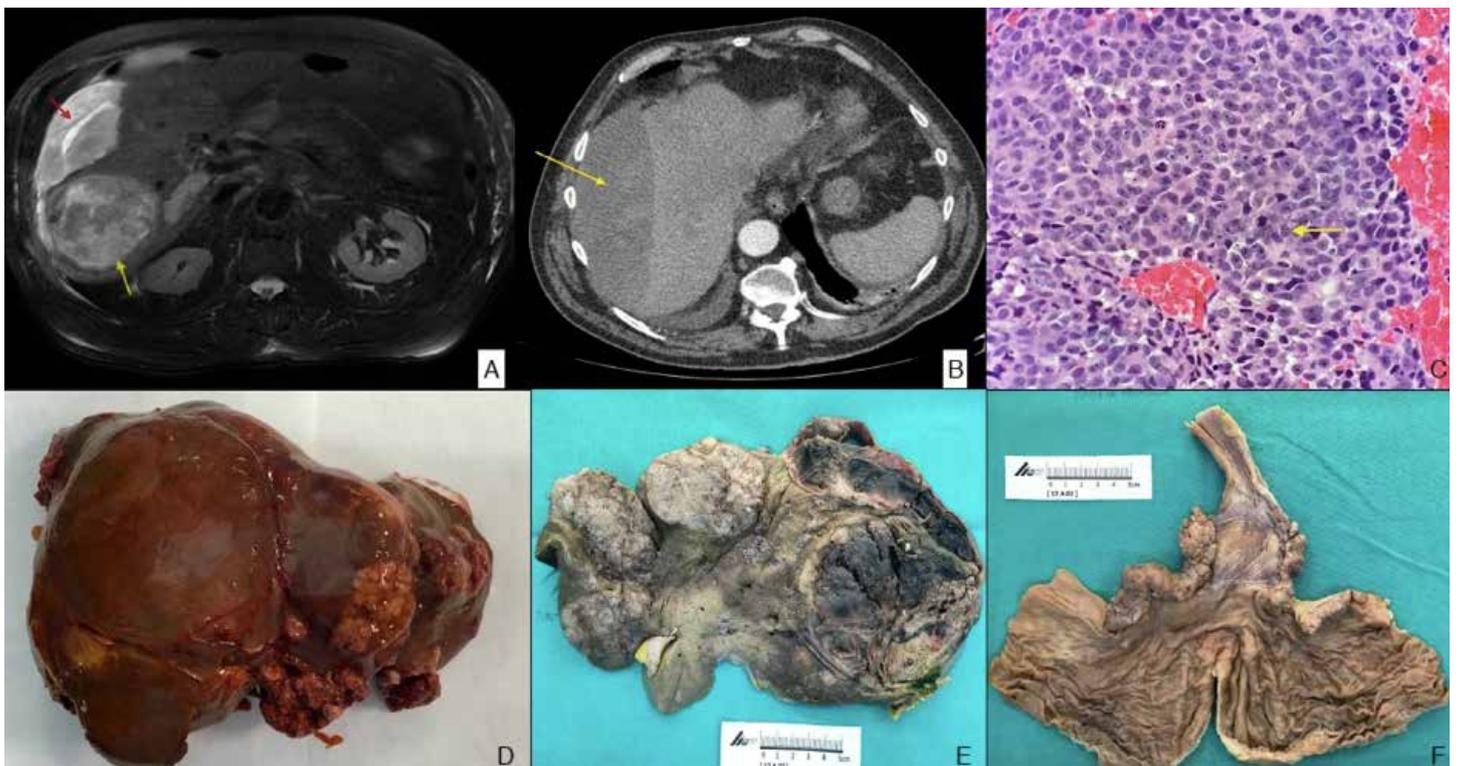

Figure #107. Autopsy neuroendocrine tumor.

#112 - Abstract

AUTOIMMUNE HEPATITIS (AIH): THE IMPACT OF AGEING ON SEVERITY, TREATMENT RESPONSE AND OUTCOME OF AUTOIMMUNE HEPATITIS (AIH)

Kalliopi Azariadis¹, Nikolaos K. Gatselis^{1,2}, Pinelopi Arvaniti¹, Vasiliki Lygoura¹, Stella Gampeta¹, Kalliopi Zachou^{1,2}, George N. Dalekos^{1,2}

¹ Department of Medicine and Research Laboratory of Internal Medicine, University Hospital of Larissa, Larissa, Greece

² Institute of Internal Medicine and Hepatology, Larissa, Greece

Background

AIH affects both sexes and all age groups. However, few studies have focused on the potential particular characteristics of AIH in older patients in terms of disease severity, response to treatment and outcome. Therefore, we investigated the baseline characteristics, treatment response and prognosis of AIH patients of ≥ 70 years

Methods

234 patients with well-established AIH prospectively followed in our center were evaluated. Treatment response was assessed in a subgroup of 202 patients.

Results

25/234 patients (10.7%) were ≥ 70 years at the time of disease onset (median 73 years) while the rest (89.3%) had a median of 47 years. The disease presentation was mainly subclinical or

insidious, similarly to the younger group (19/25, 76% vs 134/209, 64.1%, respectively, $p=0.313$). Older patients had higher levels of ALT at the time of diagnosis [199(441) vs 101(433) IU/L, $p=0.045$], but no differences were found regarding the presence of hypergammaglobulinemia and autoantibodies. Older patients were more frequently cirrhotic at diagnosis (12/25, 48% vs. 57/209, 27.3%, $p=0.032$). Importantly, similar rates of response to treatment (11/18, 61% vs. 81/184, 44%, $p=0.171$) and corticosteroid withdrawal (11/18, 61% vs 123/184, 67%, $p=0.612$) were achieved in both groups. Treatment-related adverse events were observed at the same rate between groups (6/18, 33% in older vs. 54/184, 29% in younger patients, $p=0.724$). Among treated patients ($n=202$), the age ≥ 70 -years was related only with the overall mortality [HR 11.3 (95%CI: 2.6-48.6), $p=0.001$], while liver-related mortality was similar between age-groups [HR 3.4 (95%CI: 0.4-30.0), $p=0.268$].

Conclusion

AIH should be seriously considered in older patients with unexplained impaired liver function tests as the disease is not rare in this patient group and seems to carry an increased risk for advanced disease at diagnosis. However, if immunosuppression therapy is started promptly, seems as effective and safe.

#126 - Abstract

THE CHANGING EPIDEMIOLOGY OF HEPATITIS B IN GREECE

Vasiliki Lygoura¹, Nikolaos K. Gatselis^{1,2}, Konstantinos Galanis¹, George Giannoulis¹, Stella Gabeta¹, Kalliopi Zachou^{1,2}, Eirini I. Rigopoulou^{1,2}, George N. Dalekos^{1,2}

¹ Department of Medicine and Research Laboratory of Internal Medicine, University Hospital of Larissa, Larissa, Greece

² Institute of Internal Medicine and Hepatology, Larissa, Greece

Background

Chronic hepatitis B (CHB) virus infection remains an important public health problem worldwide. However, during the last decades its epidemiology is changing due to various competing factors, such as the application of expanded vaccination programs in all newborns but also the migration of population from moderate/high to low endemicity countries. The aim of the present study was to assess trends in epidemiological and clinical characteristics of the disease during the last 20 years in the region of Thessaly, Central Greece.

Methods

1910 consecutive CHB patients (males 60.8%, mean age 42.2±15.8 years), followed in our centre during 1999-2017 were included in the analysis. At initial evaluation, 1314 (68.8%) had chronic infection (inactive carriers), 415 (21.7%) CHB, 116 (6.1%) CHB-related cirrhosis and 65 (3.4%) CHB-related hepatocellular carcinoma (HCC).

Results

1601 CHB patients were initially evaluated during the first period of 1999-2010, while the rest 309 patients evaluated for the first time during the second period (2011-2017). Patients with baseline visit at our centre during 2011-2017 were significantly older (55.1±16.1 vs 49.2±15.6 years, $p<0.001$), had longer disease duration (47±16.5 vs 41.3±15.6 years, $p<0.001$), lower BMI (26.3±3.6 vs 26.7±3.4 kg/m², $p<0.05$) and were immigrants in a significantly higher proportion (16.2% vs 8.1%, $p<0.001$) compared to those diagnosed in the previous period. Patients of the second period tended to diagnose at more advanced disease stage namely cirrhosis and/or HCC (12.3% vs 8.9%, $p=0.085$) although they characterized by lower rates of virological breakthrough (9.5% vs 45.5%, $p<0.001$), biochemical relapse during treatment (9.5% vs 43.3%, $p<0.001$), progression to cirrhosis (1.8% vs 14%, $p<0.02$) and development of HCC (5.1% vs 13.2%, $p<0.04$) compared to the patients of the first period.

Conclusion

Despite the implementation of prevention and early detection strategies during the 1999-2010 period, the proportion of CHB patients presenting at diagnosis with already established cirrhosis continues to rise. However, during the current decade the rates of relapse and disease progression to cirrhosis and HCC development in treated CHB patients seem to decline probably

because of the use of the newer potent antiviral agents which bear high barrier of resistance.

A CASE OF MESENTERIC PANNICULITIS: WHAT YOU NEED TO KNOW ABOUT IT.

Chaozer Er¹, Navin Kuthiah¹, Vanessa Hwee Ting Tey²

¹ Woodlands Health Campus, Singapore, Singapore

² Ministry of Health Holdings, Singapore, Singapore

Introduction

Mesenteric panniculitis (MP) is the inflammation of the adipose tissue of the intestinal mesentery. It is associated with abdominal trauma, surgery, infection and malignancy. Its prevalence was reported to be 0.16-2.5%. We present a case of MP associated with pancreatitis.

Case description

A 66-year-old Chinese gentleman with past medical history of diabetes mellitus, hypertension, previous pancreatitis and epilepsy, presented to us with an episode of near syncope due to hypoglycaemia. As there was raised alkaline phosphatase, he underwent an ultrasonography (US) of the abdomen. The US showed a hypoechoic lesion at the right hepatic lobe which could represent early infection. He therefore underwent a computed tomography of abdomen and pelvis (CTAP) for further evaluation. The CTAP showed no abnormality in the liver but there was incidental finding of small bowel mesenteric panniculitis (MP). Our radiologist reviewed our patient's old CTAP which was done 4 years ago. The small bowel mesenteric stranding was already present in the old scan and appeared stable in the current scan. As MP is associated with malignancy, our patient underwent upper and lower gastrointestinal endoscopy to look for neoplastic lesion. The endoscopy findings were negative of malignancy. He also underwent CT thorax which was negative of malignancy. The MP was attributed to his previous pancreatitis. He is currently on follow up with our gastroenterologist.

Discussion

MP can present as abdominal pain, fever, weight loss, diarrhoea or constipation. 10% of the patients may be asymptomatic. It is usually an incidental finding on CTAP that was done for other purposes. As it is associated with malignancy, a thorough check for malignancy should be carried out upon diagnosis of MP. Treatment options for symptomatic cases include steroid, non-steroidal anti-inflammatory drugs (NSAIDs) and immunosuppressants.

ANABOLIC STEROID-INDUCED HEPATITIS – A HIDDEN DANGER AT THE GYM

Joana Liz Pimenta, Patrícia Chow Liu, Paula Vaz Marques, Sandra Alves Morais

Centro Hospitalar de Trás-os-Montes e Alto Douro, Vila Real, Portugal

Introduction

Anabolic steroids (AS) are a cause of drug-induced hepatitis and in most cases these substances are not approved by regulatory agencies. The clinical presentation varies from mild liver enzyme elevations to fulminant hepatitis, usually within the first 3 months after consumption of AS. The medical approach is based on the suspension of the drug and supportive medical care, sometimes requiring early referral to liver transplantation.

Case description

We present a case of a 32-year-old male with no relevant past medical history, who attends the gym frequently. The patient went to the emergency department complaining of conjunctival icterus, dark yellow urine and generalized pruritus with 3 weeks of evolution. He had a history of self-administration of artificial testosterone (2,3-epithio-17 α -methyl-17 β -hydroxy-5 α -androstane) in the previous 2 months. On physical examination the patient had jaundice and blood tests showed liver dysfunction with conjugated hyperbilirubinemia [total bilirubin (BT) of 9.4 mg/dL and direct bilirubin (DB) of 9 mg/dL] and mixed dyslipidemia. Abdominal CT showed hepatomegaly, without focal lesions or biliary ducts dilatation. HBV, HCV, HAV, HEV, HIV, CMV, EBV, Herpes simplex, Syphilis and Rickettsioses were excluded. ANA, AMA, SMA, SLA, LC1, anti-actin Ab, ceruloplasmin and copper were negative. It was assumed anabolic steroid-induced hepatitis. Supportive medical care and 40mg of prednisolone daily was provided. At first, the patient presented worsening of the hepatic parameters (TB of 26 mg/dL and DB of 21 mg/dL), without neurological consequences or hemodynamic instability. A pretransplantation study was carried out concomitantly. Liver biopsy revealed discrete lesions of canalicular cholestasis, compatible with hepatitis in resolution. Given the clinical stability, close patient monitoring and symptomatic control were decided. The patient presented progressive clinical and analytical improvements until a complete resolution.

Discussion

AS are often misused by professional and amateur athletes as a way to improve physical performance and muscle mass. The presence of the 17 α -alkylated group showed an increased risk of hepatotoxicity, since the substitution of the 17 α -alkyl group was shown to delay the hepatic metabolism of AS. Cholestatic hepatitis, hepatocellular carcinoma or hepatic adenoma are some of the adverse effects related to this group. Information about the risks of these drugs becomes urgent and their use should be discouraged by health professionals.

A DIVIDED PANCREAS

Cristina Martins, Pedro Ribeiro, Armando Carvalho

Centro Hospitalar e Universitário de Coimbra - Hospital Geral, Coimbra, Portugal

Introduction

Acute pancreatitis (AP) is one of the most common pathologies of the digestive tract. It has several causes, being biliary lithiasis the most frequent. Even though there has been a decrease in the associated morbidity and mortality, there are still various cases of severe AP, which reflect the need for a correct initial assessment of its severity.

Case description

A 76 years old woman, previously cholecystectomised in the setting of lithiasis, presents to the Emergency Room complaining of abdominal pain, dyspnea and vomiting, with 24 hours evolution. Abdominal pain was constant, severe, localized to the upper abdominal quadrant and irradiating to the back. On admission she was anicteric, her abdomen was painful on the upper quadrant but without signs of peritoneal irritation, and she showed signs of shock and SIRS. Blood tests showed a conjugated hyperbilirubinemia and elevated liver enzymes, amylase and lipase (4763 UI/L). Ultrasonography (US) identified a dilated common bile duct and extrahepatic ducts. A diagnosis of AP was assumed and an abdominal CT performed, showing a normal pancreas but with a thickening of the adjacent duodenal loop, and dilated intra and extrahepatic ducts, with a common bile duct of 1.3 cm of higher caliber. The patient was admitted for treatment and etiological study of this AP, since the exams were suggestive of an obstructive cause, being the patients already cholecystectomised. A MRCP was performed revealing no alterations except for signs of a classic pancreas divisum, with a main pancreatic duct draining to the minor duodenal papilla. A final diagnosis of AP caused by microlithiasis (non-visible on the US and CT, and responsible for the biliary ducts distention), that was deeply aggravated by the presence of a pancreas divisum, was finally assumed. After 9 days of hospitalization, the patient was discharged, with normal blood tests, and oriented to a Gastroenterology consult.

Discussion

Pancreas divisum is an anatomical variant in which the usual fusion of the dorsal and ventral pancreatic ducts with formation of Wirsung doesn't occur, there being instead two independent channels, a condition that predisposes to the development of AP, since pancreatic drainage happens to occur mostly by the minor papilla. It is estimated that 10% of the world population have this variant. The described case is interesting since, even though microlithiasis is the primary cause of the AP, the presence of a pancreas divisum certainly contributed to its greater severity.

HORSE CHESTNUT DIETARY SUPPLEMENT INDUCED LIVER INJURY

Diogo Costa Santos, Graça Lérias, Isabel Madruga

Hospital de Egas Moniz - Centro Hospitalar Lisboa Ocidental, Lisbon, Portugal

Introduction

Natural dietary supplements widely available to the general population have increased in popularity throughout the last years. Few case reports associate these products with liver injury. Horse Chestnut supplements are commercialized for usage in peripheral vein disease.

Case description

A 70 year old male with hypertension and allergic rhinitis, medicated with irbesartan+hydrochlorothiazide and desloratadine, recently started an echinacea based dietary supplement. One week before admission the patient reported flu symptoms resolved with paracetamol 500 mg 8/8h taken for 2 days, prompting suspension of his dietary supplement. The patient was admitted for conjunctival icterus, white stool and choluria developed over 3 days. There was no history of adverse effects. Upon examination: icteric skin and sclera; no lymphadenopathies and abdominal palpation with no pain or palpable masses; AST 275 U/L; ALT 550 U/L; ALP 348 U/L; GGT 1451 U/L; total bilirubin 11.2 mg/dL; direct bilirubin 8.23 mg/dL; Lipase 37 U/L; no findings on abdominal ultrasound. Hepatic and cholestatic enzymes continued to rise with total bilirubin reaching 22 mg/dL. A self-limited generalized erythematous and punctiform rash including palms and soles developed. Metabolic, auto-immune and infectious causes were discarded by additional testing, including magnetic resonance cholangiopancreatography and upper endoscopic ultrasound. Due to the absence of hepatotoxicity reports regarding previously known medication, including echinacea, both the patient and his family were extensively inquired on several occasions about additional drug history, until the patient's wife remembered that other than the echinacea based supplement, an horse chestnut supplement was started one month prior and suspended a week before admission. After reviewing compatible literature, a diagnosis of drug induced liver injury due to horse chestnut dietary supplement was established. Soon after hepatic and cholestatic enzymes values progressively decreased with icterus, stool and urine resolution. Laboratory values reached normal values several weeks after the patient was discharged, during follow-up.

Discussion

Drug induced liver injury due to a horse chestnut dietary supplement is a benign self-limited rare idiosyncratic drug reaction apparent between 4 to 8 weeks after taking a single dose. A suspicion of drug induced hepatotoxicity caused requires an accurate drug history, including dietary supplements, considering their increasing popularity.

SEVERE AND UNEXPECTED SILENT COAGULOPATHYLuis Ramos Santos¹, Vítor Magno Pereira², Manuela Lélis¹, Maria Da Luz Brazão¹¹ Internal Medicine Department, Hospital Central do Funchal, Funchal, Portugal² Gastroenterology Department, Hospital Central do Funchal, Funchal, Portugal**Introduction**

Abnormal coagulation test results with or without symptoms warrant investigation for underlying acquired or congenital bleeding disorder. Personal and family history and thorough physical examination are crucial. With increasing age, acquired and systemic diseases are the most likely etiologies.

Case description

62 year-old man observed in the emergency room with complaints of loose stools for a week, with no blood or fever. He recalled unspecified weight loss. Physical examination was normal. Prior history was unremarkable. He denied easy bruising or visible blood losses. Blood tests: leukocyte count of 6.1×10^3 , hemoglobin of 13 g/dL, a severely prolonged PT of 149.5s (double checked on different samples), sodium 138 mEq/L, potassium 3.2 mEq/L, normal renal and liver tests and C-reactive protein of 100 mg/dL. Ciprofloxacin was started and patient was admitted with provisional diagnosis of acute enteritis and prolonged PT for study. On admission: patient reported four floating loose stools a day for a month, and loss of 3kg with no fever. He reported having a "weak bowel" for years but did not value or correlate with any particular ingestions. Patient's parents were first-degree cousins and patient was married to a first-degree cousin as well. He had a sister and two first degree cousins with Celiac Disease (CD). With clinical suspicion of malabsorption syndrome further studies were ordered: albumin 21.5 g/dL, corrected calcium 8.8 mg/dL, phosphorus 1.88 mg/dL, normal thyroid function, ferritin 210 ng/mL, folic acid 0.82 ng/mL, cyanocobalamin 248 pg/mL, parathyroid hormone (PTH) 84.8 pg/mL, total vitamin D 9 ng/mL. This supported the diagnosis of malabsorption of liposoluble vitamins and proximally absorbed elements. Replacement was initiated including vitamin K with normalization of PT. Anti-tissue transglutaminase IgA tested positive. Upper endoscopy had no macroscopic changes. Duodenal biopsies showed partial villous atrophy, without increased intraepithelial lymphocytes and mild inflammatory infiltrate of the corion. Gluten-free diet was started. Follow-up visit at 1 month showed symptom and weight improvement, normal PT and almost complete resolution of PTH.

Discussion

Malabsorption can cause vitamin-K deficiency, and in this patient led to severe silent coagulopathy. This case illustrates the multitude of clinical and analytic findings of CD. Most atypical cases occur with increasing age so a high level of suspicion must be maintained to ascertain the diagnosis.

GIANT MESENTERIC CYST - THE DIAGNOSTIC CHALLENGE

Inês Soler Bargiela, Maria João Gomes, Ana Sofia Ventura
Hospital Prof. Doutor Fernando Fonseca, Lisboa, Portugal

Clinical summary

We present a case of a 70-year-old female patient, who was admitted for abdominal volume increase, corresponding to exuberant ascites, having performed paracentesis with increased serum albumin gradient and positive malignant cell. CT scans revealed a significant abdominal mass of about 100x100 mm suggestive of mesenteric cyst, located at the mesenteric root, and peritoneal secondary implants. After an extensive etiological investigation that culminated in diagnostic laparotomy, a high-grade serous carcinoma was diagnosed in the uterine isthmus, with invasion of the left ovary and mesenteric cyst, which histologically corresponded to hemorrhagic cyst with associated peritoneal carcinomatosis. Mesenteric cysts are rare abdominal tumors, with malignant degeneration occurring in 3% of cases.

#211 - Abstract

THE EFFICACY OF ANTI-TNFA THERAPY IS BETTER FOR STEROIDS NAÏVE PATIENTS WITH ULCERATIVE COLITIS

Tatsuya Toyokawa, Isao Fujita, Joichiro Horii
National Hospital Organization Fukuyama Medical Center, Fukuyama,
Japan

Background

Although anti-TNF α therapy is known to be effective in the treatment of ulcerative colitis, there are few reports on who would benefit most from the therapy, when they should be prescribed and how anti-TNF α drugs should be used.

Methods

We enrolled 51 patients with ulcerative colitis undergoing treatment with anti-TNF α for over 6 months. We analysed efficacy, clinical backgrounds, therapeutic histories and laboratory data of the patients.

Results

We examined 51 patients included (30 males and 21 females) with the median age of 42 (range, 13-88) years. There were 25 total-colitis-type patients, 21 left-sided-colitis-type and 5 proctitis-type. 5-aminosalicylic acid drugs were prescribed for all patients, 32 patients received steroids, 9 had previous steroids therapy and 10 never had steroids therapy. Immuno-modulator agents were prescribed for 26 patients, calcineurin inhibitors for one and granulocyte apheresis therapy for 9. Regarding severity, 39 patients were moderate and 12 were severe. Infliximab was prescribed for 26 patients and adalimumab for 25 cases as the first anti-TNF α drug. The mean duration time from onset of disease to the prescription of anti-TNF α drug was 70 (range, 2-296) months. The mean white blood count was 9000 μ /ml, mean hemoglobin 11.6 g/dl, mean albumin 3.5 g/dl and mean C-reacting protein 1.75 mg/dl. With regard to endoscopic Mayo score, 18 patients were grade 2 and 33 were grade 3. Treatment was complete effective in 24 patients, effective (not complete) in 11 and not effective in 16. Four received surgery after anti-TNF α treatment because of disease progression.

Thereafter, we classified the patients into two groups: SN group (steroids naïve patients) and S group (patients with current or past steroids therapy). The frequencies of completely effective or effective in the SN group were significantly higher than in S group (SN group: complete effective, 8 patients, effective, 0 and not effective, 2; S group: complete effective, 16 patients, effective, 11 and not effective, 14; $p = 0.048$). There were significant differences in disease type and duration time from onset to the prescription of anti-TNF α drug; however, there were no differences in other factors, including disease activity and endoscopic findings between the two groups.

Conclusion

The efficacy of anti-TNF α therapy is better for steroids naïve patients with ulcerative colitis. This findings of this study can help in the development of an efficient therapeutic strategy against ulcerative colitis.

CROHN'S DISEASE PRESENTING AS ACUTE ABDOMEN: CASE REPORT

Martim Baltazar Alçada¹, Guilherme Violante Cunha¹, Marina Boticario¹, Rita Aranha², Aluixa Lozada¹, Catarina Ivanova¹, Maria Filomena Roque¹

¹ Hospital de Santarém EPE, Santarém, Portugal

² Faculdade de Medicina Lisboa, Lisboa, Portugal

Introduction

Crohn's disease (CD) is an immune-mediated disease characterized by transmural inflammation of the bowel wall, and is often complicated by fistula formation, bowel perforation and abscess. Abdominopelvic (AP) abscess occurs in 10–30% of the patients with CD in the Western countries and can affect the peritoneum (including the pelvis) and retroperitoneum such as psoas abscesses

Case description

A 18-year-old female was admitted in our hospital with a history of pain in the right lower abdominal quadrant, distension, fever and vomiting for the last 2 days. She had no past history of weakness, anorexia, or diarrhea. Abdominal examination revealed the features of acute abdomen. A abdominal ultrasound was suggestive of ileal inflammatory disease. She was admitted and antibiotic was performed. A CT scan showed non-specific terminal ileal transmural thickening and an adjacent 4 cm mesenteric mass.

Discussion

Intra-abdominal abscess formation affects up to one third of patient's with CD. A mixture of aerobic and anaerobic organisms can be found in these abscesses. Treatment involves bowel rest, analgesia, antibiotics, percutaneous and/ or surgical drainage. Immuno suppressants should be held until the abscess is completely drained and infection controlled. Although symptoms of CD mimic many other abdominal conditions but it should be kept in back of mind as one of the causes of acute abdomen. A colonoscopy with biopsy confirmed CD. She had a successful management after 21 days of therapy with metronidazol plus piperacilin/tazobactam. She was discharged to the outpatient inflammatory bowel disease.

#232 - Abstract

ANALYSIS OF HSD17B13: TA ALLELIC VARIANT AS A PUTATIVE PROTECTIVE FACTOR TOWARDS HCC IN PATIENTS WITH AND WITHOUT CHRONIC HEPATITIS C

Martina Fazio¹, Carla De Benedittis¹, Michela Emma Burlone², Matteo Nazzareno Barbaglia¹, Rosalba Minisini¹, Mario Pirisi¹

¹ Università del Piemonte Orientale, Translational Medicine, Novara, Italy

² AOU Maggiore della Carità, Medicina Interna, Novara, Italy

Background

The PNPLA3 single nucleotide polymorphism rs738409 (C > G) is a major genetic factor for steatosis, fibrosis progression and hepatocellular carcinoma (HCC). In fact, carriers of the G allele with chronic liver disease are more likely to progress to cirrhosis and HCC, especially when affected by alcoholic or non-alcoholic fatty liver disease (NAFLD). However, these same patients have been shown to be relatively protected against developing cirrhosis

by carriage of the HSD17B13:TA variant (rs72613567)(Abul-Husn NS et al. N Engl J Med. 2018;378:1096-106). Since cirrhosis is by far the strongest risk factor for HCC, it is conceivable that such protection might extend to HCC. We aimed to verify this hypothesis.

Methods

The study population included N=728 patients, among whom N=246 had a diagnosis of HCC (Group 1; 135 with hepatitis C virus infection, HCV, 55%); N=180 HCV infected patients (Group 2) and 302 NAFLD (Group 3) patients had chronic liver disease with and without advanced fibrosis/cirrhosis, not complicated by HCC. Restriction fragment length polymorphism analysis was performed to determine the allelic variants frequency of PNPLA3 and HSD17B13.

Results

The PNPLA3:G frequencies were 0.40, 0.31 and 0.32 for Group 1, Group 2 and Group 3, respectively (p=0.004). The HSD17B13:TA frequencies were 0.21, 0.28 and 0.16 for Group 1, Group 2 and Group 3, respectively (p<0.001). The figure shows the distribution of PNPLA3 genotype frequencies, according to the presence or absence of HCC and HSD17B13 status. By considering only the subgroup of patients negative for HCV (N=416/728, 57%), similar results were observed: based on PNPLA3 genotype, patients with HCC were 22/118 (19%) vs. 10/55 (18%) (C/C), 35/131 (27%) vs. 21/55 (38%) (C/G), and 20/45 (44%) vs. 6/12 (50%) (G/G), among HSD17B13 wild-type (p=0.002) vs. HSD17B13 variant carriers (p=0.006), respectively.

Conclusion

The HSD17B13:TA allelic variant does not appear to decrease appreciably the risk of developing HCC conferred by carriage of the PNPLA3:G allele, neither among HCV positive nor among HCV-negative patients.

#261 - Case Report

MANAGEMENT OF A MASSIVE PLEURAL EFFUSION FOLLOWING ACUTE PANCREATITIS

Florence Dutertre, Nicolas Garin, Domenico Galasso, Riadh Ksontini

HRC Monthey, Monthey, Switzerland

Introduction

Peripancreatic collections are common following acute pancreatitis. Pleural effusions are a less frequent but potentially life-threatening complication of the disease.

Case description

A 57-years old man was referred for dyspnea. Past medical history was notable for acute pancreatitis two months ago, complicated by a left-sided pleural effusion, which resolved after temporary chest tube drainage.

At admission, the patient was afebrile, hemodynamically instable, and in respiratory distress. There were dullness on percussion on the left hemithorax. Ultrasonography confirmed a massive pleural effusion. After chest tube insertion, 2000 ml of a fluid rich in lipase (140,000 U/L) were evacuated. A cholangio-MRI showed a fluid collection of the pancreatic tail, extending in the left pleura. Endoscopic ultrasonography confirmed the presence of a 13x4 cm fluid collection with partially solid content, characteristic of a walled-off necrosis (WON). During the procedure, a lumen-apposing metal stent was inserted through the stomach wall and allowed for rapid evacuation of the collection. A percutaneous gastrostomy was placed to facilitate drainage of the collection, and a nasoduodenal tube was inserted, allowing feeding of the patient while avoiding penetration of nutrients in the cavity. The patient was discharged home after 14 days. Three months later, he was in good clinical condition, with a weight gain of 3 kgs. A repeat cholangio-MRI confirmed the resolution of the WON. The stent and percutaneous gastrostomy were removed.

Discussion

Peripancreatic collections require drainage when they exert local compression or become infected. When feasible, endoscopic management is preferred over surgery.

Pancreaticopleural fistula is a rare complication following disruption of the main pancreatic duct. It manifests as a recurrent, mainly left-sided, pleural effusion, secondary to a retroperitoneal fistula tract extending through the diaphragmatic hiatus into the pleural space.

Endoscopic management requires evacuation of necrosis and exocrine secretion in the digestive tract through implantation of transmural stents under endoscopic and fluoroscopic guidance. A physiologic drainage of pancreatic secretions can also be restored through transpapillary stenting of the main pancreatic duct.

Finally, patients with acute or chronic pancreatitis have associated multifactorial malnutrition and need specialized nutritional support, preferably via the enteral route.

#267 - Case Report

CHRONIC HEPATIC DISEASE WITH SHORT TIME OF DEVELOPMENT

Rodrigo Rufino¹, Catarina Carvalho¹, Alexandra Albuquerque¹, Fátima Campante²

¹ Centro Hospitalar Barreiro-Montijo, Barreiro, Portugal

² Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Introduction

Autoimmune Hepatic Disease is a chronic inflammatory disease of the liver characterized by circulating autoantibodies, the most common are Anti-Nuclear antibodies (ANA), and elevated serum globulins. This disease is prevalent in women of any age and ethnicity. Clinical manifestations vary from asymptomatic to jaundice, ascites and splenomegaly, signals suggestive of cirrhosis or hepatic failure.

Case description

A 73 year old woman with a personal history of Gastroesophageal Reflux and Cholecystectomy due to Vesicular Lithiasis, was referred to an Internal Medicine Consultation due to dyspepsia and cutaneous pruritus, without jaundice, nausea or vomiting. She had elevation of aspartate aminotransferase (AST) 109, alanine aminotransferase (ALT) 95, gammaglutamyltranspeptidase (GGT) 95 and alkaline phosphatase (AF) 120. Total (BT) and direct (BD) bilirubin, serologies and abdominal ultrasound (ABUS) were normal. An analytical reevaluation with autoimmunity markers was requested and a follow-up consultation scheduled. The analyzes showed similar changes, with alpha-fetoprotein (AFP) 5.7, positive ANA and negative anti-mitochondrial antibodies.

After 3 months (before her next appointment), the patient is sent to the Emergency Department by her Family Doctor due to jaundice, associated with several months of anorexia and weight loss. Analytically with BT 15.1, BD 10.7, AST 695 and FA 669. Abdominal and pelvic computed tomography showed a small liver with bossy contours and a grossly structure and mild pelvic and peri-hepatic ascites. In this context, the patient was hospitalized and started treatment with ursodeoxycholic acid.

During hospitalization studies showed AFP 11.1, ANA 3.2, protein electrophoresis with gama elevation 21.5% and ABUS with liver of cirrhotic conformation with right lobe atrophy, bosselated contours, heterogeneous ecostructure by diffuse nodularity and peri-hepatic and peri-splenic ascites. Given these findings and the patients' worsening condition, a liver biopsy was attempted without success, opting to perform an evacuating paracentesis, with ascitic fluid without analytic changes. At this point, corticotherapy was initiated with improvement on discharge date. Currently, the patient is performing corticosteroid withdrawal and continues etiologic study in Hepatology Consultation.

Discussion

This case shows how a similar clinical phenotype can have different etiologies and evolution times, therefore it's important to be alert to not so frequent differential diagnosis.

#276 - Abstract

CORRELATIONS BETWEEN SERUM CREATININE, COCKROFT FORMULA AND DIRECT MEASUREMENT OF GLOMERULAR FILTRATION RATE TO LIVER TRANSPLANTATION

Marilena Stoian

Carol Davila University Of Medicine Bucharest, Bucharest, Romania

Background

Frequent impaired renal functions have a significant impact on early mortality risk, to patients with end-stage cirrhosis. Serum creatinine is one of 3 components of MELD score; however, patients with end stage cirrhosis frequently have muscular atrophy and water retention, which represent significant bias for

the interpretation of indirect markers of renal function. GFR is likely to be under or overestimated by these indirect markers.

Aims

To compare indirect markers of renal functions (SCr, Cockcroft formula and MDRD formula) to direct measurement of GFR in a population of cirrhotic patients listed for liver transplantation (LT).

Methods

91 candidates for LT (67 males, 24 females; mean age: 52 years) were studied. The cause of cirrhosis was alcohol in 48%, HBV in 11%, HCV in 27% and miscellaneous in 14%; 29% had hepatocellular carcinoma (HCC). All patients had direct measurement of GFR; mean MELD score in those without HCC was 17.

Results

SCr and calculated creatinine clearance according to Cockcroft formula were poorly correlated to measured GFR (R² of 0.3 and 0.4, respectively). Cockcroft formula overestimated creatinine clearance compared to direct measurement with a mean difference of 29±37 mL/min ($p < 0.001$). In 47% patients, there was a 30% or more overestimation of GFR with Cockcroft formula. Multivariate analysis showed that independent predictive factors for a 30% or more overestimation of GFR were low prothrombin index, young age and ascites ($p < 0.05$ for all). There was also a relatively poor correlation between calculated GFR using MDRD formula and direct measurement (R² of 0.5). In 24% patients there was a 30

Conclusion

SCr and calculated clearance using Cockcroft or MDRD formula are inaccurate markers of GFR in cirrhotic patients waiting for age, low prothrombin index (or increased INR) and ascites are significant risk factors for overestimation. Since renal function is crucial prognostic factor in cirrhotic patients, prognostic studies using measured GFR as a reference rather than SCr might help improve the performance of MELD score.

#315 - Abstract

CLINICAL PARTICULARITIES OF PORTAL VEIN THROMBOSIS IN ELDERLY PATIENTS

Doina Georgescu, Norina Basa, Mihaela Muntean, Oana Elena Ancusa, Daniel Lighezan

V Babes University of Medicine and Pharmacy, Timisoara, Romania

Background

Portal vein thrombosis (PVT) due to its diverse etiology and various clinical forms of presentation could sometimes be challenging even for experienced clinicians.

Methods

We conducted an observational study in 50 consecutive patients diagnosed with PVT, assigned into two groups, as matched pairs: 25 equally or over 65 years and 25 under 65 years. Clinical

examination, laboratory works - up, upper and lower digestive endoscopies, abdominal Duplex ultrasound, as well as CT and MRI were performed

Results

Older patients displayed significant differences concerning lower albumin level, liver malignancies and longer hospitalization, whereas comparison group showed significant differences related to admission as emergencies, digestive bleeding, abdominal pain, anticoagulant treatment (ACT) and underlying hematological diseases. No significant differences were recorded with regard to PVT severity, outcome and in hospital death. In older group we noted no correlation of outcome vs. age ($r = 0,0772$) and hospitalization length ($r = 0,03$), low correlation to albumin ($r = -0,1744$), digestive bleeding ($r = 0,1676$), ACT ($r = 0,2159$), PVT severity ($r = 0,2295$) and medium correlations to total bilirubinemia ($r = 0,2996$), emergency status at admission ($r = 0,3121$) and abdominal pain ($r = 0,3343$).

Conclusion

PVT in elderly was generally non occlusive, with good short-term outcome, mitigated symptoms, main causes being end stage liver conditions and liver malignancies. Short-term outcome in elderly was not related to age over 65 years per se, PVT severity or longer hospitalization, but more to emergency status at admission, abdominal pain and plasma total bilirubin. Causes of inpatient death in both groups were not associated to PVT severity, but to fatal cardio-vascular events.

WHEN ALCOHOL IS NOT THE ONLY GUILTY

Joel Pinto, Paulo Almeida, Fani Ribeiro, Flávio Godinho, Daniela Meireles, Susana Cavadas

Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

Introduction

The primary biliary cholangitis (PBC) is a rare autoimmune disease characterized by the destruction of the intralobular bile ducts. It manifests itself by signs of cholestasis, progressing to liver failure. Its cause is unknown, having genetic and environmental factors involved.

Case description

A 48-year-old man, with a history of chronic alcoholism, chronic liver disease (CLD), and chronic pancreatitis (CP), submitted to an endoscopic retrograde cholangiopancreatography (CP) 6 years before with placement of a temporary biliary prosthesis (BP), subsequently abandoning follow-up.

He was referred to the emergency department for uncontrollable vomiting and epigastric pain since the day before. He presented himself with icteric skin, soft abdomen, without fever or other changes in the physical examination. Blood tests revealed macrocytosis, thrombocytopenia (platelets $73 \times 10^9/L$),

international normalized ratio of 2.6, Aspartate transaminase 136 U/L, Alanine transaminase 31 U/L, Gamma-glutamyltransferase 318 U/L, Alkaline phosphatase 280 U/L, Total, Direct and Indirect bilirubin of 11.68, 6.07 and 5.61 mg/dL, respectively and without elevation of inflammatory markers. Abdominal ultrasound revealed diffuse hepatic steatosis, heterogeneous echo texture compatible with CLD, intrahepatic and extrahepatic bile ducts dilatation, without peritoneal effusion. He was presumed to have alcoholic hepatitis, with Maddrey score 71.9, being hospitalized under steroid therapy.

He presented a progressive reduction of cholestasis markers. The etiological study of CLD was extended, showing an increase in immunoglobulins M (282 mg/dL) and G (2600 mg/dL). Serologies for human immunodeficiency virus, A, B, C and E hepatitis were negative, as well as for Cytomegalovirus, Epstein-Barr virus, Herpes simplex 1 and 2. Antibody tests, including anti-mitochondrial antibodies (AMA) were all negative with exception for anti-Sp100 and anti-Ro52, which were positive. A magnetic resonance CP revealed changes compatible with CP and dilatation of intrahepatic biliary ducts. Previous implanted BP wasn't found. Liver biopsy was done and histological evaluation revealed chronic cholestatic syndrome compatible with PBC in cirrhotic stage. He was discharged medicated with ursodeoxycholic acid.

Discussion

With this case, authors emphasize the need of excluding other etiologies for CLD that can overlap with alcohol abuse. Absence of positive AMA does not exclude the diagnosis of PBC, since these may be absent in up to 5% of cases.

A CURIOUS LIVER ABSCESS

Filipa Coroado Ferreira, João Paulo Vilas-Boas, Ines Pinheiro, Érica Ferreira, Clarinda Neves, Rosa Jorge
Centro Hospitalar do Baixo-Vouga, Aveiro, Portugal

Introduction

Liver abscesses are the most common type of visceral abscesses. Risk factors include diabetes mellitus, underlying hepatobiliary or pancreatic disease, liver transplant and regular use of proton-pump inhibitors. *K. pneumoniae* is a frequent pathogen and several studies have suggested an association with underlying colorectal cancer. It relates to portal vein pyemia, direct spread from biliary infection, surgical or penetrating wounds or from hematogenous seeding. Treatment usually includes drainage and antibiotic therapy.

Case description

A 78-year-old man recurred to the Emergency Department due to head injury, non-preferential gait imbalance and disorientation over the previous 2 days. He had dementia nevertheless, treated with donepezilo 10 mg od. He was feverish, tachycardic, hypotensive – severe sepsis. He had normocytic, normochromic

anemia, lymphopenia and thrombocytopenia, acute kidney injury, hepatic citolysis and elevated reactive C protein and procalcitonin. Cranioencephalic CT showed no traumatic or vascular lesions. Cerebrospinal fluid, urinalysis and chest X-ray had no suggestion of infection. Two blood cultures were performed and antibiotic therapy was started empirically with ceftriaxone 1g 12/12h. Abdominal ultrasound showed echogenic nodular lesion of 57mm diameter, requiring CT study. Because of maintenance of daily fever and elevation of inflammatory parameters, antibiotic therapy was altered to piperacillin/tazobactam 6/6h. The thoracoabdominopelvic CT was made and revealed an heterogeneous oval formation of the right hepatic lobe, with heterogeneous enhancement after IV contrast, with several liquid hypodense loci, surrounded by a capillary wall, with 80x68mm dimension, admitting the diagnosis of multiloculated hepatic abscess. No agent was identified on blood cultures. He evolved with clinical and analytical improvement with antibiotic therapy and no drainage was performed. After 4 weeks on piperacillin/tazobactam, antibiotherapy was altered to amoxicillin + clavulanic acid per os. A colonoscopy was performed, he had no alterations.

Discussion

The authors highlight this case for the unusual diagnosis and the lack of risk factors described by the literature for this pathology. There are few cases described with good resolution only with medical treatment, so the presentation of this case becomes relevant.

#394 - Abstract

CHRONIC LIVER DISEASE AND DIRECT ORAL ANTICOAGULANTS

Joana Arana Ribeiro, Andreia Póvoa Vicente, Tiago Silva, David Rabiço Costa, Lurie Pantazi, Rita Gomes
Unidade Local de Saúde da Guarda, Guarda, Portugal

Background

The management of anticoagulation therapy in Chronic Liver Disease (CLD) is challenging. The haemostasis and fibrinolysis are changed, due to alterations in production of anti/procoagulation factors, predisposing to haemorrhagic and thrombotic events. Furthermore, the liver metabolism of anticoagulants is modified, leading it to unpredictable levels.

The Direct Oral Anticoagulants (DOAC) are attractive in CLD, although phase 3 trials excluded CLD patients. The current usage is based on small studies.

The aim of this study is report the experience of an hospital with CLD patient taking DOAC, including haemorrhagic events and predictor of bleeding.

Methods

We reviewed clinical processes of Consultations in Liver Diseases and we identified and followed up the ones taking DOAC. CLD was defined based on history and/or evidence of

Chronic Liver Dysfunction visible through ultrasound providing by hepatomegaly and/or persistent abnormalities in liver test for more than 6 months. We registered age, sex, Charlson Index, CLD aetiology, haemorrhagic events, esophageal varices, INR, platelet count and antiaggregation therapy.

To test association between independent variables and haemorrhagic events, Cox regression analysis was performed.

Results

Of the 18 patients identified, the mean age was 68 year (SD 10.3), 13 (72.2%) were males and the Charlson Index mean was 5.5 (SD 2.1), corresponding 26% estimate 10 years survival. The most prevalent CLD aetiology was alcohol (15, 83.3%), followed by nonalcoholic steatohepatitis (1, 5.6%) and primary biliary cholangitis (1, 5.6%). they were taking dabigatran (6, 33.3%), apixaban (6, 33.3%), rivaroxaban (4, 22.2%) and edoxaban (2, 11.1%). The indications for DOAC were atrial fibrillation (11, 61.1%), portal vein thrombosis (2, 11.1%), pulmonary thrombosis (2, 11.1%) and renal artery thrombosis (1, 5.6%).

33.3% (n 6) of the patient had 1 or more bleeding episode that motivated a medical assist, at mean 20.8 (SD 20.8) months of DOACs. 2 of them were clinically relevant, both gastrointestinal with need for transfusions. We didn't register major bleedings.

There's no significant statistical predictors to bleeding events, namely DOAC type, time of anticoagulation, Charlson Index, esophageal varices, INR, platelet count and antiaggregation.

Conclusion

The current utilization of DOACs in CLD must be careful due to the unpredictability of these drugs in those patients, even if the major bleeding events seems to be low. Larger and robust studies are still needed.

DIGITAL CLUBBING

Joana Arana Ribeiro, David Rabiço Costa, Iurie Pantazi, Rita Gomes
Unidade Local de Saúde da Guarda, Guarda, Portugal

Clinical summary

The digital clubbing is one of the oldest clinical signs in medicine. It's characterized by enlargement of terminal fingers/toes segments and loss of normal 160° angle between nail and nail bed, caused by the proliferation of connective tissues between nail matrix and distal phalange.

The pathogenesis is unclear, but it's acceptable that platelet clusters in digital vasculature, enhanced by hypoxia, release PDGF and VEGF that induce angiogenesis and proliferation of fibroblasts and osteoblasts.

This sign often reflects a serious condition. Most commonly pulmonary diseases (90%), although it may be present in cardiac, gastrointestinal or endocrine disease.

These feet belong to a 51-year-old man with history of alcoholic cirrhosis hospitalized with diagnosis of portal vein thrombosis.

Figure #398.

ACUTE HEPATITIS AT YOUNG AGES, A DIFFERENTIAL DIAGNOSIS

Joana Sousa Morais, Ana Andrade Oliveira, Olga Pires, Inês Burmester, Maria João Regadas, Paulo Gouveia
Hospital de Braga, Braga, Portugal

Introduction

Hepatitis is a disease that can manifest in several ways, the most common being jaundice and abdominal pain. The most common causes are infectious, however, especially in young patients, toxicity and immune diseases should also be taken into account. Some drugs can lead to the development of immune disease, called idiosyncratic reactions, especially when they are episodes of acute repeat disease.

Case description

A 30-year-old woman with a history of autoimmune thyroiditis and hospitalization 7 years ago, due to acute hepatitis, whose etiological study was inconclusive. Was referred to the emergency department for jaundice with two days of evolution, with no other complaints. She said she had been taking minocycline for a month, but stopped a week ago. In the complementary diagnostic exams, an increase in transaminases (alaninotransferase (ALT) - 1756U / L and aminotransferase (AST) - 1421 U/I), bilirubin at the direct cost (Total Bilirubin - 7.68 mg/dL), Alkaline Phosphatase - 208 U/L) and LDH (424 U/L). During hospitalization, the patient remained clinically stable, with jaundice at the objective examination, but no other alterations, and analytically with increase of bilirubin values reaching maximum values of 10 mg/dL, but stability of transaminases, AF and LDH in similar, without hepatic dysfunction or thrombocytopenia. From the rest study request to point out, serology and immunological study negative and normal imaging studies. However, at the end of one week of hospitalization, due to maintaining clinical picture and analytical aggravation, it was opted to initiate acetylsysteine (600 mg, 2x/day) and since then

with clinical and analytical improvement. With bilirubin values below 5 mg/dl, hepatic biopsy was performed and the patient was discharged for reassessment in consultation. In consultation, patient without jaundice, analytically bilirubin and transaminases values normalized and provided result of liver biopsy that has been shown to treat of toxic hepatitis.

Discussion

This is a case of a young patient with a second episode of acute hepatitis with an immune disease, who was medicated with minocycline, one of the drugs with the highest association with idiosyncratic reactions leading immunological liver disease and whose resolution of the clinical picture was quite time consuming. Therefore, exclusion of a non-toxic etiology is fundamental.

#421 - Abstract

ALTERED EXPRESSION OF DNA METHYLATION/HYDROXYMETHYLATION ENZYMES IN PATIENTS WITH AUTOIMMUNE HEPATITIS (AIH).

Pinelopi Arvaniti¹, Kalliopi Zachou¹, Aggeliki Lymperopoulou¹, Eirini Sevdali², Matthaios Speletas², Yves Renaudineau³, George N Dalekos¹

¹ Department of Medicine and Research Laboratory of Internal Medicine, University Hospital of Larissa, Larissa, Greece

² Department of Immunology and Histocompatibility, Faculty of Medicine, School of Health Sciences, University of Thessaly, Larissa, Greece

³ Laboratory of Immunology and Immunotherapy, INSERM UMR 1227, CHU de Brest, Brest, France

Background

AIH is a chronic liver disease of unknown aetiology, characterized by hypergammaglobulinemia, circulating autoantibodies, interface hepatitis on liver histology and favourable response to immunosuppression. Little is known about the impact of epigenetics on disease pathogenesis. The aim of our study was to assess potential epigenetic modifications in peripheral blood mononuclear cells (PBMCs) from patients with AIH through an altered expression of DNA methylation/hydroxymethylation enzymes.

Methods

PBMCs were isolated from 10 patients with AIH at diagnosis, 8 AIH patients at remission, 9 primary biliary cholangitis (PBC) patients followed at the Department of Medicine and Research Laboratory of Internal Medicine of Larissa University Hospital and 6 healthy controls (HC). CD19(+) B and CD4(+) T lymphocytes were isolated with positive and negative selection respectively, by ROBOSEP platform. The mRNA levels of DNA methyl-transferases (DNMT1, DNMT3A, DNMT3B) and Ten-Eleven Translocation (TET) enzymes (TET1, TET2, TET3) were determined by quantitative real-time PCR.

Results

Regarding CD4(+) T cells, AIH patients at diagnosis (n=10) were characterized by increased DNMT3A expression (p=0.007 and p=0.001) and reduced TET1 expression (p=0.03 and p=0.02) compared to HC and PBC patients respectively. The same significant findings were observed in CD19(+) B cells concerning DNMT3A and TET1 expression. No differences in DNMT1, TET2 and TET3 levels were observed between AIH patients and HC, while DNMT3B levels were beyond the detection threshold so no further analysis was made. DNMT3A and TET1 levels in CD4(+) T cells were correlated with circulating IgG levels (r=-0.673, p=0.05; and r=0.715, p=0.03, respectively), and a trend was observed for DNMT3A in CD19(+) B cells (r=-0.600, p=0.08). In contrast no association with other clinical, biochemical and serological parameters was observed. Interestingly, the increased DNMT3A expression was reversed after treatment administration in PBMCs of the 8 AIH patients at remission in both cell populations (p=0.025 for both CD19(+) and CD4(+) cells).

Conclusion

Altered expression of DNMT3A and TET1 characterizes immune cells from patients with AIH. The abnormal expression of DNMT3A is reversible after achieving complete remission a fact that could be amenable to novel therapeutic interventions.

#432 - Case Report

NON-CIRRHOTIC PORTAL HYPERTENSION

Catarina Parente, António Cardoso, Fátima Campante
Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Introduction

Liver cirrhosis is the most common cause of portal hypertension, but there are other etiologies collectively termed non-cirrhotic portal hypertension, including, primary biliary cholangitis or Budd-Chiari syndrome.

Idiopathic non-cirrhotic portal hypertension occurs when there is no attributable cause identified, and may be secondary to autoimmune diseases, infectious, drug, genetic or thrombophilic causes.

Case description

A 53-year-old male patient, with no relevant personal history, presented to the Emergency Department for hematemesis with 2 isolated episodes of bright red blood vomit with clots. He also reported black stools for a week-long and the taking of anti-inflammatories due to lumbar pain.

The complementary study detected anemia requiring transfusional support and the endoscopic study revealed ulcerated gastric variceal cord. Posteriorly, abdomino-pelvic computed tomography (CT) showed dilatation of the suprahepatic veins, enlargement of portal and splenic vein caliber, and extensive collateral circulation - aspects compatible with portal hypertension - liver with regular contours and conserved dimensions. Thrombosis of

the portal venous system was excluded by abdominal Doppler ultrasonography. There were no changes in liver function laboratory parameters.

After discharge, the patient continued investigation, with serologies, autoimmunity, parasitological examination of feces, ferritin and ceruloplasmin assays, hepatic magnetic resonance imaging and angiography, which did not reveal alterations beyond those already identified in CT.

Hepatic biopsy was proposed and the patient refused.

Discussion

Idiopathic portal hypertension is established by diagnosis of exclusion, implying the identification of unequivocal signs of portal hypertension, absence of hepatic veins and portal vein thrombosis, and absence of cirrhosis or advanced fibrosis confirmed by biopsy. This case report demonstrates the diagnostic challenge with a patient who refuses an invasive approach, emphasizing, however, the absence of significant implications in the therapeutic management and allowing the discussion of alternative diagnostic methods with a greater degree of acceptability for patients as in transient hepatic elastography.

Idiopathic non-cirrhotic portal hypertension is a rare cause of portal hypertension requiring a high degree of clinical suspicion for the early identification of the pathology and institution of therapy in order to avoid potentially serious complications of the disease.

#433 - Case Report

CHRONIC HEPATITIS B INFECTION AND HEPATOCELLULAR CARCINOMA IN A NON-CIRRHOTIC LIVER

Catarina Parente, António Cardoso, Fátima Campante
Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Introduction

Chronic hepatitis B virus (HBV) infection is an important cause of hepatocellular carcinoma (HCC) associated with either a process of integrating viral genetic material into the host cell genome or a sustained inflammatory state with necrosis and high rate of cell regeneration that promotes chronic changes of the organ itself with accumulation of mutations that ultimately cause neoplastic lesions.

Case description

A 45-year-old male, a native of Guinea-Bissau, with a history of moderate ethanolic habits that had ceased about 6 months prior to admission, presented to the emergency department for abdominal pain located in the upper quadrants with two weeks of evolution. The physical examination showed only sensitivity to palpation of the right hypochondrium and the abdominal ultrasound revealed two nodular lesions described as non-draining abscesses, in a normodimensional liver without other alterations.

The patient was admitted for intravenous antibiotic therapy.

Serological tests for HBV antigens (HBs, HBc and Hbe) were requested with a positive result, with subsequent assay of HBV viral load, which was greater than 2,000 IU/mL.

Magnetic resonance imaging was performed for evolutionary control and for better characterization of the hepatic lesions that showed solid nodular lesions with enhancement characteristics suggestive of HCC.

The patient was then referred to Hepato-Biliary Surgery, having been oriented for chemoembolization.

Discussion

The present case report is illustrative of the importance of complementary diagnostic tests in current clinical practice and in therapeutic orientation, as well as the particularity of a case of multifocal HCC in a non-cirrhotic liver, highlighting the direct oncogenic effects of hepatitis B virus independent of its pathogenic effects closely related to chronic inflammatory changes and repeated cellular regeneration leading to cirrhosis and carcinogenesis.

#458 - Case Report

ACUTE ALITIASIC CHOLECYSTITIS AS UNUSUAL PRESENTATION OF HEPATIC SARCOIDOSIS ASSOCIATED TO SJÖGREN SYNDROME

Alessandro Croce, Alice Pirovano, Erika Zecca, Mattia Bellan, Mario Pirisi, Rachele Rapetti
Ospedale Maggiore della Carità, Novara, Italy

Introduction

Sarcoidosis (SS) is a multisystemic disease characterized by the presence of noncaseating granulomas usually non necrotizing, but sometimes described necrotizing too. It can affect any organ, with prevalence of lungs and lymph nodes. Hepatic SS is reported in 50-65% of cases, mostly asymptomatic. SS can occur together with Sjögren's Syndrome (SjS), an autoimmune disorder characterized by reduction of gland excretion.

Case description

A 55-year-old woman with a history of hypothyroidism, mild xerostomia and xerophthalmia, and fatigue since 9 months, developed acute onset of fever during a holiday in Corsica, with alteration of liver biochemistry tests (LBTs) and abdominal bulkiness. She was then transferred to an Italian surgery for suspected acute cholecystitis. Abdominal ultrasonography and computed tomography (CT) were performed: enlarged liver, some enlarged hepatic hilar lymph nodes, a mild splenomegaly and pericholecystic effusion were found. After starting antibiotic therapy LBTs improved, but a liver biopsy showed necrotizing granulomas made up by giant multinucleated cells with eosinophilic infiltration. Infectious diseases were excluded since serologies for HIV, HAV, HBV, HCV resulted negative; screening for autoimmune diseases revealed ANA 1:320, granular pattern; anti-

Ro60>27496 CU and anti-Ro52 417,3 CU; ANCA, anti-β2GP1, anti-cardiolipin negative; Shirmer test was positive; respiratory function tests and echocardiogram were normal. After 1 month, at a new CT scan and a PET non homogeneous pathological tissue at the hepatic hilum, wrapped around vena cava and also near small gastric curvature was seen, and was consistent with colligated adenopathies. Also EGDS and laparoscopy with multiple biopsies from liver and ilar lymph nodes were performed, and confirmed results of necrotizing granulomas. A diagnosis of SS was finally made and steroids were started.

Discussion

Acalculous cholecystitis is typically seen in patients who are hospitalized and critically ill, but it is also possible in outpatient setting in cases of risk factors or several underlying chronic diseases, such as immune-mediated disorders. SS should be suspected in patients with lymphadenopathy, manifestations of SjS and acalculous cholecystitis, once other diseases have been excluded. The decision to treat gastrointestinal SS is based upon the activity and extent of disease. For symptomatic patients steroids are the treatment of choice.

#462 - Abstract

VONOPRAZAN VERSUS PROTON PUMP INHIBITORS FOR THE MANAGEMENT OF GASTRIC ENDOSCOPIC SUBMUCOSAL DISSECTION-INDUCED ARTIFICIAL ULCER: A SYSTEMATIC REVIEW

Beom Jin Kim, Hyun Kang, Jae Gyu Kim

Chung-Ang University Hospital, Seoul, South Korea

Background

There is a growing number of reports comparing the effectiveness of a novel potassium-competitive acid blocking agent called vonoprazan with that of PPIs in treating ESD-induced ulcers. However, the findings have been variable, and reported outcomes are conflicting. Furthermore, no previous systematic review and meta-analysis has been published regarding this issue. Therefore, we have performed a systematic review and meta-analysis to assess and compare the effects of vonoprazan and PPI in the treatment of ESD-induced artificial ulcers and prevention of delayed bleeding in randomized clinical trials (RCT) and cohort studies.

Methods

We searched OVID-MEDLINE, EMBASE, Cochrane Central Register of Controlled Trials (CENTRAL), Google Scholar, and clinical trial registries in April 2018 to identify all studies that assess and compare the effects of vonoprazan and PPI in treating ESD-induced artificial ulcers and preventing delayed bleeding. Primary outcome of ulcer healing rate and secondary outcomes of shrinkage rate, ulcer size, and delayed bleeding were studied.

Results

A total of 1265 patients from 12 studies was included in the final analysis. Healing rate at 4 weeks post-ESD was significantly higher in the vonoprazan group than in the PPI group (RR 1.20 (1.03–1.40)). However, healing rate at 8 weeks post-ESD was significantly higher in the PPI group than in the vonoprazan group (RR 0.68 (0.48–0.97)).

There was no evidence of significant difference between groups in shrinkage rate at 4 weeks post-ESD, shrinkage rate at 8 weeks post-ESD, delayed bleeding, ulcer size at 0 weeks post-ESD, and ulcer size at 8 weeks post-ESD.

Conclusion

There was no substantial difference in ulcer healing and post-ESD bleeding between vonoprazan and PPIs. However, vonoprazan more rapidly and effectively treated artificial ulcers after ESD than did PPIs.

#469 - Case Report

COEXISTENCE OF H63D HETEROZYGOSITY AND ALPHA-1 ANTITRYPSIN DEFICIENCY IN A PATIENT WITH IRON OVERLOAD

Carolina Teles¹, Carlos Dias Da Silva¹, Teresa Vaio^{1,2}, Armando Carvalho^{1,2}

¹ Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

² Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal

Introduction

Multiple etiologies are responsible for liver iron overload. Hereditary hemochromatosis, an autosomal recessive condition predominantly caused by mutations in the HFE gene (C282Y and H63D), stands out as the most frequent one. H63D heterozygous patients rarely have clinical manifestations. Coexistence of alpha-1 antitrypsin deficiency is uncommon and may contribute to the development of liver siderosis in these cases.

Case description

43-year-old male patient referred for an Internal Medicine consultation due to hyperferritinemia (1458 ng/mL). Asymptomatic. Plethoric face and malar telangiectasia were visible on physical examination. He had a personal history of hepatic steatosis, chronic alcoholism, arterial hypertension, dyslipidemia and infertility. Laboratory studies showed normal hepatic enzymes and function, decreased alpha-1 antitrypsin, ferritinemia of 699 ng/mL, transferrin saturation at the normal upper limit, as well as negative serologies for hepatotropic viruses and liver autoimmune disease. Genetic testing revealed H63D heterozygous mutation and homozygosity for the PI*S allele of the alpha-1 antitrypsin gene. Abdominal ultrasound showed hepatic steatosis, with F0-F1 fibrosis and S2 steatosis on Fibroscan. Hepatic Magnetic Resonance Imaging confirmed liver iron overload with an iron concentration of 128 (± 20) μmol/g. Respiratory function tests were normal. Thoracic Computed Tomography showed a

tracheal diverticulum and small subsegmental atelectasis, without panlobular emphysema. Treatment with monthly phlebotomies was initiated, normalizing ferritinemia after 12 months, without anemia.

Discussion

This is a patient with H63D heterozygosity and alpha-1 antitrypsin deficiency with confirmed liver iron overload, suggesting the potential relevance of this coexistence. In addition, fatty liver disease likely had a contributory role in the development of hyperferritinemia and liver siderosis. Therefore, this case highlights the importance of the etiological association in liver disease, which may potentiate the expression or exacerbation of clinical manifestations.

#471 - Case Report

THE IMPORTANCE OF BEING WARY LEADING TO THE DIAGNOSIS OF PRIMARY SCLEROSING CHOLANGITIS

Maria João Correia, Catarina Mateus, Renato Guerreiro, Cândida Fonseca, Luís Campos

Hospital São Francisco Xavier - CHLO, Lisboa, Portugal

Introduction

Primary sclerosing cholangitis (PSC) is a chronic cholestatic disease characterized by inflammation, fibrosis, and stenosis of intra and extrahepatic bile ducts, leading to terminal liver disease. Two thirds of patients with PSC have concomitant inflammatory bowel disease (IBD), most often ulcerative colitis (UC).

The clinical presentation of PSC is heterogenous - from totally asymptomatic, only analytical alterations of the liver tests, to exuberant symptoms related to hepatic cholestasis. Magnetic resonance cholangiopancreatography (MRCP) is the preferred diagnostic method, with high sensibility and specificity.

There are multiple PSC complications, highlighting the high incidence of neoplasia (mainly hepatic, gallbladder and colon). Liver transplantation is the only effective therapy.

Case description

A 79-year old man with personal history of hypertension, UC, chronic obstructive pulmonary disease and bronchiectasis. He was admitted at the hospital for watery diarrhea, nausea and fever, associated with gait imbalance in the previous 2 days. No major alterations to the physical examination. The laboratory work showed elevation of inflammatory parameters (leukocytosis, CRP of 24.9 mg/dL, ferritin of 2705 ng/mL), and hepatic cholestasis with normal bilirubin. Abdominal ultrasound was normal. An aggravation of UC was excluded. Given the resolution of diarrhea and no clear signs of infection there was no need to start antibiotic therapy. He underwent thoraco-abdominal-pelvic CT, in which hepatosplenomegaly stands out, with microcysts compatible with irregularities of the caliber of intrahepatic bile ducts. Since there was clinical improvement

and resolution of inflammatory parameters with symptomatic therapy, it was decided to complement an outpatient study to clarify the suspicion of PSC. The MRCP revealed a pattern suggestive of PSC, with irregularities of the left main intrahepatic biliary branch, characterized by segmental ectasias, and zones of annular stenosis. After confirming the diagnosis he was referred to gastroenterology consultation for follow-up interventions.

Discussion

This is a case of fever with no clear focus, since the patient presented to us with nonspecific clinic and alteration of liver tests, reason why a high level of suspicion was necessary for the diagnosis. Given the association of IBD and PSC, it was possible to timely diagnose a rare pathology, which will modify the patient's prognosis requiring a closer clinical surveillance.

#476 - Case Report

FROM INFECTION TO CROHN DISEASE

Francisco Lopes Morgado, Bárbara Saraiva, João Costa, Celestina Blanco Torres, João Correia

ULS Guarda, Guarda, Portugal

Introduction

The internist is in a privileged position for the best approach to systemic pictures. We present the case of a patient whose acute event served as the starting point for the diagnostic march of a chronic disease, which, being relatively common and well-known, is sometimes forgotten due to its clinical variability.

Case description

A 25-year-old man admitted in the Emergency Department (ER) with generalized arthralgia, anorexia and fever. There is a previous history of recurrences to the ER due to diarrhea, abdominal pain and fever during the last month, as well as recent contact with rural animals and a tick bite 2 weeks before the admission. No known personal history other than multiple episodes of diarrhea throughout adolescence as well as frequent episodes of arthralgia. Examination showed painful complaints in the lumbosacral spine and wrists, with functional impotence and aggravation with mobilization, without any other relevant findings. Complementary study revealed a significant increase of inflammatory parameters as well as a Weil-Felix positive test.

Taking these findings into account, the patient was hospitalized with the presumed diagnosis of Mediterranean Spotted Fever and treatment started accordingly.

During hospitalization, the patient presented a rapid resolution of the febrile condition accompanied by a gradual descent of the inflammatory parameters, but with persistent arthralgia, as well as episodes of bloody diarrhea. By this time serologic studies confirmed the diagnosis of admission. Bacteriological and parasitological study of faeces was negative and fecal calprotectin was greatly increased; endoscopic gastrointestinal exams only revealed nonspecific ileal changes suggestive of ileitis.

These findings allowed the diagnosis of enteropathic arthropathy related to a probable underlying Crohn disease. Induction therapy was successfully performed the patient was discharged for ambulatory follow-up under maintenance therapy.

At the follow-up consultation the rest of the autoimmune study was compatible with Crohn Disease as well as the associated presence of Sjogren's syndrome.

Discussion

Crohn disease is one of the major intestinal inflammatory conditions with the particularity of being able to involve any portion of the digestive tract. In spite of this, there are frequent extra-intestinal manifestations. For this reason, its diagnosis should not only be based on complementary tests, but also in a detailed clinical history, especially during its initial course.

#480 - Abstract

PATIENTS WITH CIRRHOSIS PRESENT A VERY LOW ADHERENCE TO NUTRITIONAL RECOMMENDATIONS: RESULTS FROM A PROSPECTIVE OBSERVATIONAL STUDY

Francesco Palmese¹, Ilaria Bolondi¹, Ferdinando Antonino Giannone², Maurizio Baldassarre³, Giacomo Zaccherini¹, Manuel Tufoni¹, Silvia Boffelli¹, Sonia Berardi⁴, Franco Trevisani¹, Paolo Caraceni¹

¹ Department of Medical and Surgical Sciences, Alma Mater Studiorum University of Bologna, Bologna, Italy

² Support Services and People Care, General Direction, S.Orsola-Malpighi University Hospital, Bologna, Italy

³ Center for Applied Biomedical Research (C.R.B.A.), Alma Mater Studiorum University of Bologna, Bologna, Italy

⁴ Department of Care of Organ Failures and Transplants, Internal Medicine for the Treatment of Severe Organ Failures, Sant'Orsola-Malpighi University Hospital, Bologna, Italy

Background

Malnutrition is a frequent complication in patients with cirrhosis but still remains underestimated and often untreated, affecting the global prognosis of patients.

Patients with cirrhosis represent a very heterogeneous population in terms of nutritional requirements, which can be determined only through a personalized assessment of the complex interaction between their nutritional status and clinical condition.

The aim of the study was to evaluate the level of patients' adherence to the current international nutritional recommendations adapted to the individual clinical status.

Methods

192 outpatients with cirrhosis were prospectively evaluated. 161 were considered at risk of impaired nutrition as they present at least one of the following factors: altered body mass index score, non-volitional body weight changes, ascites, peripheral edema, hepatic encephalopathy, or diabetes. Patients at risk were offered

a nutritional assessment by a certified specialist, including a 3-days food diary and hand-grip strength (HGS) test. Only 78 patients returned the diaries properly filled in.

Results

The analysis of food diaries showed a low-level adherence to the nutritional recommendations: caloric intake was insufficient, in excess and adequate in 75%, 13% and 12% of cases, respectively. An appropriate consumption of carbohydrates, protein and fibers was found only in 10-15% of cases, while the intake of simple sugars, lipids, and water resulted adequate in up to 55%. The protein intake was more frequently insufficient in patients with more advanced disease. HGS test was altered in 49% of patients, without significant correlations with macronutrient intakes. Twenty-seven subjects (17%) refused the nutritional assessment: these patients presented a significantly less severe disease and a lower number of risk factors.

Conclusion

This observational study shows that patients with cirrhosis present a very low adherence to the nutritional recommendations. This can be explained both by the limited knowledge on foods and by the lack of an educational program on nutrition. These results highlight the importance of a nutritional intervention tailored to the needs of the individual patient as part of a multidisciplinary approach. Finally, this nutritional intervention should start from the initial stage of the disease, when lower is the awareness of patients and higher the probability of success in positively influencing patient's prognosis and quality of life.

#484 - Abstract

DECOMPENSATED ALCOHOLIC LIVER CIRRHOSIS IN AN INTERNAL MEDICINE DEPARTMENT

Ana Teresa Goes

Hospital Litoral Alentejano, Santiago Do Cacém, Portugal

Background

Alcoholic liver cirrhosis is an important public health problem in Portugal. Recent studies have revealed that in 15 years more than 80 000 patients with cirrhosis of the liver have been hospitalized, of which 85% with alcoholic cirrhosis, with long hospitalizations and high mortality. Liver disease is the fifth leading cause of death, according to data from Direção Geral de Saúde (DGS).

With this study the author aims to characterize the hospital admissions for decompensated alcoholic liver cirrhosis in an Internal Medicine Service (IMS) during a three-year period.

Methods

A retrospective observational study with a reference period from January 2014 to December 2016, through consultation of clinical processes of the hospitalized patients with the main diagnosis of alcoholic liver cirrhosis in an IMS.

Results

A total of 47 cases were analyzed, covering 31 patients (93.62% men), with a mean age of 62.23 years (minimum 44, maximum 84). The mean length of hospital stay was 12.11 days (minimum 3, maximum 46). The most prevalent cause of alcoholic liver cirrhosis decompensation was hepatic encephalopathy (42.55%), followed by ascites (21.28%) and spontaneous bacterial peritonitis (14.89%). It should be noted that in most cases alcohol consumption remained active (59.57%). There were nine deaths, most in the context of progression of the underlying disease (55.56%).

Conclusion

The complications resulting from alcoholic cirrhosis require important health care and consume many economic resources, with great emphasis in Portugal, registered as the eleventh country with the largest consumption of alcohol worldwide. Alcoholic liver disease has a great impact on hospital admissions, with high complexity and mortality, as confirmed by the data analyzed, also reflecting the need for a multidisciplinary and constant approach, before, during and after hospitalization.

SCLEROSING MESENTERITIS AS CAUSE OF ABDOMINAL PAIN

Nina Jancar, Filipa Gonçalves, Mariana Simões, Patricio Aguiar, José Luís Ducla Soares

Hospital de Santa Maria, CHLN, Lisbon, Portugal

Clinical summary

A 67 year old patient, with a history of rectal adenocarcinoma (T3N2M0, stage IIIb), submitted to anterior resection of the rectum with ileostomy in 2018, admitted to the hospital due to periumbilical pain (without any trigger or aggravating factors), post-prandial vomiting, within the three previous days, acute kidney injury (AKIN II) of pre-renal etiology and a rise in inflammatory parameters. An abdominal and pelvic CT scan was performed and it showed: "densification of mesenteric fatty tissue and small mesenteric ganglia (sclerosing mesenteritis), densification of pre-sacral fatty tissue and a small herniation of mesenteric fatty tissue", thus confirming the diagnosis of sclerosing mesenteritis in the context of recent surgical intervention as cause of abdominal pain.

Figure #491. Sclerosing mesenteritis as cause of abdominal pain.

MORGAGNI HERNIA - AN INCIDENTAL DIAGNOSIS.

Gonçalo Mesquita, Vera Seara, Sónia Fernandes, Luciana Faria, Catarina Patronillo, Juliana Xu, Luísa Guimarães
Centro Hospitalar Póvoa de Varzim - Vila do Conde, Vila Do Conde, Portugal

Clinical summary

An 85-year-old woman presents herself to the emergency department after an episode of syncope with amnesia for the event. The postero-anterior chest X-ray (Figure 1) shows bowel loops in the right hemithorax, retrosternal located by the right lateral radiograph (Figure 2). A CT scan of the thorax revealed a Morgagni hernia to the right, with the hepatic angle of the colon in the hernial sac. After a period of surveillance, the patient was asymptomatic. Conservative treatment and surveillance were decided. Morgagni hernia is very rare, comprising about 3% to 5% of all types of congenital diaphragmatic hernias. It is usually diagnosed during childhood but, may remain asymptomatic until adulthood. Its diagnosis may be incidental to unrelated events when a chest X-ray is performed.

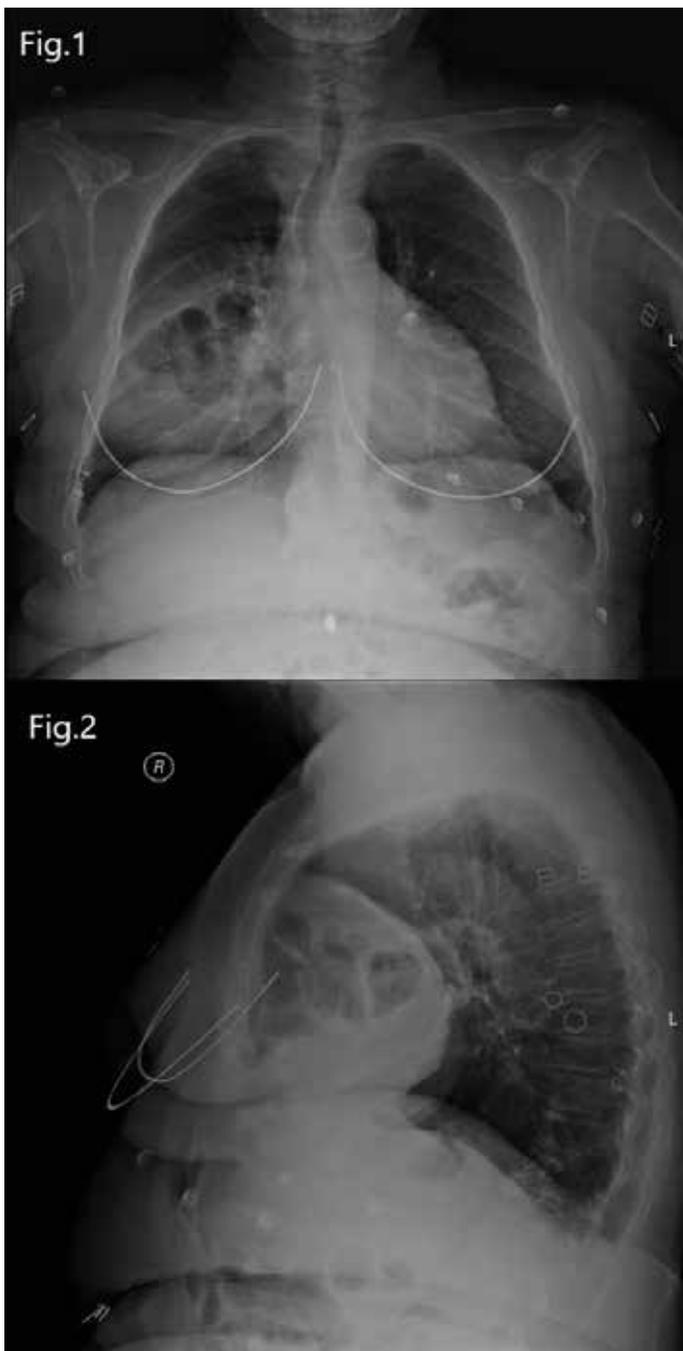

Figure #514.

CARDIOVASCULAR STUDY AND EVALUATION OF SUBCLINICAL ARTERIOSCLEROSIS IN PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE

Mario Salcedo^{1,2}, Sergio Palacios-Fernández^{3,2}, Natalia García Morales¹, María Sahuquillo Serrano¹, Jon Ortiz Carrera¹, Ángela Zaragoza¹, Cristina Campo¹, Carmen Morata¹

¹ Hospital Universitario y Politécnico La Fe, Valencia, Spain

² Universidad de Valencia, Valencia, Spain

³ Hospital Clínico Universitario San Juan de Alicante, San Juan De Alicante, Spain

Background

NAFLD represents the most common chronic liver disease. A relationship with CVD has been described. NASH is currently considered the liver manifestation of the metabolic syndrome; however, it is emerging as a possible independent risk factor for CVD. Objective is to describe the epidemiology of the various cardiovascular risk factors (CRFs) in nonalcoholic fatty liver disease (NAFLD) and to assess their relationship with subclinical atherosclerosis.

Methods

We prospectively studied 68 adult patients diagnosed with NAFLD through liver biopsy. The histological findings were classified according to the FLIP (fatty liver inhibition of progression) Pathology Consortium algorithm based on the SAF score (Steatosis, Activity, Fibrosis).

We studied the prevalence of the following CRFs: hypertension, dyslipemia, diabetes, metabolic syndrome and hyperuricemia.

The study of subclinical atherosclerosis was based on three noninvasive tests and following the 2013 guidelines on hypertension of the European Society of Hypertension:

- Doppler ultrasonography of the supra-aortic trunk (SAT) through mode B ultrasonography of the arterial wall in both carotid arteries, assessing the intima media complex thickness (IMT) following the recommendations of European Guide of Hypertension 2013 (pathological if >0.9 mm and atheromatous plaques are present)
- Study of arterial stiffness through tonometry by flattening using a pressure transducer connected to a SphygmoCor® device measuring the pulse wave velocity (PWV) (pathological if >10 m/s)
- Ankle brachial index (ABI) using a double-digit oscillometer (considered pathological if <0.9)

Results

78.4% of the study patients were diagnosed with nonalcoholic steatohepatitis (NASH) and 21.6% were diagnosed with steatosis. 64.9% of the patients had metabolic syndrome, 64.9% dyslipemia, 59.5% hypertension, 45.9% diabetes and 10.89% hyperuricemia. 16.2% were smokers.

There were atheromatous plaques in 24.3% of the patients and abnormalities in the intima-media complex in 35.1%. 35.1% of the patients had an increase in the PWV, and 5.4% had a pathological ABI.

Conclusion

As conclusion, our study shows patients with NAFLD had high prevalence of CVF and a moderate-high rate of subclinical atherosclerosis, supporting the current evidence of a close relationship among the NAFLD and the CVD.

#540 - Case Report

VON MEYENBURG COMPLEXES. CASE REPORT

Juan Francisco Barrios, Luis Benjamin Godínez, Gabriel Antonio Ríos

Instituto Guatemalteco de Seguridad Social, Guatemala, Guatemala

Introduction

The bile duct hamartoma or Von Meyenburg complex is a rare hepatic lesion consisting of a deformation and disorganization of the bile ducts, forming cystic structures that vary in size. These cysts come from the biliary tract, but the cysts do not communicate with them.

Case description

A 51-year-old female patient with no medical history consulted with a 6-month history of abdominal distension associated with pain located in the right hypochondrium, sensation of gastric fullness, which is associated with respiratory distress. Imaging studies were performed in which the enlarged liver was observed, at the expense of the right hepatic lobe dominated by a hypodense image with thin lobed walls and fine fine septa with an estimated volume of 1,405 cc, data in relation to hepatic polycystosis. She was taken to the operating room for hepatic cyst resection that includes segments 4, 5 and 8, with serobiliary fluid of approximately 1,300 cc inside, thickened walls adhered to vascular structures and bile ducts inside. Pathologically the cyst wall lined with cuboidal simple epithelium, multiple small bile ducts with benign epithelium were observed, on a fibrous background and with a small zone of normal hepatic parenchyma. Compatible with a Biliary Hamartoma (von Meyenburg complex).

Discussion

The majority of von Meyenburg complexes are discovered incidentally, this condition is incidentally detected in from 0.5 to 5.6% of autopsies and is generally asymptomatic. In contrast our patient presented with abdominal distension and pain located in the right hypochondrium. These complexes do not require treatment, but a long-term follow-up is indicated due to the possibility of more frequent cholangiocarcinoma in patients with von Meyenburg complexes. Currently the patient is clinically stable and with adequate evolution with radiographic follow-up. This is probably the first case report of the von Meyenburg complexes described in Guatemala.

#541 - Case Report

A DRINK OF ASPIRIN

Filipa Rodrigues, Carmen Valdivieso, Eugénia Madureira, Pedro Verão, Maria Castro, Andreia Diegues

ULSNE, Bragança, Portugal

Introduction

Esophageal varices and Mallory Weiss syndrome are two major esophageal bleeding disorders and the management of both these

conditions remains a challenge. Mallory Weiss in particular is responsible for up to 15% of upper GI bleeds and it was initially described in association with vomiting following an alcoholic binge. On the other hand, acute bleeding of esophageal varices occurs in 25% to 40% of cirrhotic patients and carries a high mortality.

Case description

37-year-old female, with a past medical history of alcohol, that following a fall, which resulted in the right malleolus fracture that she self-medicated with aspirin, was admitted in the ER with a massive upper gastrointestinal bleeding, caused by a Mallory Weiss tear with bleeding of grade II esophageal varices newly diagnosed.

She developed hemorrhagic shock and was admitted in the ICU where she stayed for approximately 8 days with severe organ dysfunction, encephalopathy and severe hepatic dysfunction.

The patient had a good clinical and laboratory evolution, being able to discharge the ICU and being transferred to the ward, to further control and evaluation and was then discharged from the hospital, and has since been followed in an outpatient regimen.

Discussion

The connection between Mallory Weiss and cirrhosis is poorly studied but there are some studies that say the severity of bleeding from this syndrome is related to the status of the liver function and therefore develop mainly in patients with chronic alcoholism. An important risk factor is, of course, the concomitant use of aspirin, reported in about 30% of patients, highlighting recent findings that even low dose aspirin use increases major GI bleeding risk by 58% in healthy adults which raises concerns with the wide-use of aspirin in the present medical practice, and of course, the harm of self-medication with apparent innocuous pills.

DIEULAFOY'S LESION AND ACUTE KIDNEY INJURY: THE SAME ETIOLOGY?

Ana Sá, Paulo Medeiros, Narciso Oliveira, Teresa Pimentel

Hospital de Braga, Braga, Portugal

Introduction

Dieulafoy's lesion, also termed "caliber persistent artery", is a rare and potentially life-threatening cause of acute gastrointestinal (GI) bleeding, accounting for up to 2% of total episodes. Typically presents with severe, active GI bleeding, without prior symptoms. The stomach is the most common site for Dieulafoy's lesion. Approximately one-third of lesions are extra-gastric, most frequently in the duodenum followed by the colon. Although its etiology remains unknown, it is often associated with alcohol and non-steroidal anti-inflammatory drugs (NSAIDs).

Case description

An 83-year-old man, with hypertension and alcoholism, went to the emergency room due to asthenia, peripheral edema and

decreased urine output. He had been medicated 7 days before with non-steroidal anti-inflammatory drugs for right knee pain after falling. He had oliguric acute kidney injury (creatinine 5.2 mg/dL), hyperkalemia and hyperlactacidemia. Renal ultrasound had no pathological changes. Multiple sessions of hemodialysis were performed without clinical renal recovery. During hospitalization, he had acute onset of hematemesis, melena, hypotension, acute drop in the hemoglobin value (11,1 g/dL to 6,2 g/dL) and hypotension, requiring transfusion of multiple units of packed erythrocyte and high volume fluid administration. Esophagogastroduodenoscopy showed GI bleeding secondary to Dieulafoy's lesion, treated with local epinephrine injection. Despite all therapeutic measures, the patient eventually died.

Discussion

Unlike normal vessels of the gastrointestinal tract which become progressively smaller in caliber peripherally, Dieulafoy's lesions maintain a large caliber despite their peripheral, submucosal, location within gastrointestinal wall. Dieulafoy's lesion is an important cause of acute GI bleeding. Although etiology still uncertain, it is more common in males hospitalised, with cardiopulmonary dysfunction or renal failure. Dieulafoy's lesion is often associated with alcoholism and NSAIDs. This patient has been hospitalized with acute kidney injury and Dieulafoy lesion, probably by non-steroidal anti-inflammatory drugs. Endoscopy is the first diagnostic test and endoscopic therapy (including clips, sclerotherapy, argon plasma coagulation, thermocoagulation, or electrocoagulation) is the recommended initial therapy. Dual endoscopic therapy of epinephrine injection followed by ablative or mechanical therapy appears to be effective.

#611 - Abstract

NEW INTERFERON FREE ANTIVIRAL THERAPY AND INCIDENCE OF AUTOIMMUNE MANIFESTATIONS IN PATIENTS WITH VIRAL HEPATITIS C

Anca Belu, Mihaela-Maria Ghinea, Daniela Belu, Traian Tache, Zizi Niculescu, Eduard Circo

Constanta County Emergency Hospital, Ovidius University Constanta, Constanta, Romania

Background

The interferon free treatment in viral chronic hepatitis C is a great chance for this patients and the beginning of a new era for the fight against the hepatic virus C.

The treatment can also be applied to patients with liver cirrhosis - this was not possible with previous and is shorter but a median of 12 weeks. Moreover, there is no age limit for treatment and the side effects are much less than with interferon.

But, what about the autoimmune reaction?

There have been numerous studies that demonstrated that autoimmune side effects in these patients were due both to interferon therapy but also to replication of the virus in various

organs- extrahepatic reservoir of viral replication (eg thyroid, kidney) or autoantibody development due to the existence of a common sequence present in both the structure virus, and also in self structures of the human body.

Can the new treatment solve the autoimmune implications of hepatitis C virus infection? Our objective is to have an answer at this question.

Methods

We studied a group of 157 patients diagnosed with chronic type C viral hepatitis, (69 patients- liver cirrhosis stage). They were treated with VIEKIRAX (ombitasvir, paritaprevir and ritonavir) in combination with EXVIERA (dasabuvir).

All patients had undetectable viremia at the end of treatment, and none discontinued treatment due to side effects.

Results

Among these patients, 52,8% (83 patients) had previously received Interferon treatment without a favorable therapeutic response. At the beginning of treatment, we had the following situation: 33,7% (53 patients) had autoimmune thyroiditis, 12,1% (19 patients) mixed cryoglobulinemia, 6,4% (10 patients)- membranoproliferative glomerulonephritis and 5% (8 patients) with secondary autoimmune hepatitis.

6 months after the end of the treatment - 12,7% (20 patients) still had autoimmune thyroiditis, only 5% (8 patients) of the mixed cryoglobulinemia were biological reconfirmed, the clinical manifestations and the paraclinical determinations denies the secondary autoimmune reactions in the kidney and liver.

Conclusion

The introduction of new interferon free therapies in the treatment of viral hepatitis C represents a major benefit for these patients in terms of fighting the virus itself as well as all autoimmune associated manifestations.

We consider this study as a prove of new infinite opportunities for the internal medicine.

⁶ Department of Medicine and Martin Zeitz Centre for Rare Diseases, University Medical Centre Hamburg-Eppendorf, Hamburg, Germany

⁷ Department of Medicine, Teikyo University School of Medicine, Itabashiku, Tokyo, Japan

Background

Non-alcoholic fatty liver disease (NAFLD) and steatohepatitis (NASH) affect 17-46% of western countries population, making the coexistence with other liver diseases inevitable. Our aim was to investigate the prevalence and clinical significance of NAFLD/NASH in patients with autoimmune hepatitis (AIH), in a multicentric large cohort.

Methods

Prospectively collected data from patients with well-established AIH from 6 academic centers (Greece, Canada, Japan, Germany and Spain) were evaluated retrospectively. The presence of NAFLD and NASH in liver biopsy reports was recorded in detail in order to compare the clinical and laboratory data as well as the outcome between AIH patients with and without NAFLD/NASH.

Results

580 patients (433 females, 74.7%; age at AIH diagnosis 46+/-18 years; 175 from Greece, 309 from Canada, 44 from Japan, 29 from Germany, 13 from Spain; follow-up 103+/-86 months) were included. NAFLD was present in 123/580 (21.2%) baseline biopsies. In more detail, 107/580 (18.4%) had NAFLD (64/107 steatosis only; 43/107 steatosis and lobular inflammation) and 16/580 (2.7%) NASH. Patients with AIH-NAFLD/NASH were older at AIH diagnosis ($p=0.004$), had higher BMI ($p<0.001$), lower AST, ALT, ALP and bilirubin ($p<0.05$ for each), but higher albumin ($p<0.001$), triglycerides ($p=0.05$) and lower simplified score ($p=0.02$)

compared to those without NAFLD/NASH. AIH-NAFLD/NASH patients suffered more frequently from hypertension, diabetes and obesity ($p<0.001$ for each). AIH-NAFLD/NASH patients were less likely to be anti-SLA/LP positive ($p=0.005$), but more likely to be anti-LKM positive ($p=0.02$). Although progression to cirrhosis was not associated with NAFLD/NASH presence, AIH-NAFLD/NASH cirrhotic patients (39/197) were more likely to decompensate during follow-up ($p=0.01$). The presence of NAFLD/NASH did not affect response to treatment or overall prognosis (liver related death or liver transplantation).

Conclusion

Despite the high prevalence of NAFLD/NASH in one fifth of AIH patients, there is no evidence that NAFLD/NASH acts as an aggravating factor since response to treatment and the overall prognosis of AIH patients were not affected. However, the low number of patients with AIH and NASH could be responsible for these findings. Nevertheless, special attention might be needed for those with established AIH-related cirrhosis and concurrence NAFLD/NASH.

#613 - Case Report

A CASE OF EXTREME CACHEXIA

Sandra Celeste Dias Rebelo, Ana Tornada, Tiago Marques

Centro Hospitalar Lisboa Norte - Hospital de Santa Maria, Lisboa, Portugal

Introduction

Indeterminate colitis (IC) or idiopathic chronic colitis (ICC) is characterized by a presentation comparable to Ulcerative Colitis (UC), although with a more extensive and severe presentation, often with extraintestinal manifestations such as in Crohn's disease (CD). It is an overlapping of clinical, histological and serological characteristics of both UC and CD, compelling for a diagnosis of exclusion.

Case description

We report a case of a 55-year-old Cape Verdean man, hospitalized for dysphagia for solids, weight loss over 10% of the body mass index (BMI), diarrhea with hematochezia, vomiting, anorexia and asthenia with insidious onset in the previous 6 months. At admission, the patient presented extreme cachexia (BMI of 13.8 kg/m²), jaundice and deep dehydration with severe hyposmolar hyponatremia (Na 95 mmol/L), acute kidney injury, liver dysfunction and hypergammaglobulinemia. Several opportunistic infections (esophageal candidiasis, pseudomembranous colitis and Cytomegalovirus (CMV) colitis and latent tuberculosis) were diagnosed. With elevation of fecal calprotectin, positive Antineutrophil cytoplasmic antibody (PR3) and Anti-Saccharomyces cerevisiae Antibody (ASCA) the differential diagnosis of the etiology of pancolitis which was documented in computed tomography and magnetic resonance imaging was a challenge. Serial endoscopic examinations confirmed findings consistent with the infections above mentioned and macroscopic

and histopathological findings suggested both UC and CD, difficult to distinguish because of the mucosal ulceration due to CMV over infection. The duodenal biopsies, revealed aspects of celiac disease, with HLA DQA1 and DQB1 associated with DQ2 heterodimer and trans configuration DQ7.5, despite not having Anti-transglutaminase, antiendomysium and antigliadin antibodies. By exclusion criteria we defined the final diagnostic suggestive of ICC and celiac-like disease. Parenteral nutrition, mesalazine and systemic corticotherapy were introduced with a subsequent switch to infliximab and azathioprine to control inflammatory activity, with a notable improvement. He had a portal vein thrombosis as an extraintestinal manifestation.

Discussion

The occurrence of pancolitis and malabsorption syndrome may lead to the occurrence of opportunistic diseases, which difficult the differential diagnosis. The rare association among ICC and celiac-like disease raise a dilemma on the early institution of biological immunosuppressant therapy, given the opportunistic infection.

CAMERON LESIONS – A STILL OVERLOOKED DIAGNOSIS

Magda Sofia Silva, Francelino Ferreira, Rúben Reis, Laurinda Pereira, Anneke Joosten, Ana Paula Pona, Fátima Campante
Centro Hospitalar Barreiro Montijo, Barreiro, Portugal

Clinical summary

We report the case of a 76-year-old woman admitted for asthenia and fatigue. At the observation she was pale, tachycardic and polypneic. The analytical evaluation revealed iron deficiency anemia with hemoglobin of 5.7 g/dL and serum iron of 10 µg/dL. Upper gastrointestinal endoscopy identified a large hiatus hernia with Cameron lesions. She started treatment with proton pump inhibitor and oral iron supplementation.

This case illustrate an uncommon and still overlooked diagnosis of indolent digestive hemorrhage and consequent iron deficiency anemia. These lesions are identified in only about 5% of patients with hiatal hernia.

#634 - Abstract

LEAKY COLONIC BARRIER IN OBESE PATIENTS. AN OPEN GATE TO LIVER STEATOSIS

Emilio Molina-Molina¹, Domenica Maria Di Palo¹, Agostino Di Ciaula², Harshitha Shanmugam¹, Leonilde Bonfrate¹, Eric Mossel³, Piero Portincasa¹

¹ Clinica Medica “A. Murri”, Department of Biomedical Sciences and Human Oncology, University of Bari “Aldo Moro” Medical School, Bari, Italy

² Division of Internal Medicine, Hospital of Bisceglie, Bisceglie, Italy

³ AB Analitica, Padua, Italy

Background

The role of intestinal permeability (IP) in the pathogenesis of fatty liver is poorly explored.

Methods

113 subjects (74F) underwent the study of IP by measurement of urinary recovery of selectively absorbed sugar probes, i.e. sucrose [SO] 20g (stomach-duodenum), lactulose [LA] 5g + mannitol [MA] 1g (small intestine), sucralose [SA] 1g (colon) dissolved in 200 mL water. Urines were collected for 6-hr and sugar concentrations were measured by triple quadrupole mass spectrometry and HPLC (AB Analitica, Padua, Italy). Liver steatosis was scored semiquantitatively (absent, mild, severe) by ultrasonography (Hitachi Noblus 3.5MHz equipment). Adherence to Mediterranean diet (M-diet) was assessed by questionnaire.

Results

While urinary recovery of all sugars was similar in males and females, MA and SA recovery correlated inversely with age. Urinary recovery of SO, LA, MA were comparable, while SA recovery was higher in obese (BMI ≥ 30 Kg/m²) than in overweight (BMI 25-29.9 Kg/m²) and lean subjects (mean ± SE 1.6 ± 0.1%, vs. 1.0 ± 0.1% vs. 1.0 ± 0.06%, respectively, P = 0.0006, ANOVA). This finding was independent from age, which was similar in the three subgroups (P = NS, ANOVA). SA recovery increased with BMI (P = 0.001) and degree of fatty liver (1.0 ± 0.06% vs. 1.2 ± 0.1% vs. 1.5 ± 0.1% in absent, mild and severe steatosis, respectively, P = 0.005 ANOVA). Subjects following a “sufficiently adequate” M-diet (n = 89) had lower SA recovery (1.0 ± 0.04%) than subjects following a “scarcely adequate” M-diet (1.4 ± 0.2%, P = 0.03), although mean BMI was similar in these two subgroups (P = NS).

Conclusion

Obese display a leaky colonic barrier, independently from age and sex; the highest value of colonic permeability was recorded when the highest degree of fatty liver was present; adherence to M-diet could have beneficial effects on colonic permeability, the role of which needs to be further defined.

#655 - Case Report

OGILVIE’S SYNDROME: A CASE REPORT

Cátia Pereira, Sandra Santos, Joana Paixão, Joana Costa, Amílcar Silva

Centro Hospitalar Universitário de Coimbra, Coimbra, Portugal

Introduction

Ogilvie’s syndrome was first described by William Ogilvie in 1948 and is also known as pseudo-obstruction syndrome.

Clinically it is characterized by dilation of the blind and right colon in the absence of colonic obstruction in relation to a dysfunction of the autonomic nervous system. The diagnosis is confirmed by radiological studies.

This syndrome can be treated in most of the times with food

interruption, insertion of a rectal and nasogastric tube. The infection treatment and the correction of possible metabolic disorders are extremely important.

Diagnosis failure can increase the risk viscera perforation, which is rare but significantly increases patient mortality.

Case description

The authors presents a case of a 36-year-old man totally dependent for life activities with a history of hemophilia (factor VIII deficit) and a hemorrhagic cerebral vascular disease at age 11. He contacts a medical appointment for abdominal distension with abdominal pain and fecaloid vomit with about 24 hours of evolution, later aggravated by dyspnea, acute respiratory distress syndrome, wheezing and reflex tachycardia. Constipation with 4 days of evolution. At the emergency service he was prostrate, with abdominal distension, tachypnea, pulmonary auscultation with wheezing and low saturations (91% with oxygen at 5L/min). Started therapy with fluid therapy and bronchodilator for stabilization. Due to a suspicion of acute intestinal obstruction he presented a new episode of vomiting of dark stasis vomit and one anti-emetic agent was administered after the insertion of one nasogastric tube. Two enemas were performed with two episodes of pasty stools.

Prophylactic antibiotic therapy with piperacillin-tazobactam was started and was admitted in the internal medicine department.

Discussion

This case allows to warn that despite being a rare syndrome, most often manifests as a medical urgency whose rapid approach to significantly reduce the morbimortality of patients.

#659 - Case Report

GASTROINTESTINAL BLEEDING FROM AN UNEXPECTED SOURCE

Claudia Janeiro, Pedro Mesquita, Rosario Eça, João Teixeira, Ines Santos, Raquel Mesquita

Hospital Santo António dos Capuchos - CHULC, Lisboa, Portugal

Introduction

Lower gastrointestinal bleeding (LGIB) is a frequent cause of hospital admission and is a factor in hospital morbidity and mortality, particularly among elderly patients. It accounts for approximately 20-33% of episodes of gastrointestinal (GI) hemorrhage.

The etiology of lower gastrointestinal bleeding is essential for patient management and outcome. Colorectal polyps/neoplasms, Dieulafoy lesion, inflammatory bowel disease, and anorectal conditions are the most common etiologies of acute severe LGIB. Effective management with less invasive modalities has also reduced healthcare costs and, more importantly, patient morbidity and mortality.

Case description

The authors describe a case of 75 years-old woman with past

medical history of hypertension and atrial fibrillation, taking anti-hypertensive and anti-coagulant therapy with ACE inhibitors and novel oral anticoagulants.

The patient comes to the emergency room with history of lower GI bleeding, that started 2 months ago. At the beginning, the patient was on medical ward for studying the source of blood loss, so a colonoscopy was performed and the diagnosis of diverticular disease was made (but without identification of bleeding source). She was discharged assuming bleeding from diverticular disease and once the bleeding remained, doctors decided to stop anticoagulant therapy and further evaluation in outpatient clinic. The patient remained anemic, with almost daily episodes of hematochesia, with need of frequent blood transfusions so that the doctors decided to admit patient in medical ward for further examination. During her second stay in ward she needed blood transfusions frequently and all initial exams were inconclusive: angio abdominal CT scan, rectosigmoidoscopy and colonoscopy (always with active bleeding and no identification of source). She made a last left colonoscopy and was finally found 25 cm from anal margin a 'strange body' with metallic consistency with approximately 4 cm long, with active hemorrhage adjacent to that site. After that the hemoglobin remained stable and no more episodes of GI bleeding happened.

Discussion

Lower GI bleeding in elderly is frequently associated with diverticular disease. In this particular case it was really difficult to imagine another etiology for the GI bleeding, but once the signs and symptoms persisted, further examination had to be performed and luckily we found this (strange) bleeding source.

And the question remains: How did this strange body reached colon?

#669 - Case Report

ESOPHAGEAL RUPTURE AND LUNG EMPYEMA IN A PATIENT WITH ESOPHAGEAL CANCER, AFTER PALLIATIVE TREATMENT WITH ESOPHAGEAL STENT PLACEMENT

Dimitris Tsilivarakis, Vasiliki Papanikolaou, Antonios Gikopoulos, Dimitra Karadima, Afroditi Roumpou, Ioanna Papaioannou, Christos E Lampropoulos

Panarcadian General Hospital, Tripoli, Greece

Introduction

Esophageal cancer is a devastating disease with poor prognosis (5-year survival rate <20%). Most of patients have inoperable disease at time of diagnosis. Symptoms include anorexia, dysphagia, weight loss or hoarseness (recurrent laryngeal nerve paralysis). Infiltration of surrounding tissues may cause esophageal perforation, hydro-pneumothorax, empyema, mediastinitis and sepsis with high mortality. Treatment consists of chemoradiotherapy (with or without surgery) or/and endoscopic self-expanding metal stent (SEMS) placement for esophageal dilation, as palliative therapy for dysphagia.

Case description

A 71-year old male presented right chest pain extending to the abdomen. Medical history included esophageal cancer with SEMS 3 months ago. Clinical examination revealed low blood pressure, rales of right lung fields and diffuse abdominal tenderness with borderline rebound tenderness. Thoracic X-ray showed infiltrates and pleural effusion of right lung. Laboratory investigation showed leukocytosis, high ESR, anemia, renal failure and malnutrition (protein=5.2g/dL). Empirical antibiotic treatment was applied (piperacillin/tazobactam, moxifloxacin). The third day the patient developed septic shock with hemodynamic compromise (BP=75/55mmHg), respiratory deficiency and pain deterioration. New x-ray showed air-fluid level at right lung apex and mediastinal expansion. Thoracic CT (IV contrast, gastrografin meal) revealed esophageal rupture with gastrografin and air leakage into the pleural fluid and mediastinum. The patient was operated with excision of the ruptured area and drainage of the empyema. He remained in the Intensive Care Unit for 15 days, where he unfortunately died, despite being alert, mainly because of his cancerous cachexia.

Discussion

The newer SEMS are safer than the previous conventional ones, regarding aspiration pneumonia, bleeding, stent migration or reintervention due to stent dysfunction. Nevertheless, major complications still occur in 20-30% of patients. Esophageal rupture is a rare complication of esophageal cancer with high mortality (>35%). Risk factors for perforation include age younger than 60 years, extracapsular lymph nodes involving the esophagus, T4 stage of disease and repeated courses of radiotherapy. The risk is lower after SEMS placement for palliative esophageal dilation. Perforation may occur immediately during stent procedure or a few months later. Despite surgical intervention, mortality is high because of mediastinitis, empyema and septic shock.

#684 - Case Report

FULMINANT HEPATIC FAILURE

María De Los Ángeles Gallardo, Cristina Lojo

Hospital Universitario Virgen de Valme, Sevilla, Spain

Introduction

A 42-year-old male with active smoking and drinking habits; history of myocarditis and positivity for markers of chronic hepatitis B virus (precore mutant).

Case description

He was admitted at the hospital due to right hypochondrium pain, low-grade fever and increased abdominal perimeter with malleolar edemas of 24 hours of evolution. The analytics showed leukocytosis, prothrombin time of 49% and bilirubin 2.59 mg/dl. Abdominal ultrasound shows poorly defined area in right hepatic lobe, splenomegaly and abundant ascitic fluid. During

the admission he presents arterial hypotension, tachypnea, tachycardia, jaundice and worsening of ascites. Paracentesis was performed with cloudy peritoneal fluid, with 340 leukocytes with 80% mononuclear, 1100 red blood cells and 3.7 proteins.

He enters ICU with poor clinical evolution, hypothermic, maintained hypotension and tachycardic. The analytics shows severe metabolic acidosis (pH 6.9, EB-26), leukocytosis of 56,000, hemoglobin 17g/l, INR up to 7.15, bilirubin up to 2.86mg / dl with transaminases of 7110 and creatinine 4.5. Abdominal CT shows left basal condensation, hepatic steatosis with permeable portal vein, splenomegaly and ascites. Normal echocardiography, negative coombs test, smear normal, with PMN leukocytosis, lactate 27, blood cultures, rose bengal and negative serology. Antibiotic therapy with cefotaxime and metronidazole was initiated and hemodiafiltration. Finally, presents fulminant hepatic failure with multiorgan failure and he died.

Necropsy is compatible with severe hemorrhagic centrilobular necrosis liver associated with thrombosis of suprahepatic and intrahepatic efferent veins, all compatible with Budd-Chiari syndrome.

Discussion

Budd-Chiari syndrome is defined as an obstruction of the hepatic venous outlet tract. Patients may present acute fulminant hepatic failure. Symptoms may include fever, abdominal pain, ascites, edema, jaundice, gastrointestinal bleeding (due to varicose veins or hypertensive portal gastropathy) and / or hepatic encephalopathy. The diagnosis can be established with Doppler ultrasound. Coagulopathy, encephalopathy and hepatorenal syndrome are indicative of a poor prognosis. If thrombolytic therapy and angioplasty fails, liver transplantation should be considered. Without treatment, the prognosis is poor.

PORTO-SINUSOIDAL VASCULAR DISEASE: RAISING AWARENESS FOR AN OLD NEW ENTITY

Adriana Soares, Sofia Monteiro, Alda Tavares, Elia Cipriano, Filipe Andrade, Artur Silva, Fernanda Estevinho, Carlos Sottomayor

Hospital Pedro Hispano, Porto, Portugal

Introduction

Porto-sinusoidal vascular liver disease (PSVD) occurs in the presence of portal hypertension in the absence of portal vein thrombosis, without cirrhosis and with mild or moderate alterations of liver histology. This new entity encompasses a heterogeneous group of vascular liver diseases previously described, namely idiopathic non-cirrhotic portal hypertension or nodular regenerative hyperplasia.

PSVD has multiple etiologies such as immunologic, blood and genetic diseases, prothrombotic conditions and drugs. Oxaliplatin is one of the most common associated chemotherapy agents, described in until 15% of patients.

Case description

We present a case of a 60-year old man, without previous history of liver disease, submitted in April 2012 to a total gastrectomy due to a signet-ring cell gastric cancer (pT1N1M0), followed by a total of 6 cycles of adjuvant chemotherapy with EOX regimen (epirubicin, oxaliplatin and capecitabine) and surveillance.

Patient was asymptomatic until January 2017 when he was admitted with acute esophageal variceal bleeding. Abdominal CT scan showed patency of portal vein, perihepatic ascites and nodular configuration of segment III. Tumor markers were normal and common causes of cirrhosis were excluded. Median liver elastography was 10.1 kPa and hepatic venous pressure gradient was 4 mmHg. A liver biopsy of segment III and of the right lobe was performed which excluded cirrhosis or neoplastic involvement. Diagnosis of PSVD due to oxaliplatin was made.

Discussion

In patients treated with oxaliplatin in the presence of clinical signs of portal hypertension, the diagnosis of vascular liver disease should be suspected. Findings can mimic liver neoplastic involvement as described in our case report. In this population biopsy should be pursued to exclude the diagnosis of malignancy and avoid overtreatment. The natural history of PSVD is not yet fully known but patients require screening for portal vein thrombosis and management of portal hypertension complications.

SOLID PSEUDOPAPILLARY TUMOR: A RARE PANCREATIC NEOPLASM

Lucía Pérez, Ana Blanco, Ana Barreiro

Complejo Hospitalario Universitario Ourense, Ourense, Spain

Introduction

The solid pseudopapillary tumor (SPT) of pancreas is a rare neoplasm with low potential of malignancy, more common in women. It represents between 0.2% and 2.7% of the exocrine pancreas neoplasm, even though some authors maintain that in recent years this percentage has increased to 6% due to a better diagnosis.

Case description

A 27-year-old woman with familiar hyperlipidemia and mild smoking as the only relevant personal medical history. In a routine revision, a solid mass in the tail of the pancreas was carried out by an abdominal echography. The patient was asymptomatic and the physical examination was anodyne, as well as the analytical data. In view of the ultrasound finding, abdominal CT was performed, which revealed a tumor dependent on the tail of the pancreas suggestive of a macrocystic adenoma or cystic mucinous neoplasm. It was decided then to make a laparotomy, in which a cystic tumor of the tail of the pancreas of 6 cm of diameter was found. A corporo-caudal splenopancreatectomy was performed, without complications. The anatomic-pathological study of the

surgical specimen revealed a SPT of the pancreas, without criteria of malignancy, of 6.5 cm. The surgical margins were free and the extracted nodes did not have significant alterations, neither did the spleen. The patient has remained asymptomatic since then and without evidence of recurrence on CT, PET-CT and ultrasound, after a 9 years follow-up.

Discussion

The SPT predominates in women between 20 and 30 years old. The most common location is the tail of the pancreas. The embryological origin of SPT is not clear although it has been postulated that they could be derived from female genital tissue. Clinical presentation is nonspecific, with abdominal pain occurring in 58-72% of cases, although up to 30% of patients are asymptomatic. Routine analytics and tumor markers are not useful in the diagnosis of SPT. Imaging techniques typically show a heterogeneous mass with a solid and cystic component, well defined by a peripheral capsule, with occasional calcifications. Most SPTs have a benign course, although in a small percentage of the cases it has caused a distant disease, being the liver the most frequently affected organ. The chosen treatment is the complete tumor resection, regardless of stage, and incomplete resections should be avoided, given the risk of complications such as tumor dissemination and a higher rate of recurrence. The overall mortality of SPT is estimated at 2%, and recurrence after resection is calculated at 10-15%.

#772 - Case Report

MIGRATED FISH BONE CAUSED LIVER ABSCESS PRESENTED AS A GASTRIC SUBEPITHELIAL LESION (MASS) IN CLINICAL PRACTICE DIAGNOSED BY ECHOENDOSCOPY

Metin Basaranoglu

Bezmialem Vakif University, Istanbul, Turkey

Introduction

A 63-year-old man presented with a one-month history of abdominal pain. The final diagnosis was a fish bone caused liver and gastric wall abscesses presented as a gastrointestinal stromal tumor diagnosed by echoendoscopy (EUS).

Case description

A 63-year-old man presented with a one-month history of abdominal pain. Esophagogastroduodenoscopy revealed a 40 mm subepithelial lesion located at gastric antrum. Gastrointestinal stromal tumor (GIST) was suspected. Then, an endosonographic (EUS) evaluation was performed.

A curvilinear echoendoscope (EG-530UT; Fujinon, Japan) was used. Endosonographic (EUS) evaluation was performed and showed that a 23x27 mm hypoechoic mass arising from gastric wall and producing pus by the pressure of the tip of the EUS (Figure 1). Additionally, there was a linear hyperechoic tract that was located between the gastric antrum and 3rd segment of the left liver lobe (Figure 2).

Apex of the subepitelial lesion producing pus by the pressure of EUS device. Inferior part of the gastric lesion did spread to the left lobe of the liver. On this liver segment, there was a hypo-echoic mass lesion.

Discussion

Suppurative gastritis may develop secondary to pancreatitis, cholecystitis, appendicitis, and diverticulitis (1-5). It may also arise from foreign body ingestion.

Patient-related risk factors for the development of suppurative gastritis include alcoholism, older age, diabetes mellitus, hypochlorhydria or achlorhydria, and immunosuppression. Abdominal pain and nausea usually dominate the clinical picture in these cases.

The most common appearance of a gastric wall abscess is a submucosal tumor. Both radial and curved linear array endoscopic ultrasound provides a unique imaging modality for evaluating the gastric wall with an excellent visualization of the layers of the gastric wall. EUS features include a heterogeneous mass often with solid and cystic components. Suppurative gastritis may progress to peritonitis and death from sepsis with delayed diagnosis and treatment. Surgery is definitive therapy.

Cases of hepatic abscess due to fish bone penetration are rare and may be fatal with delayed diagnosis and treatment (6,7).

In summary;

EUS may provide an additional diagnostic tool in the evaluation of patients with suspected gastric wall abscess. EUS is fundamental on the diagnosis of suspect foreign bodies and their complication.

#773 - Case Report

AN OLD MALE WITH CROHN'S DISEASE PRESENTED BY SUBILEUS CLINIC AND DIAGNOSED BY DOUBLE BALLOON ENTEROSCOPY AND HISTOLOGIC EXAMINATIONS

Metin Basaranoglu, Gokcen Basaranoglu
Bezmialem Vakif University, Istanbul, Turkey

Introduction

Crohn's disease (CD) is a disease that causes inflammation or swelling of any part of the gastrointestinal (GI) tract. The part most commonly affected is the end part of the small intestine, called the ileum. We, here, presented a case with CD diagnosed by taken specimens during the double balloon enteroscopy and enteroscopy findings.

Case description

A 60-year-old male was admitted to the clinic with abdominal pain and vomiting. His medical history includes diabetes and hypertension, besides cholecystectomy and inguinal hernia operation. He was an ex-smoker. Laboratory examination showed nothing. Abdominal tomography showed that the wall of the jejunum and ileum were thickened. Small bowel contrast

examination revealed thickened wall in the ileum with ulceration and nodularity. Colonoscopy showed no abnormality in the colon and 15 cm of the distal part of the ileum. Oral double balloon enteroscopy first performed and showed multiple xantomas in the jejunum and proximal ileum segments. Then, double balloon enteroscopy performed by anal route and showed semicircular ulcers and narrowing in the ileum, approximately 100 cm far from the ileocecal region. Multiple biopsies performed and specimens showed ulceration with active inflammation. Quantiferon was positive as PCR-tuberculosis of the specimens from the ileum was negative. Chest examination was normal. Crohn's disease was diagnosed in this elderly patient.

Discussion

Crohn's disease affects men and women equally and seems to run in some families. Crohn's disease occurs in people of all ages, but it most commonly starts in people between the ages of 13 and 30. Men and women who smoke are more likely than nonsmokers to develop Crohn's disease. People of Jewish heritage have an increased risk of developing Crohn's disease, and African Americans have a decreased risk. The most common symptoms of Crohn's disease are abdominal pain, often in the lower right area, and diarrhea. In our presented case, suspected radiological findings confirmed by double balloon enteroscopy with histologic examination. Tuberculosis should be carefully excluded in patients with ileum ulcers and positive blood quantiferon test results, particularly in developing countries which tuberculosis still is endemic.

ACHALASIA

Margarida Gonçalves Coelho, Lília Castelo Branco, Cátia Pereira, Elisabete Pinelo, Eugénia Madureira

Serviço de Medicina Interna, Unidade Hospitalar de Bragança, Unidade Local de Saúde do Nordeste, Bragança, Portugal

Clinical summary

Achalasia is a rare disease with loss of ganglion cells in the esophagus myenteric plexus, characterized by insufficient lower esophageal sphincter (LES) relaxation and loss of esophageal peristalsis. Manifestations include dysphagia, regurgitation, chest pain and weight loss. Diagnostic confirmation needs radiograph of barium swallowing and/or esophageal manometry. We report the case of a 72-year-old woman with psoriatic arthritis and complaints of solids and liquids dysphagia and regurgitation, chest pain and weight loss (15 kg). Barium esophagram showed diffuse spasm and uncoordinated tertiary waves that lead to segmentation of the lower 2/3 of the esophagus and dilation of the upper third. The manometry demonstrated type 2 achalasia. She was oriented to LES endoscopic balloon dilation.

Figure #774. Dilatation of the esophagus with incomplete emptying, hydroaerial level and tapering in the LES region, resulting in the appearance similar to that of a bird-beak.

#834 - Abstract

INCIDENCE OF CHOLANGIOCARCINOMA AND RISK FACTORS IN NORTHERN ITALY: AN ANALYSIS OF 403295 CONSECUTIVE PATIENTS.

Francesca Colapietro¹, Vincenzo Craviotto¹, Monia Aloise², Roberto Ceriani², Guido Torzilli¹, Salvatore Badalamenti², Antonio Voza², Alessio Aghemo¹, Ana Lleo¹

¹ Humanitas University, Milano, Italy

² Humanitas Clinical and Research Hospital, Milano, Italy

Background

Cholangiocarcinomas (CCAs) are a heterogeneous group of tumors that arise from the biliary tract epithelia, and account for nearly 3% of all gastrointestinal tumors. Although CCA is on the rise in most countries, the epidemiology of these cancers has been poorly understood. We therefore aim to assess the prevalence, demographics and risk factors of patients with new diagnosis of CCA presenting in the Emergency Room (ER) of an Academic Italian Hospital

Methods

We retrospectively analyzed all ER cases between January 2010 and December 2017 at Humanitas Research Hospital in Milano Italy.

Results

From January 2010 to December 2017 403295 patients entered the ER, in 203 (0.05%) of them the diagnosis was CCA. CCA cases increased from 38 in the 2010-2011 period (38/102103: 0.03%) to 66 in the 2016-2017 period (66/101337: 0.07%) ($p=0.007$).

The most frequent reasons for hospitalization in patients with CCA were jaundice ($n=106$, 52%), abdominal pain ($n=30$, 15%) and abnormal liver function tests ($n=13$, 6%). During the study period 1224 patients (0.3%) entered the ER for jaundice, CCA accounted for 9% of those cases. Out of the 203 patients with CCA, 109 were male (53.7%), the mean age was 68 years (24-88). No patient had PSC, only 6 (2.9%) had cirrhosis, while 32 had diabetes (15.7%). The anatomical location of the identified CCA was intrahepatic in 21.6% of the cases, perihilar in 29%, distal in 26.6%, and gallbladder in 21%. Tumor staging was 1 in 27 (13.3%), 2 in 57 (28.1%), 3 in 29 (14.3%) and 4 in 90 patients (44.3%). Treatment of CCA could be analyzed in 135 patients, 51 patients (38%) received best supportive care, 43 received Chemotherapy (32%), while 41 underwent surgery (30%). The rates of surgery increased during the enrolment period however without reaching significant differences (19.7% in 2010-2011 vs 32.5% in 2016-2017, $p=0.3$).

Conclusion

CCA is a rare presentation in the ER, however with increasing incidence. CCA was found in 9% of all cases presenting with jaundice. Importantly, none of the identified CCA patients had PSC. Further, the low rate of patients with coexisting liver disease (2.9%), the high prevalence of advanced cancer stage (47%) as well as the low rate of surgical treatment (30%) reported by our study highlights the need for research in the field.

#837 - Abstract

DIRECTLY ACTING ANTIVIRALS ARE SAFE AND EFFECTIVE IN HCV ELDERLY PATIENTS

Maria Corina Plaz Torres¹, Francesca Colapietro², Rossella Meli¹, Massimo Colombo¹, Alessio Aghemo², Ana Lleo²

¹ Humanitas Clinical and Research Hospital, Milano, Italy

² Humanitas University, Milano, Italy

Background

Treatment of chronic Hepatitis C (HCV) with directly acting antivirals (DAAs) can lead to sustained virological response (SVR) in nearly 95% of patients. Treatment efficacy and safety in elderly patients has not been extensively studied.

Methods

We retrospectively analyzed treatment efficacy and safety in HCV patients ≥ 80 years of age who consecutively received DAAs at the Humanitas Research Hospital between 2015 and 2018. DAAs were given following the EASL recommendations.

Results

During the study period 976 patients received DAA treatment in our center, 40 patients (4%) were ≥ 80 years old and were included in the study. Their mean age was 81.8 years (80-88), 25 patients were female (62.5%), HCV genotype 1b (29) and 2 (10) were the most prevalent HCV genotypes. Advanced fibrosis (F3-F4) defined by transient elastography was present in 21 (52.5%), six patients

had CPT score >A5 and 8 (20%) had previously failed IFN based treatment. Sofosbuvir based therapies (SOF/LDV, SOF/VEL and SOF + RBV) were given to 21 patients, Paritaprevir/Ombitasvir/Dasabuvir was used in 3, G/P in 7 and Grazoprevir/Elbasvir in 9. Concomitant medications were common in our cohort with 39 (97%) patients taking at least 1 drug and 23 (57,5%) taking 4 or more concomitant drugs. In 3 cases concomitant therapy had to be modified to start DAA treatment for potential significant Drug-Drug interactions. Five patients reported side effects during treatment, side effects were always mild, and no serious adverse events were reported, no patient discontinued treatment prematurely. Seven patients are still completing the follow-up and could not be assessed for SVR. In the remaining 33 patients a SVR was achieved in 32 (97%). The only treatment failure was a patient lost to follow-up after the End of treatment visit.

Conclusion

Our study shows that DAA treatment in HCV Patients older than 80 years of age is safe and effective. Due to high rate of comorbidities DDI need to be carefully assessed before starting treatment.

#871 - Abstract

AUTOIMMUNITY AGAINST TYPE I COLLAGEN IN ULCERATIVE COLITIS

Diliara Mukhametova¹, Diana Abdulganieva¹, Oleg Zinkevich², Nellya Saphina², Marina Koporulina², Alfiya Odintsova³

¹ Kazan State Medical University, Kazan, Russia

² Kazan State Medical Academy, Kazan, Russia

³ Republican Clinical Hospital, Kazan, Russia

Background

Immunological disorders play an important role in the pathogenesis of ulcerative colitis (UC). Collagen is the main component of the intercellular matrix of connective tissue. It can be assumed that the immune disorders leading to the production of autoantibodies to collagen play a role in the pathogenesis of UC.

The aim is to study the level of IgM and IgG to type I collagen (COL1) in UC.

Methods

We prospectively included 61 patients with UC and 30 healthy controls. Mean age in UC was 37±1,5 years and in control group – 30±1,5. Severity of UC was assessed by Mayo score: remission – 5, mild – 25, moderate – 26, severe – 5. Extraintestinal manifestations of UC were in 24 patients (39%). Level of serum IgM and IgG to COL1 was assessed by enzyme immunoassay.

Results

In active UC levels of IgM to COL1 was increased (0,17 [0,10; 0,20] mkg/ml) compared with healthy (0,09 [0,07; 0,12] mkg/ml; p<0,01). The difference between remission (0,1 [0,09; 0,19] mkg/ml) and exacerbation, remission and control group was not

detected (p>0,05). In patients with severe UC IgM to COL1 was 0,19 [0,18; 0,25] mkg/ml, which was higher than in moderate UC – 0,12 [0,08; 0,17] mkg/ml (p<0,05) and mild – 0,18 [0,11; 0,20] mkg/ml (p>0,05). There was a tendency to increase of IgM to COL1 in patients with extraintestinal manifestations (0,17 [0,10; 0,22] mkg/ml) than without them (0,12 [0,09; 0,18] mkg/ml).

The level of IgG to COL1 in active UC (24,69 [16,36; 99,12] mkg/ml) was higher than in the control group 11,36 [6,93; 19,83] (p<0,05) and remission – 13,15 [8,88; 26,21] (p>0,05). There was not revealed the difference of IgG levels depending on the severity of disease. There was a tendency to increase of IgG to COL1 in patients with extraintestinal manifestations (16,18 [9,46; 26,21] mkg/ml), than without them (12,78 [8,81; 28,31] mkg/ml).

There was increasing of ESR (r=0,36; p<0,05) and leukocytosis (r=0,32; p<0,05) with increase of IgM level to COL1.

Conclusion

In active UC the level of serum antibodies of class IgM and IgG to COL1 increased compared with healthy. The maximum increase was found in the group of patients with severe relapse and in the presence of extraintestinal manifestations.

#876 - Case Report

AUTOIMMUNE HEPATITIS - AN UNEXPECTED RECURRENCE

Paula Marques Ferreira¹, Marli Cruz², Sofia Ferreira³, Judit Gandara³, Helena Pessegueiro³, Jorge Daniel³, Vitor Lopes³

¹ Centro Hospitalar Vila Nova de Gaia / Espinho, Vila Nova De Gaia, Portugal

² Hospital da Luz Arrábida, Vila Nova De Gaia, Portugal

³ Centro Hospitalar Universitário do Porto, Porto, Portugal

Introduction

Autoimmune hepatitis (AIH) is a pathology caused by an immune disorder, that

may lead to liver fibrosis and cirrhosis. Despite timely and correct immunosuppressive therapy, AIH can progress unfavorably to decompensated cirrhosis with a worrying short-term mortality. In these situations, liver transplantation may be an effective treatment, with an expected survival rate of 75% at 10 years. The recurrence of AIH after transplantation may occur, and its frequency is variable and apparently independent of the immunosuppressive treatment used in the context of transplantation.

Case description

The authors present the case of a 30-year-old woman diagnosed with autoimmune liver cirrhosis (elevation of IgG and IgM Immunoglobulins, ANA 1/160 with mottled pattern and anti-gp210 positive) with 9 years of evolution. In 2013 she was hospitalized for decompensation of liver cirrhosis with no identified factor. She had ascites and was Child C and MELD 21. She was submitted to liver transplantation in the same year, without surgical complications.

In the first month she had cell rejection, according to graft dysfunction and hepatic histology. She presented normalization of the analytical profile after adjustment of therapeutic use of prednisolone, mycophenolate mofetil and tacrolimus. The patient maintained medication compliance (tacrolimus with adequate and stable levels and 2.5 mg prednisolone / day) and an always normal graft until October 2017, when she presented unexpected graft dysfunction with contemporary hepatic histology showing portal inflammatory infiltrate with hepatitis interface as well as portal fibrosis with some septa, results compatible with relapse of AIH. The dose increase of prednisolone to 60 mg / day was insufficient, so azathioprine was added, which also allowed a reduction in the dose of prednisolone and normalization of the graft at the end of 3 months.

Discussion

We are faced with an autoimmune disease prior to transplantation with evidence of relapse in the graft, which must be conformed by histology. Immunosuppressive treatment requires reintroduction of other immunosuppressants in addition to calcineurin inhibitors.

#880 - Case Report

PANCREATITIS DUE TO AN INTRA-GASTRIC BALLOON

Marine Pierson, Frederique-Estelle Etogo-Asse, Fazia Mana
Clinique Saint-Jean, Brussels, Belgium

Introduction

Obesity is an important world-wide problem which took epidemical proportions. Intra-gastric Balloons (IGB) are space-occupying devices in the stomach and one of many treatments for obesity. The advantage of IGB over surgery is the fact that they preserve the anatomy of the stomach and that it is reversible and safe. We report a case of pancreatitis due to an IGB.

Case description

A 20-years-old obese girl presented to the emergency with acute abdominal pain which started several hours before presentation, associated with nausea and vomiting. She used no medication, did not smoke and not drink alcohol. Her medical history was negative except for the placement of an IGB 5 months earlier. A blood test including calcium, triglycerides and autoimmune markers was unremarkable besides the isolated elevation of lipase. The CT-scan demonstrated a compression of the pancreatic body by the IGB, associated with a moderate acute pancreatitis of the tail of the pancreas. The IGB was removed by endoscopy the same day of admission. She recovered quickly and left the hospital pain free 2 days afterwards.

Discussion

IGB placement for the treatment of obesity is frequently used in spite of the moderate results on long term weight loss and this because of several advantages: it can be placed and removed

easily, it is reversible, no major surgery is necessary and it can often be done in patient who are not fit for surgery. Furthermore it is considered safe with a mortality of 0.05%. The most frequent side effect occur in the first hours/days of the placement with nausea, dyspepsia, pyrosis, vomiting and abdominal pain, usually responsive to supportive treatment and resolving spontaneously (up to 30 % of patients). However early removal can be necessary in persisting symptoms. Major side effects are rare and consists of gastric ulceration, intestinal perforation and balloon deflation with migration and bowel obstruction (<1%). Pancreatitis is rare and mostly described in case reports and case series and not always reported in review articles (Laing P, 2017). Most cases are mild and resolve quickly after removal of the IGB. However, removal does not always seem to be necessary (Alsohaibani FI,2019). Although it is thought that acute pancreatitis from IGB use is due to the mass effect from the balloon on the pancreas, it can occur at any time point after placement and can also occur in balloons filled with gas. In our patient a pressure of the balloon on the body of the pancreas could be seen on the CT-scan.

SEVERE POLYNEUROPATHY DUE TO VITAMIN B12 DEFICIENCY

Vera Seara, Sónia Da Costa Fernandes, Gonçalo R. Mesquita, Lilian Maia, Teresa Pinto
CHPVVC, Vila Do Conde, Portugal

Introduction

Polyneuropathy is associated with a wide range of causes, which can vary from the common diabetes mellitus and alcohol abuse, to the rare hereditary forms. It is often a manifestation of a systemic disease, so its presence should lead to a prompt investigation.

Case description

The authors describe the case of a 44-year-old male, with insidious onset of paresthesia in the feet and hands, bilateral and symmetrical, progressing for a year. He presented hypoesthesia with stocking-glove distribution and distal hyporeflexia, with no other neurological changes. The electromyographic study was compatible with severe sensory-motor polyneuropathy. Blood test showed serum cyanocobalamin (Cb) levels of 178 pg/ml, hemoglobin (Hb) 12.1 g/dl, MGV 106 fl, with hyper-segmented neutrophils on peripheral blood smear and positive anti-parietal cell antibodies.

The upper endoscopy performed revealed the presence of atrophic gastritis and an ulcerated pulp formation, which was biopsied. The anatomopathological exam enabled the diagnosis of a well differentiated neuroendocrine tumor (NET), type 1.

Treatment with parenteral Cb was started, with a marked improvement in neurological symptoms and an Hb of 14.8 g/dl and MGV of 86.5fl, after a month. Complete excision of the gastric lesion was crucial, with no signs of recurrence on endoscopic follow up at 6 months. The patient maintains follow up in endocrinology and neurology outpatient clinic.

Discussion

This case emphasizes the importance of increased suspicion in patients presenting with peripheral neuropathic symptoms. The thorough investigation led to the recognition of pernicious anemia and later to the rare diagnosis of a well differentiated gastric NET. Pernicious anemia is a rare form of anemia caused by Cb deficiency. It often presents with megaloblastic anemia and neurological disorders, the last often as the presenting symptom.

Cb deficiency neuropathy is a rare, debilitating disease, and an early identification and correction of Cb deficiency is essential in preventing long term complications that can account for significant morbidity. Delayed treatment permits progression of the anemia and neurologic complications; therefore, a timely diagnosis is pivotal in the prognosis.

Cb supplementation, however, does not cure the atrophic gastritis, which can progress to gastric cancer.

Type 1 NET are associated with chronic atrophic gastritis and frequently with pernicious anemia (65%). They account for 70-80% of all gastric NET.

IN SEARCH OF THE PRIMARY ABSCESS: A CLINICAL CASE OF CHRONIC APPENDICITIS

Yolanda De Sá Pereira¹, João Roque¹, Nuno Vieira Brito², Jorge Silova Ferreira², Maira Joao Gomes², Vitor Ramalhinho²

¹ Centro Hospitalar Universitário Lisboa Norte, Lisbon, Portugal

² Centro Hospitalar Universitario Lisboa Norte, Lisboa, Portugal

Introduction

Chronic appendicitis corresponds to 1% of all cases of appendicitis and has an atypical clinical presentation, being its diagnosis usually late and already in the presence of complications.

Case description

A 60 year old male recently released from prison without any previous diagnosis or chronic medication, and with past smoking and alcohol consumption, presented with complaints of asthenia and weight loss (15 kg in 4 months), associated with a 2-week history of constipation. At clinical examination the patient was emaciated, afebrile, with hepatomegaly, and a painless mass in the lower right abdominal quadrant. His laboratory finding showed, Hb 8.5g / L, ESR 62 mm, INR 1.33, Alkaline phosphatase 168 U/L, Gamma glutamyl transferase 68 U/L, Albumin 2.9 g/dL, Reactive Protein C 22.3 mg/dL, with no further changes. A Thoraco-Abdomino-Pelvic CT scan was performed, which identified 2 liver abscessed collections (17 cm of greatest diameter) and multiple fistulous trajectories with a starting point in the cecum region, and no thickening of the intestinal wall. Aspiration of the lesions were performed and empirical antibiotic therapy was initiated. Multisensitive *Escherichia coli* and Meticillin-resistant *Staphylococcus aureus* were isolated. Serologies of HIV, HBV and HCV were negative. Colonoscopy did not identify changes in the intestinal mucosa. Blood cultures, coproculture, eggs, cysts and

parasites in the faeces, the IGRA test, and assays of ANCA, AMA and alpha-fetoprotein were all negative. Fecal Calprotectin was elevated (2064 µg/g, reference <200). At the 30th day of antibiotic therapy, clinical improvement and favorable analytical response were observed. Comparative imaging was performed by CT scans that showed residual hepatic lesions without evidence of fistulas. Taking into account the clinical presentation and the findings of extensive fistulation of the vermiform appendix that resolved with antibiotic therapy, we established the diagnosis of Chronic Appendicitis.

Discussion

This case demonstrates how the diagnosis of Chronic Appendicitis can be complex, alerting to the need to include this entity in the differential diagnosis of nonspecific abdominal complaints, in order to avoid the complications that are frequently associated with it. It is also evident the need for a systematic review of the topic, in order to clearly define strategies for diagnosis and treatment.

¹ Humanitas University, Milano, Italy

² Humanitas Clinical and Research Hospital, Milano, Italy

Background

Non-invasive diagnosis of hepatocellular carcinoma (HCC) in cirrhotic patients requires demonstration of wash-in and wash-out on contrast-enhanced imaging. Recent studies have reported misclassification of mass-forming intrahepatic cholangiocarcinoma (MFCCC) as HCC. We aimed to analyze the contrast enhancement patterns of MFCCC and their association with prognosis, focusing especially on lesions mimicking HCC.

Methods

We retrospectively evaluated all consecutive patients with MFCCC who underwent surgery between 2007 and 2017. Patients with mixed HCC-MFCCC were excluded. Two expert radiologists reviewed preoperative CT and MRI. Full-nodule hyperenhancement in the arterial phase in conjunction with hypoenhancement in the portal/late phase was classified as an "HCC-like pattern". Imaging of MFCCCs with an HCC-like pattern was reviewed by an additional radiologist blinded to clinical data.

Results

The imaging studies of 92 patients were reviewed (18%

cirrhotics). All patients were investigated with multiphase CT and 85 with MRI. Twelve tumors (13%) showed full-nodule arterial hyperenhancement. Of these, four were hypoenhancing in the portal/late phase. Overall, 4/92 (4%) MFCCCs (4/45 in patients with cirrhosis/hepatitis, 9%) showed an HCC-like pattern accounting for misclassification as HCC on imaging review. HCC-like MFCCCs accounted for 9% of single tumors ≤ 50 mm. All HCC-like MFCCCs occurred in patients with cirrhosis or hepatitis, whereas only 47% of non-HCC-like MFCCCs did so ($p=0.053$). After a median follow-up of 29 months, 3-year survival was 62%. All patients with HCC-like MFCCCs are alive and disease-free (median 64 months).

Conclusion

MFCCC was misdiagnosed as typical HCC in 4% of all cases and in 9% of patients with single tumors ≤ 50 mm or with cirrhosis/hepatitis. Patients with HCC-like MFCCCs show a favorable survival. The risk of misdiagnosis should be considered prior to treatment planning.

ATYPICAL EPSTEIN-BARR PRESENTATION - CASE REPORT

Pedro Carlos¹, Ana Dionísio¹, Clara Jorge¹, Sónia Coelho¹, Catarina Chaves², Artur Gama¹, Leopoldina Vicente¹

¹ Centro Hospitalar Universitário Cova da Beira, Covilhã, Portugal

² Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal

Introduction

Epstein-Barr virus (EBV) is a widely disseminated member of the herpesvirus family, infecting up to 90% of the general population by the second decade of life. Infectious mononucleosis (IM) is the more frequent and recognizable presentation, with a triad of fever, generalized lymphadenopathy and pharyngitis. Mild liver involvement is common (80-90%), although clinical evident manifestations of hepatitis are infrequent and even more rarely, its sole presentation.

Case description

Woman, 66 years old, admitted to inpatient care with a 6-day duration clinical presentation characterized by asthenia, anorexia, postprandial vomit, right hypochondrial discomfort and intermittent fever with late-afternoon predominance. No mention of odynophagia, dysphagia or respiratory, genitourinary or other symptoms.

Previous relevant history of a probable unregistered episode of viral hepatitis 44 years prior and multiple hepatic cavernous haemangiomas with routine follow-up. No history of previous or recent usage of intravenous drugs or known hepatotoxic ingestion. No reference to known risk exposure.

On admission, mild hepatic involvement with cytolysis and cholestatic findings (AST 207, ALT 310, ALP 255, GGT 101, Total Bilirubin 0.8) and discrete elevation of c-reactive protein, abnormal

coagulation tests and thrombocytopenia. Clinical examination with no findings besides a mild hepatomegaly, anicteric without evidence of pharyngitis or lymphadenopathy.

Abdominal echography reveals only the cavernous haemangiomas previously found, no signs of splenomegaly. Further study concludes negative autoimmune markers, viral serology with positive EBV IgM and IgG antibody and HVA IgG antibody.

During hospital care, gradual remission of original symptoms with symptomatic treatment and supportive care. No complications besides mild transient increase of cytolysis and cholestatic pattern during the first week of stay and maintenance of intermittent fever until 48h before discharge (after 11 days).

Discussion

EBV primary infection frequently assumes a typical IM presentation, although its frequent liver involvement as a mild, self-limited and predominantly cholestatic pattern injury makes this an entity to be considered in the differential diagnosis of febrile anicteric cholestatic illness in immunocompetent adults, even in the rare cases with an atypical presentation such as described here. Therefore, an early investigation for EBV in these patients can promote a more expedite diagnosis and treatment in such cases.

AMINOPHYLLINE SIDE EFFECT AS A RARE CAUSE OF CHRONIC DIARRHOEA: THE IMPORTANCE OF A CAREFUL HISTORY

Bruno Mendes^{1,2}, Carlos Figueiredo^{1,2}, Jose Sousa^{3,2}, Mariana Cabral^{3,2}, Catarina Pires^{3,2}, Tiago Pack^{3,2}, Afonso Rodrigues³, Teresa Garcia^{3,2}, Alexandra Mineiro^{1,2}, António Guerreiro^{3,2}, João Cardoso^{1,2}

¹ Pulmonology Department - Hospital Santa Marta, CHLC, Lisboa, Portugal

² Faculdade de Ciências Médicas, Universidade NOVA, Lisboa, Portugal

³ Internal Medicine Department - Hospital Santa Marta, CHLC, Lisboa, Portugal

Introduction

Chronic diarrhoea could be defined as persistent alteration of stool consistency and increased frequency greater than 4 weeks duration. Aminophylline is rarely associated with diarrhoea. We present a clinical case of difficult control chronic diarrhoea, where complementary diagnostic exams were inconclusive, and only a methodical review of clinical history allowed diagnosis.

Case description

81 year-old female, medicated with valsartan, furosemide, indacaterol/glicopyrronium and aminophylline. Known history of arterial hypertension, chronic obstructive pulmonary disease and heart failure. The patient went to emergency room because of 2 months weakness and diarrhoea, described as 3 to 4 defecations day of watery stool, with no blood or mucus. She lost 4 kilograms during this period. The patient didn't realize any change in diet or

medication. At examination she was hypotensive and dehydrated with no fever or abdominal pain during palpation. Abdominal radiography was clear. Laboratory exams revealed hypokalaemia and acute kidney lesion due to dehydration. During 2 weeks stay in internal medicine department she was medicated with valsartan, inhaled bronchodilators and intravenous fluid replacement. No diarrhoea or fever was ever recorded. Thoracic abdominopelvic computed tomography and colonoscopy were innocent. Biopsies of cecum mucosa showed the possibility of a microscopic colitis. The patient started rifaximin and mesalazine and was discharged with the same medication previous to admittance. She returned after three weeks of persistent symptoms, with new hypokalaemia. A detailed clinical history and records consultation was done. We found that aminophylline 225 mg oral was started, after a pulmonology consultation, two months before first admittance to hospital. This period was coincident with the beginning of diarrhoea. The fact was never mentioned by the patient. Aminophylline was never given during hospital stay. Aminophylline, rifaximin and mesalazine were suspended. Since one year no further diarrhoea was recorded.

Discussion

Diarrhoea as aminophylline's side effect was described in less than 1% of patients. The wide range of conditions that may lead to diarrhoea make it difficult to establish an investigation pathway. Nevertheless, clinical history is always the first and most important step in the diagnostic approach. Often patients are not able to give a detailed clinical history and a meticulous study of the clinical records is needed.

#982 - Abstract

PERIOSTIN ROLE IN LIVER CARCINOGENESIS

Carla De Benedittis, Mattia Bellan, Mauro Grandi, Violante Mulas, Martina Crevola, Rosalba Minisini, Martina Costanzo, Matteo Nazzareno Barbaglia, Venkata Ramana Mallela, Mario Pirisi
Università del Piemonte Orientale UPO, Novara, Italy

Background

Human Hepatocellular Carcinoma (HCC) represents a growing threat in developed countries, being the second leading cause of cancer-related death. The majority of HCC cases (90%) develops in the context of a chronic liver disease (CLD). Periostin is an extracellular matrix protein, which has been recently proposed as a promising determinant of liver disease progression from CLD.

Aim of the present study was to investigate the possible role of periostin plasma levels as an early marker of HCC development in patients with CLD and to evaluate the impact of three periostin gene (POSTN) single nucleotide polymorphisms (SNPs) on CLD and circulating Periostin levels.

Methods

A total of N.=399 cases (N.=247 HCC, N.=74 HCV and N.=78 NAFLD patients) and N.=104 healthy controls were genotyped for

POSTN gene SNPs with restriction fragment length polymorphisms technique and a haplotype analysis was performed. An ELISA assay was performed on available serum samples in all the 4 groups to determine circulating Periostin concentrations. Clinical data were collected for the whole population.

Results

The genotype and haplotype analysis found 7 haplotypes, of which haplotype 2 was the most prevalent. A dominant model for haplotype 2 was built and analysed in the different groups: in patients with CLD haplotype 2 was more prevalent than in those with HCC, nearly touching statistical significance (84.% vs 76.1%; p=0.053).

The median circulating periostin was 31.9 ng/ml (21 – 50.1) in HCC group, 11.4 ng/ml (9.1–16.5) in the HCV group, 10.1 ng/ml (7.1–13.8) in the NAFLD group being, therefore significantly higher in patients with HCC than in case of CLD alone (p<0.001). The carriers of haplotype 2, according to a dominant model, showed a lower periostin plasma levels (14.5 [9.6-21.4] ng/ml vs. 18.8 [10.7-30.4] ng/ml for 2/*+2/2 vs. */* respectively; p=0.02).

Conclusion

Periostin is a promising marker of HCC among CLD patients; moreover, the presence of POSTN haplotype 2, in a dominant model, might confer protection from progression to HCC, being associated to a lower periostin plasma concentration.

A CASE OF MULTIPLE KLEBSIELLA LIVER ABSCESES: A HISTORY TO BE CONTINUED?

Mariana Brandão, Telmo Borges Coelho, Maria Alves, Paula Ferreira, Manuela Sequeira, Vítor Paixão Dias
Centro Hospitalar Vila Nova de Gaia/Espinho, Vila Nova De Gaia, Portugal

Introduction

Liver abscess (LA) is usually caused by enteric gram-negative bacilli. LA typically occur in the presence of predisposing factors, such as biliary tract disease, surgery or peritonitis. An association between Klebsiella LA (KLA) and gastrointestinal (GI) malignancy was suggested in retrospective studies, mainly in Asia.

Case description

A previously asymptomatic 63-year-old man, with prior smoking and alcoholism, presented to the emergency room with a 2-day-history of fever, shivering, anorexia and abdominal pain in the right upper quadrant. He denied other GI symptoms, choloria or pruritus. He also denied previous abdominal surgery, contact with cattle or contaminated water, recent travel or risky sexual behavior. On examination, he had tenderness in the right hypochondrium and a palpable liver edge. Laboratory testing revealed normocytic normochromic anemia (Hb 11.6 g/dl) and elevated C reactive protein (10.5 mg/dl), without liver cytolysis or cholestasis. Abdominal tomography (CT) showed periportal

edema and countless millimetric hypocoaptant thin-walled hepatic lesions (Figure 1), suggestive of microabscesses, without evidence of biliary disease (BD). Empirical therapy with Ceftriaxone and Metronidazole was initiated. Blood cultures (BC) were positive for *Klebsiella oxytoca*. Additional serologic tests and viral markers were negative. Transthoracic echocardiogram was negative for vegetations. The patient gradually improved, and BC became negative. Upon discharge, 2 weeks after, multiple lesions without halo persisted on CT. Hence, he was referred to our Day Hospital Unit for clinical and imaging reevaluation and endoscopic screening for colorectal disease (CRD) [results pending]. Cefuroxime was prescribed to complete 6 weeks of antimicrobial therapy.

Discussion

In this case, LA presents without an apparent causal mechanism, with an unusually reported agent in European countries. Still, the patient had a history of alcoholism, a risk factor for *Klebsiella* infection. CT was remarkable for typical findings in KLA, such as thin-walled lesions without halo. However, KLA are usually solitary, and countless lesions were observed here. Given the absence of hepatobiliary disease, the possibility of concurrent CRD was considered, and the patient was referred for endoscopy. In previous studies, patients with LA caused by *Klebsiella pneumoniae* had a stronger association with subsequent colorectal cancer. Therefore, in patients with KLA without underlying BD, wary screening for CRD is encouraged.

AUTOIMMUNE ATROPHIC GASTRITIS: A CASE REPORT

Carolina Nunes Coelho, Iuliana Cusnir, Diana Vital
Hospital de Santarém, Lisboa, Portugal

Introduction

Autoimmune Metaplastic Atrophic Gastritis (AMAG) is a form of chronic gastritis associated with autoantibodies against parietal cells, which can lead to vitamin B12 malabsorption. It is a rare condition, generally asymptomatic, and therefore a challenging diagnosis to the clinicians.

Case description

The authors presents a case of a 71 years old man with type 2 diabetes, arterial hypertension and dyslipidemia. At admission in the emergency department he presented with symptom of fatigue with several weeks long, and routine blood analysis with anaemia. Therefore he was hospitalised in our Internal Medicine ward to further investigation. Laboratory testing reveal low valor of hemoglobin (9.2 g/dL, with high valor of VGM), leucopenia ($25 \times 10^9/L$ with 35.6% of neutrophils) and trombocitopenia ($78 \times 10^9/L$). Reticulocyte were above the normal range. Other laboratory findings disclose a very low level of vitamin B12 <83 pg/ml (normal range 187-883 pg/ml), with normal folates and iron metabolism. He was positive for antiparietal cell antibodies but

negative anti-intrinsic factor antibodies. The patient underwent endoscopy examination which revealed diffuse atrophy of the gastric mucosa, with no suspicious lesions. Biopsy samples were endoscopically taken from antrum and gastric body and showed chronic gastritis with severe atrophy and intestinal metaplasia, consistent with AMAG findings. *Helicobacter pylori* testing was negative. Thyroid function was normal and there was no signs of vitiligo. It was initiated vitamina B12 correction and the patient was discharged with oral cyanocobalamin supplements. About 3 months later, the patient was reassessed in hospital consultation with no symptoms and new laboratory results showed normal level of hemoglobin, white cells and plaquets.

Discussion

This case report show the workup from unespecif symptom (fatigue) and anaemia to the diagnosis of a rare autoimmune disease. The diagnostic criteria have not yet been established, moreover the diagnosis of AMAG is made on laboratory testing, endoscopic examination, and biopsy results. AMAG is frequently associated with others autoimmune pathologies, but not presented in this case. The patient is still ongoing being monitored because of associated risk with gastric cancer.

UPPER GASTROINTESTINAL BLEEDING: ARE PATIENTS WITH LOW LEVEL HEMOGLOBIN ANY DIFFERENT?

Carolina Nunes Coelho, Bruna Nascimento, Ana Garrido Gomes, Iuliana Cusnir, Bruno David Freitas, Marta Guisado Orantos, Maryna Telychko, Diana Vital, Stela Calugareanu, Sandra António
Hospital de Santarém, Santarém, Portugal

Background

Upper Gastrointestinal Bleeding (UGB) is defined as mucosal bleeding from the proximal portion of the esophagus to the ligament of Treitz, with a high global mortality rate. Level of hemoglobin at admission is a valuable contribution to the risk stratification of clinical outcome. Objective: We aim to analyse the group of patients with an hemoglobin level at admission <8g/dL, within all cases diagnosis of UGB hospitalized in an Internal Medicine (IM) ward.

Methods

The authors consider all patients with the diagnosis of UGB hospitalized in a IM ward between january and december 2018. Through revision of clinical electronic data, we evaluated the following variables in both groups: age, sex, comorbidities, ambulatory medication, endoscopic findings, medical intervention, hospitalization length.

Results

There were a total of 38 cases with UGB hospitalized in our IM ward in 2018. The median age of the patients was 75.1 years, and

the majority were men (68.4%). Twenty cases (52.6%) presented to the emergency department with a hemoglobin level lower than 8g/dL. Average age was equal in both groups, however patients which presented with lower hemoglobin were more frequently women (45.0% vs 16.7%). The clinical presentation was also different between both groups, melenas were present in 70% of the patients who was admitted with Hb <8g/dL, and only in 44.4% of the remain. In this group of patients there was a higher history of anticoagulant therapy (35% vs 16.7%). However, the antiplatelet agents were used by 50% of the patients with higher hemoglobin level at admission, in comparison with 20% of the rest. The average Glasgow Blatchford Score (GBS) in the group with <8 g/dl of hemoglobin was 14.0 and 10.2 in the group with higher level of hemoglobin. The endoscopic examination was more frequently done in patients with lower hemoglobin (90%) than with cases with >8g/dl of hemoglobin (77.8%) Patients with a lower hemoglobin level had a prolonged length of hospital stay (13.2 days in opposition to 8.7 days). There was only one death in-hospital and it was a patient who presented a 5.7 g/dL level of hemoglobin at admission.

Conclusion

The studied group of patients with the diagnosis of UGB with hemoglobin <8g/dl at admission were more frequently women, presented more often with melenas, and taking anticoagulant therapy. Also, the GBS score was higher and had a longer hospital stay.

#1015 - Abstract

ONE YEAR HISTORY OF UPPER GASTROINTESTINAL BLEEDING

Ana Garrido Gomes, Carolina Nunes Coelho, Bruna Nascimento, Bruno David Freitas, Iuliana Cusnir, Marta Guisado Orantos, Maryna Telychko, Diana Vital, Stela Calugareanu, Sandra António Hospital de Santarém, Santarém, Portugal

Background

Upper Gastrointestinal Bleeding (UGB) is a common medical emergency, with a high global mortality rate. The correct initial evaluation of these patients and therapeutic management still a clinical challenge.

The objective is to evaluate the cases with the diagnosis of UGB hospitalized in an Internal Medicine (IM) ward.

Methods

The authors consider all patients with the diagnosis of UGB hospitalized in a IM ward between January and December 2018. Through revision of clinical electronic data, we evaluated the following variables: age, sex, comorbidities, ambulatory medication, endoscopic findings, medical intervention, hospitalization length and outcome. The Glasgow-Blatchford scoring (GBS) system was calculated with clinical and laboratory data in the emergency department (ED).

Results

There were a total of 38 cases with UGB hospitalized in our IM ward in 2018. The median age of the patients was 75.1 years, and the majority were men (68.4%). Ten patients were previously anticoagulant users and n=13 patients were taking anti-platelet drugs. Five patients were described as having a prolonged history of NSAIDs intake. Six patients had a history of previous admissions with UGB and four had chronic hepatic disease diagnosed at an early stage. At the ED, 57.9% of the patients had melena and 36.8% had hematemesis. The mean value of hemoglobin was 8.39 g/dL. The average GBS score at admission was 12.2, with a minimum value of 5 and maximum of 16. In regard to medical treatment, 89.5% were prescribed a perfusion of proton-pump inhibitor. The majority of the patients (71.1%) required blood transfusion and 23.7% underwent plasma transfusion. Endoscopy is the primary tool for diagnosis and treatment. Only 26.3% of the endoscopic exams were performed in the first 24 hours since admission. The most common endoscopic findings were gastric (n=11) and duodenal ulcer (n=9), with two patients having esophageal varices. The endoscopy did not reveal the specific site of hemorrhage in 23.7% of the cases. None of the patients were submitted to surgical treatment. We obtained a medium in-hospital stay of 11.0 days. The in-hospital mortality was 2.6% (n=1).

Conclusion

The studied population showed increased age, major medical conditions, previous antithrombotic therapy and high clinical risk at presentation. It is necessary to improve management of these patients with early therapeutic endoscopy medical treatment to reduce the risk of life threatening bleeding and decrease mortality.

#1074 - Abstract

INTRAMUSCULAR DICLOFENAC AS PROPHYLAXIS FOR POST-ERCP PANCREATITIS

Luis Fernando Sandoval, Gerson Emir Avila, Abel Sánchez Hospital Roosevelt, Guatemala, Guatemala

Background

Post-ERCP pancreatitis (PEP) is one of the potentially serious complications of this procedure; in general population it occurs in approximately 1% to 10% of patients, but most cases are mild or moderate. Several studies have demonstrated the safety and efficacy of NSAIDs in the prevention of PEP. However, most of these trials have used the rectal route and it is not clear whether the parenteral route of administration is as effective as the rectal route.

Methods

We proceeded to take the data of all patients scheduled for ERCP in the Gastroenterology Unit of Hospital Roosevelt, during the months of March and April of 2019. After the procedure they were followed up for 24 hours looking for signs of acute pancreatitis. If suspected, it was confirmed and the complication was managed.

Results

A total of 42 patients were included, which were randomized in the study group - 18 (diclofenac 75 mg) and control group - 24 (0.9% saline). Two patients presented PEP, which is equivalent to 4.76% of the sample. The use of intramuscular diclofenac was not statistically significant among the patients studied. The only value that showed difference was the white blood cell count.

Conclusion

There is no difference between the events of acute pancreatitis in patients undergoing ERCP with the use of diclofenac 75mg intramuscularly.

SEVERE HYPOMAGNESEMIA INDUCED BY CHRONIC USE OF PPI

Antonio Eliseu, Teresa Furtado, Paula Lopes, Filipa Silva, Lucia Gil, Rita Silverio, Ermelinda Pedroso

Centro Hospitalar de Setúbal, Setúbal, Portugal

Introduction

Proton pump inhibitors are a pivotal therapy for all gastric acid-related diseases. The chronic use of PPI (> 1 year) have been described in small numbers of case reports to induce hypomagnesemia. The presumed mechanism is impaired absorption of magnesium by intestinal epithelial cells. Severe hypomagnesemia is rare, being generally asymptomatic until reaching serum levels < 1.25 mg/dL. Symptomatic magnesium depletion is usually associated with biochemical abnormalities such as hypocalcemia and hypokalemia. The major clinical manifestations are neuromuscular, cardiovascular and abnormalities of calcium metabolism. Very low levels of magnesium lead to a hypoparathyroidism state and parathyroid hormone resistance.

Case description

Male, 64 years old

Past medical history: Hypertension, DM type 2 and GERD.

Medication history: ARB+Thiazide, Beta Blocker, PPI (> 1 year), Aspirin and metformin.

The patient was admitted in the emergency room with altered level of consciousness associated with tonic clonic seizures. He also complained of thoracic pain, hemisensory loss in the left arm, nausea and vomiting and had history of muscle cramps for the last 6 months. His laboratory evaluation revealed a hypocalcemia (6.2 mg/dL), hypokalemia (2.6 mmol/L) and a severe hypomagnesemia (<0.7 mg/dL). The ECG had a Long-QT and Head-CT had no pathological features. It was initiated electrolyte replacement therapy (Magnesium Sulphate, Calcium Gluconate and Potassium Chloride) and the patient was moved to Internal Medicine ward. More laboratory studies were done showing a serum PTH low-normal level and a 24h urine sample with low urinary magnesium level. After a couple of days of magnesium repletion, the PTH levels

showed a rapid rise and magnesium, calcium and potassium levels reached normal values. It was admitted a severe hypomagnesemia induced by the chronic use of PPI. The use of PPI was suspended and initiated ranitidine in substitution. The patient was discharged and reevaluated being asymptomatic and with normal levels of magnesium.

Discussion

We should suspect of hypomagnesemia when patients present with hypocalcemia and hypokalemia of unknown etiology, especially if they are being refractory to electrolyte replacement. In patients with chronic use of PPI measurement of magnesium serum levels is recommended before treatment initiation and periodically. Hypomagnesemia resolves with cessation of PPI therapy.

PANCREATIC LIPOMA, AN UNUSUAL FINDING

Carla Pereira Fontes, José Moura Meireles

Centro Hospitalar de Entre o Douro e Vouga (CHEDV), Santa Maria Da Feira, Portugal

Clinical summary

A 45-year-old man, with no significant comorbidities, presented with epigastric discomfort and vomiting of 2-hour duration. Beyond epigastric tenderness, physical examination was unremarkable. Laboratory evaluation, including liver function tests and pancreatic enzymes, was normal. Considering his persistent complaints, an abdominal computed tomography was performed and a 15 mm fat containing lesion in the pancreatic body was noted.

Pancreatic lipoma is a rare and benign mesenchymal tumor, consisting of adipocytes. It's commonly asymptomatic appearing as an incidental mass during screening, and usually managed in a conservative way with radiologic monitoring; surgery treatment is only offered when it's causing symptoms, compressing on vital structures, or if any malignant changes occur.

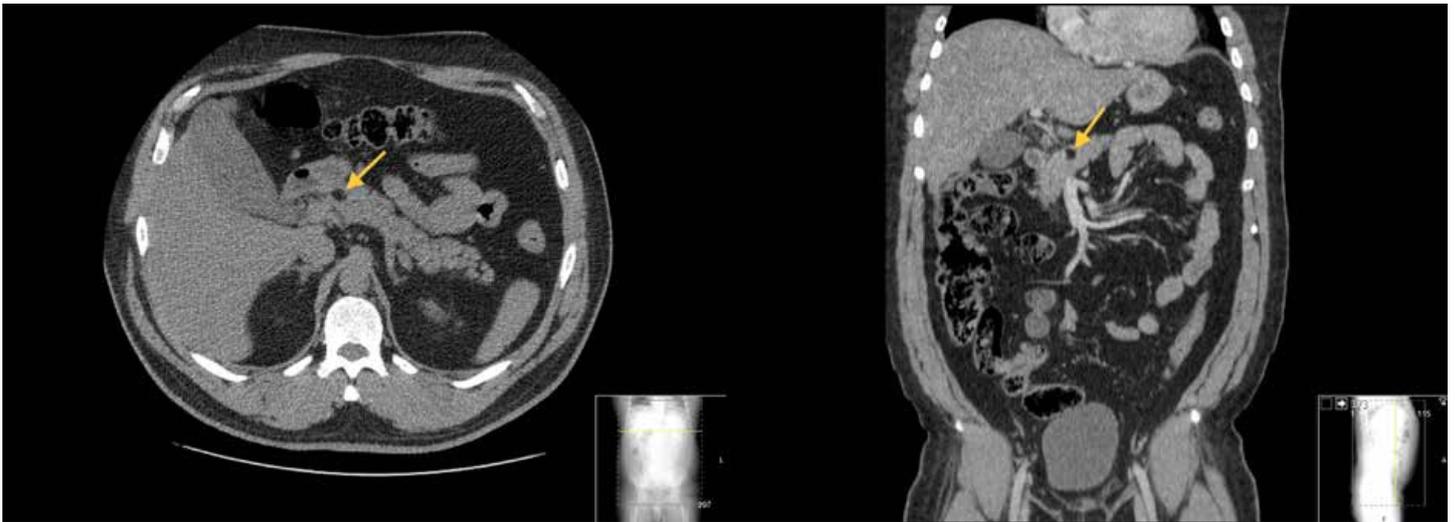

Figure #1101. Lipoma of the pancreatic body on the transverse (left) and coronal (right) contrast-enhanced computed tomography scan: a 15-mm, round, fatty, nonenhancing mass circumscribed by normal parenchyma (arrows).

#1107 - Case Report

MACROCYTIC ANEMIA DUE TO VITAMIN B12 DEFICIENCY: DO NOT OVERLOOK CELIAC DISEASE

Annelies Meuwissen¹, Gil Verschelden¹, Shaira Sahebali², Sabine D. Allard¹, Rembert Mertens¹, Patrick Lacor¹

¹ UZ Brussel, Department of Internal Medicine, Brussels, Belgium

² UZ Brussel, Department of Anatomopathology, Brussels, Belgium

Introduction

The causes of Vitamin B12 deficiency include disorders affecting absorption in the small bowel. Among these is celiac disease. The mechanism is not completely understood and probably multifactorial. It is hypothesized that decreased pancreatic protease production resulting in inhibition of binding of intrinsic factor to vitamin B12 might be involved.

Case description

A 45-year-old male was admitted to the hospital because of general weakness, lowered exercise tolerance and vague epigastric pain. On physical examination, he appeared pale and slightly icteric. Blood analysis revealed a macrocytic anemia (hemoglobin 7 g/dl, MCV 116 fl), with a normal white blood cell count and differential, and a slight thrombocytopenia ($149.000/\text{mm}^3$). There were signs of hemolysis (serum unconjugated bilirubin 2.14 mg/dl, LDH 5510 IU/l, haptoglobin <0.10 g/l) with a negative direct antiglobulin test. Vitamin B12 serum level was unmeasurably low (<0.1 µg/l), folic acid in serum and red blood cells was normal, as well as serum ferritin (181 µg/l). Auto-antibodies to intrinsic factor and parietal cells were negative. Measurement of immunoglobulin levels showed selective IgA deficiency. Serum tissue-transglutaminase IgA antibodies were absent, serum anti-deamidated gliadin peptide-IgG was positive. Gastric endoscopy showed signs of duodenitis with duodenal villous atrophy Marsh-Oberhuber type 3b on biopsy, leading to a diagnosis of celiac disease.

Discussion

Although iron deficiency anemia is the most common extra-intestinal sign of celiac disease, vitamin B12 deficiency can also be involved in the pathogenesis of anemia in these patients. In our patient, it appeared to be the sole mechanism. This finding illustrates the importance of including celiac disease in the differential diagnosis of macrocytic anemia, even in the absence of iron deficiency.

#1122 - Abstract

CHANGES IN SERUM LEVEL OF KERATIN-18 (TPS) IN PATIENTS WITH CHRONIC HEPATITIS C WHO RECEIVED DIRECT-ACTING ANTIVIRAL THERAPY

Cristina Macía-Rodríguez¹, Emilio Paez-Guillán², Alba García-Villafranca², Ana Teresa Afonso², Esteban Otero², Santiago Tomé², Arturo González-Quintela²

¹ POVISA, Vigo, Spain

² Complejo Hospitalario Universitario Santiago de Compostela, Santiago De Compostela, Spain

Background

Hepatocytes apoptosis plays an important role in the pathogenesis of chronic hepatitis C and in the development of liver fibrosis. Keratin-18 is a major component of hepatocyte cytoskeleton. During the apoptosis is cleaved by caspases and its fragments (TPS) are released to the blood stream.

Methods

The study included patients with chronic hepatitis C treated with direct-acting antiviral therapy in the Internal Medicine Department of the Santiago de Compostela University Teaching Hospital (NW Spain) between 1 February 2015 and 1 February 2016. Serum K-18 (TPS) was measured before and after the treatment.

Results

We included a total of 149 patients, 68.5% men and median age 53.0 years (IQR: 46.0-58.0 years). 98.0% of the patients achieved sustained virological response 12 weeks after treatment. After treatment, we observed a significant reduction of serum TPS levels. 12 weeks after treatment, 51.7% of the patients presented an elevated TPS and 66.0% of them presented another cause of TPS alteration: 13 metabolic syndrome with mellitus diabetes or obesity, 11 were alcohol-consuming, 3 had a pharmacological hepatotoxicity, 2 presented a hepatocellular carcinoma, 4 had a carcinoma different than hepatocellular, 1 presented a recurrence of hepatitis C virus and 1 an autoimmune hepatitis.

Conclusion

After treatment we observed an improvement of K-18 fragments levels. A persistent elevation of K-18 fragments after treatment can indicate the coexistence of another liver damage.

#1166 - Medical Image

AN UNEXPECTED FINDING

Ana Filipa Pinho, Isabel Silva

Hospital de Braga, Braga, Portugal

Clinical summary

Klatskin tumors are cholangiocarcinoma of the hepatic hilar duct bifurcation, that have distinct biological behavior, natural history and therapeutic strategy from distal cholangiocarcinoma. Risk factors are primary sclerosing cholangitis, biliary calculi and parasitic liver disease. The absence of early symptoms explains the advanced stages at diagnosis. An 86-year-old woman performed a thoracic CT scan to rule out pulmonary thromboembolism. Incidentally it was found a dilated intrahepatic bile duct with an hyperdense area in the biliary duct bifurcation of 15 mm (CT scan - images 1-2, MR cholangiopancreatography 3-4). Diagnosis: Bismuth-Corlette type II Klatskin Tumor. The advanced age and multiple comorbidities determined that the patient was not a candidate for surgery.

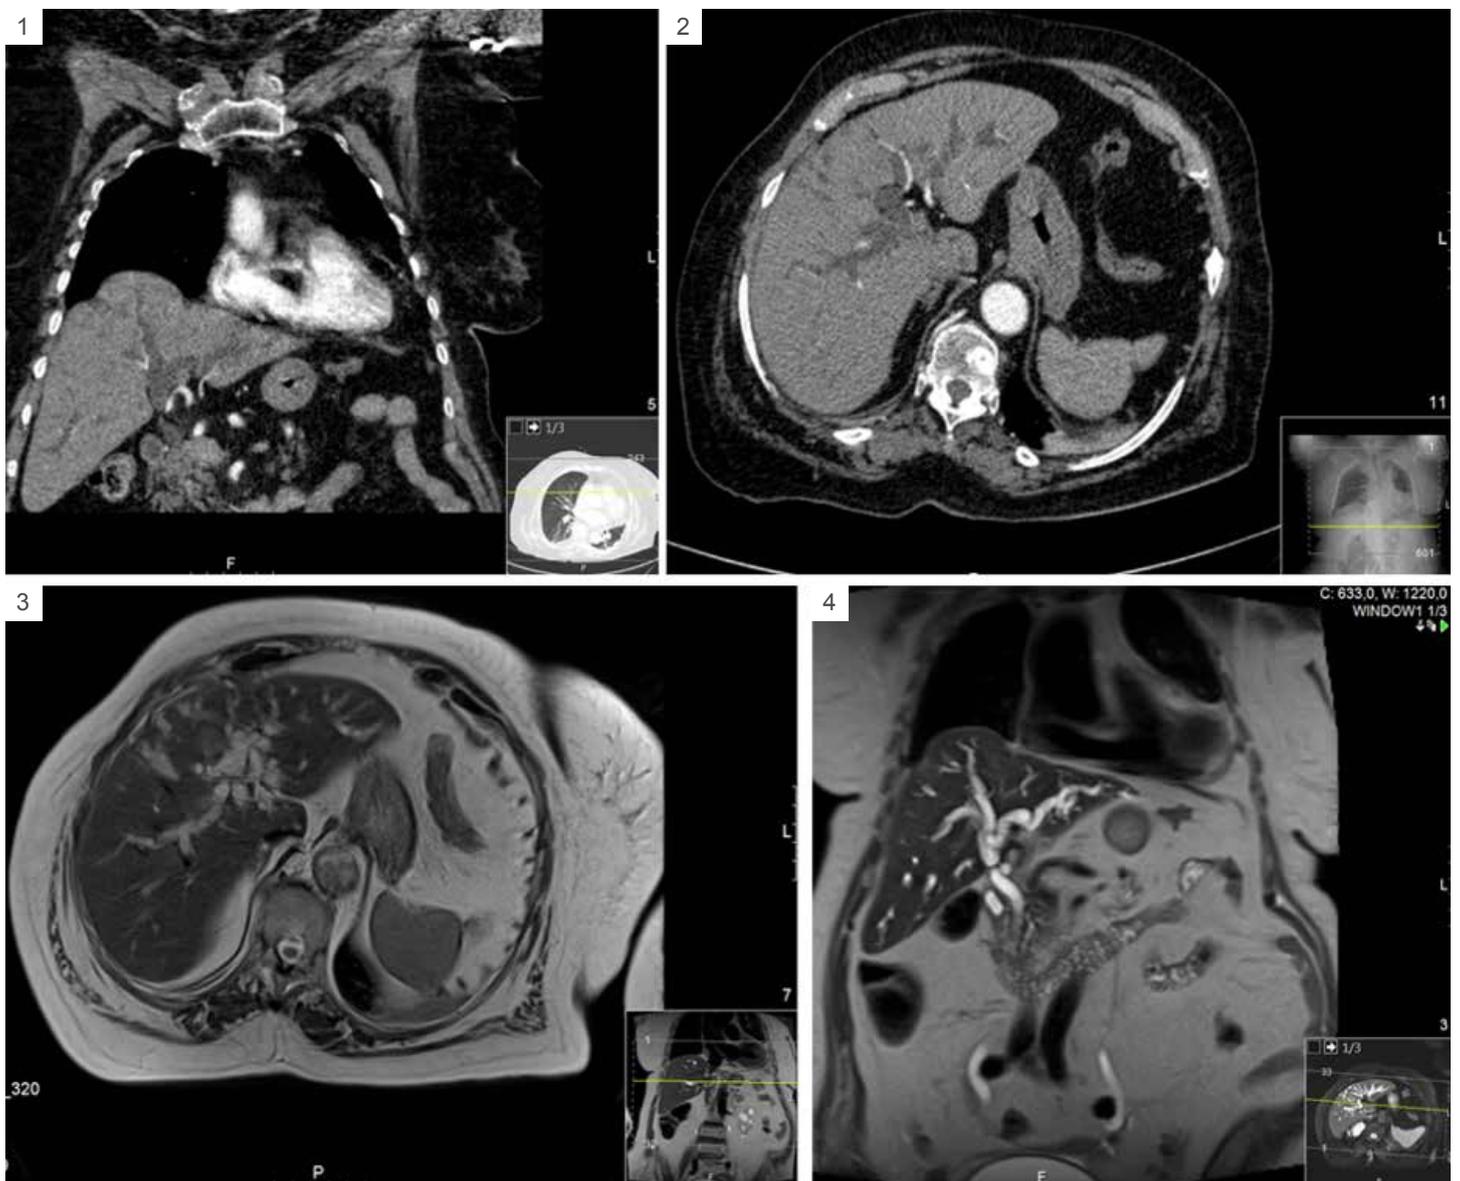

Figure #1166. Above - 1 and 2 - CT scan. Below - 3 and 4 - RM cholangiopancreatography.

#1174 - Abstract

SERUM KERATIN 18 FRAGMENTS (TPS) ARE RELATED TO LIVER FIBROSIS IN PATIENTS WITH CHRONIC HEPATITIS C

Cristina Macía-Rodríguez¹, Emilio Paez-Guillán², Alba García-Villafranca², Ana Teresa Afonso², Esteban Otero Anton², Santiago Tomé Martínez De Rituerto², Arturo González-Quintela²

¹ POVISA, Vigo, Spain

² Complejo Hospitalario Universitario de Santiago de Compostela, Santiago De Compostela, Spain

Background

Hepatocytes apoptosis plays an important role in the pathogenesis of the disease and in the development of liver fibrosis. Keratin-18 is a major component of hepatocyte cytoskeleton. During the apoptosis keratin-18 is cleaved by caspases and its fragments (TPS) are released to the blood stream.

Methods

We included patients with chronic hepatitis C. We measured serum TPS and performed a transient elastography and we calculated the fibrosis biomarkers score APRI and FIB-4. We used Spearman's rank test (for bivariate correlation) to analyze the relation between the variables, and COR curves were used to evaluate the capability of TPS and biomarkers score to predict liver stillness. We considered $p < 0.05$ to be statistically significant.

Results

We included a total of 111 patients, 67.6% men and median age 52.0 years (IQR: 46.0-57.0 years).

Serum TPS levels were significant correlated with liver stillness ($\rho = 0.47$). We plotted ROC curves to evaluate if TPS or biomarkers score could predict liver stillness. The area under the ROC curve (AUC) for discriminating severe fibrosis (more than grade 3 using transient elastography, $F \geq 3$) was 0.75 (CI 95% 0.65-0.84) with TPS, 0.77 (CI 95% 0.69-0.87) with Fib-4 and 0.80 (CI 95% 0.72-0.89) with APRI. The cut-off point at 140 U/l of TPS predicted $F \geq 3$ with a sensibility of 80.6 % and a specificity of 54.5%. The cut-off point at 1.5 of APRI predicted $F \geq 3$ with a sensibility of 45.5% and a specificity of 92.9%. The cut-off point at 3.25 of Fib-4 predicted $F \geq 3$ with a sensibility of 42.4% and a specificity of 85.7%

Conclusion

In conclusion, serum levels of K-18 fragments can be used to estimate liver fibrosis.

CROH'S FULMINANT DISEASE IN A VIH-1 PATIENT

Domingos Sousa^{1,2}, Sérgio Antunes Silva¹, Catarina Jorge¹, Rita Martins Fernandes¹, Ana Isabel Rodrigues¹, Margarida Viana Coelho¹, Rui Osório¹, Amparo Mingo¹, Elena Rios¹, Armindo Figueiredo¹

¹ Centro Hospitalar Universitário do Algarve, Faro, Portugal

² Faculdade de Ciências da Saúde - Universidade da Beira Interior, Covilhã, Portugal

Introduction

Crohn's disease (CD) is a chronic inflammatory disease of unknown cause, characterized by discontinuously affected areas with transmural granulomatous inflammation and/or fistula. CD can affect any region in the digestive tract from the mouth to the anus but is more likely to involve the small and large intestines (especially the ileocecum) and the perianal region. The inflammation is initiated and perpetuated by an overly aggressive T-cell-mediated immune response to an unknown environmental antigen in a genetically susceptible host. In the rare cases where CD and HIV infection coexist, it has been speculated that a progressive decline in CD4+ count, caused by HIV, might remit CD disease activity.

Case description

A 51-year-old woman with a past medical history of HIV-1 with a good immunological state (T-cell CD4+ 634 cells/mm³) and virologic suppression, diabetes mellitus type 2, former iv-drug user and active smoker was admitted with a 3-month history of weakness, intermittent diarrhoea and anorexia. Laboratory studies revealed elevation of inflammation markers and a microcytic hypochromic anaemia (6.0 g/dL) with evidence of iron deficiency. Colonoscopy revealed small ulcerations at the cecum and ascending colon. Biopsy of colonic mucosa described acute inflammation with cryptitis and cryptic abscess and was negative for helicobacter pilori. Coprocultures, Clostridium difficile and tissue transglutaminase (IgA and IgG) antibody were negative. Faecal calprotectin was elevated (6421 µg/g).

Patient's evolution was unfavourable with development of a septic shock with multiorgan failure being transferred to an intensive care unit and eventually dying.

Discussion

CD cardinal symptoms are chronic diarrhoea with abdominal pain that was present on our case. In addition, the histopathological findings and elevated faecal calprotectin further support the diagnosis of CD.

Our case highlights that HIV patients with a good immunological state can present with more aggressive CD because T-cell CD4+ play a major role on the pathophysiology of immune response in CD. CD is a result of a dysregulation of mucosal immune system with activation of mucosal T-lymphocytes and production of proinflammatory cytokines which leads to extensive mucosal or transmural injury which caused the patient's to develop a septic shock.

ANTI-HU SYNDROME - A TRULY RARE ENTITYFilipa Lucas¹, Miguel Alve², Tatiana Oliveira¹¹ Hospital de Cascais, Cascais, Portugal² ULS Nordeste, Bragança, Portugal**Introduction**

Chronic intestinal pseudo-obstruction (POIC) is a rare disorder characterized by partial/total absence of gastrointestinal propulsion.

This entity may be idiopathic or secondary to infections, drugs, paraneoplastic syndromes, etc. Of these, we highlight the anti-Hu syndrome, which almost always appears in a paraneoplastic context, and is mediated by autoantibodies, which react against neuronal proteins. Anti-Hu antibodies correspond to an antineuronal antibody that recognizes a protein expressed in the nuclei of the neuron (ANNA-1) and neoplastic cells.

In POIC these autoantibodies attack the intestinal nervous plexuses. The common genesis seems to be an immune disorder that conditions injury of the intestinal nerve plexuses with alteration of motor plaque transmission and subsequent aganglionosis.

Case description

Two clinical cases with early postprandial constipation and vomiting are presented, in which serology revealed anti-neuronal antibody anti-HU positivity.

The study of one case revealed a thymoma as an etiology. The other remains idiopathic, so screening for an underlying neoplasm remains an imperative, since there may be a 8 years delay between symptoms and tumor.

Discussion

Paraneoplastic CIPO is a very rare entity and is highly difficult to treat. Advances in functional studies and histological analysis have enabled a better understanding of the pathogenesis of this syndrome, which is defined as an enteric neuromuscular disorder that frequently involves various segments of the digestive tract. Screening for Anti-HU antibodies is recommended for diagnosing intestinal dysmotility associated with enteric ganglionitis.

The treatment of this entity is based on a symptomatic approach, using cholinergic, immunomodulatory, and prokinetic therapy, plasmapheresis, but without significant benefits.

We highlight these two highly rare and complex cases (about 30 cases reported in the literature), that pose several diagnostic and therapeutic challenges.

APPROACH OF ASCITES – THE IMPORTANCE OF MEDICAL HISTORY

Luciana Silva, Catarina Almeida, Ana Mondragão, Joana Cochicho, Luís Andrade, Vitor Paixão Dias

Centro Hospitalar de Vila Nova de Gaia e Espinho, Vila Nova De Gaia, Portugal

Introduction

Ascites is a frequent complication of cirrhosis but up to 20% of the cases are related to other conditions such as heart failure, nephrotic syndrome, malignant conditions, granulomatous diseases or infections.

Case description

A 42-year-old woman born in Angola, living in Portugal since 2002, presented to the emergency department with nonbloody diarrhea preceded by abdominal colic pain. The symptoms began 6 days before and were associated with vomiting. On the 3rd day, fever started and she noticed a gradual increase in abdominal girth. She mentioned asthenia and anorexia, without weight loss or night sweats. Her medical history was relevant to sickle cell trait and asthma.

At presentation, she was febrile with a swollen painful abdomen compatible with large ascites. The blood analyses revealed hemoglobin of 10,5 g/dl, no leukocytosis or thrombocytopenia, Na⁺ 130 mmol/L, LDH 426 U/L and C-reactive protein of 19,21 mg/dl. The abdominal US and abdominal CT showed ascites and increased density in mesenteric root's resembling peritoneal carcinomatosis.

She was admitted to the Internal Medicine ward for further evaluation. The peritoneal fluid (PF) analysis revealed 1528 leukocytes/uL 28% polymorphonuclear and 72% mononuclear, LDH 642 U/L, proteins 6.1 g/dl, ADA 255 U/L and serum-ascites albumin gradient was <1,1. Microbiological analysis of PF and Ziehl-Neelson (ZN) stain were negative. PET-CT reported hypermetabolic focus suggesting adenopathies, peritoneal lesions suggesting malignant infiltration and hypermetabolic focuses between the hepatic hilus, head of the pancreas and spleen. The peritoneal implants biopsy's revealed chronic inflammatory infiltrate that included epithelioid histiocytes with granuloma formation without necrosis.

Three weeks later the culture for mycobacteria came positive for Mycobacterium tuberculosis complex, leading to the diagnosis of peritoneal tuberculosis (TB). At this time, the patient revealed that she had pulmonary TB when she was in Angola. She started antituberculous treatment.

Discussion

TB is characterized by generic symptoms and involvement of a range of organs. The peritoneum is one of the extrapulmonary sites more frequently affected. The ADA elevation and the prevalence of mononuclear cells in PF led us to consider this diagnosis. However the negativity of ZN stain and the radiological suggestion of malignancy led to further evaluation.

Despite the effective treatment, there is still a social stigma associated with TB, hindering its control.

#1199 - Abstract

CORRELATION BETWEEN SYSTEMIC AND LOCAL INFLAMMATION IN INTESTINAL TRANSIT DISORDERSCristina Voicu¹, Sorin Rugina²¹ Sfântul Apostol Andrei, Constanta, Romania² Ovidius, Constanta, Romania**Background**

Chronic diarrhea is a challenge for the clinician as it has a significant impact on the overall health and quality of life. Statistically, an adult has at least five episodes of diarrhea per year.

Methods

81 patients were included in the Medical Clinic I and the Gastroenterology Department of Constanta Emergency County Hospital between October 2014 and October 2017 and had fulfilled the required criteria, respectively manifested transit disorders of the type diarrhea or alternating diarrhea/constipation of at least four weeks duration, excluding the infectious pathology. Out of the 64 patients 39 are men and 42 women aged 19 to 89 years. The batch of tests included biological investigations in the blood (blood count, inflammatory syndrome represented by the reactive C protein, velocity of sedimentation of red blood cells and fibrinogen, serum proteins), in faeces (coprocitogram, coproparasitologic, coproculture, calprotectin) and endoscopic investigations, respectively superior digestive endoscopy and endoscopic colonoscopy (biopsy where applicable).

Results

The average age was 54 years. A total of 31 patients with Crohn's disease, 7 patients with microscopic colitis, 7 patients with ulcerative haemorrhage colitis, 4 patients with celiac disease, 14 patients with colorectal neoplasms and 18 patients with irritable bowel have been diagnosed.

Depending on the complications, three stenosis forms, a stenosis-shaped form, and a complicated Crohn's disease with two fistulas (entero-enteral and entero-bladder) were diagnosed. Systemic inflammation is not correlated with intestinal inflammation, since in patients without systemic inflammatory syndrome, faecal calprotectin ranges from 79 mg/kg to 3,635 mg/kg, a value comparable to that of patients in whom the inflammatory syndrome is represented by the four measured components (leukocyte count, VSR, RCP and fibrinogen).

Conclusion

A correct assessment of intestinal inflammation can be diagnosed with pathologies with a high impact on health and quality of life at an early stage. It has been shown that systemic inflammation markers do not reflect intestinal inflammation and can not be used in quantification of inflammation. Using faecal calprotectin in diagnostic test batches for transit disorders, in particular chronic diarrhea, morbidity and mortality can be reduced by organic intestinal disorders, proving a high accuracy marker in assessing inflammation in the intestine.

BOWEL DYSFUNCTION IN MULTIPLE SCLEROSIS

Beatriz Porteiro, Mariana Costa, Rodrigo Moraes, Filipa Nunes, Whine Pedro, Marinela Major

Hospital Professor Doutor Fernando da Fonseca, Lisboa, Portugal

Clinical summary

Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system in which loss of neurological functions occurs due to an autoimmune demyelination. Often it leads to slowed bowel activity. We present a case of a 51-year old male with a MS diagnosis, that shows significant physical disability, presented with a subacute painful abdominal distention with a firm and mobile abdominal mass. There was no history of irregular bowel transit. Imagiological investigation revealed a giant fecaloma condition redistribution of mesenteric vascular structures and stomach collapse. After unsuccessful conservative measures the management plan was to proceed to surgery. A timely surgical intervention in fecal impactions may prevent perforation that is associated with high mortality.

Figure #1203. Computed tomography revealed the presence of a giant fecaloma condition redistribution of mesenteric vascular structures and stomach collapse.

#1215 - Abstract

ALCOHOL WITHDRAWAL SYNDROME AND CHRONIC LIVER DISEASE IN A THIRD LEVEL HOSPITAL

Néstor Vázquez Agra, Ana Teresa Marques Afonso, Martiño Vidal Vázquez, Jonathan Geovany Montoya Valdés, Lucía Barrera López, Hadrian Pernas Pardavila, María López Ródriguez, Ariadna Helena Andrade Piña, Ignacio Novo Veleiro, Lara Maria Mateo Mosquera

Clinical Hospital Of Santiago De Compostela, Santiago De Compostela, Spain

Background

Alcohol withdrawal syndrome (AWS) is a common alcohol-related diagnosis which consists of a set of signs and symptoms ranging from autonomic hyperactivation (nausea, vomiting and tachycardia), tremors and nervousness to more serious ones such as disturbances of perception, psychomotor agitation and convulsions. It represents a major cause for inpatient and ICU admission.

It is well known that alcohol dependence and consumption pattern are related to AWS and liver injury; and there is at least a clinical conviction that patients with chronic liver disease (CLD) suffer from less AWS. The aim of this study is to investigate the possible relationship between CLD and AWS.

Methods

We conducted an observational and retrospective study of patients with an alcohol related diagnosis admitted to a internal medicine service (Hospital of Santiago de Compostela, Galicia. Spain). They were included older than 18, non-diabetic, non-complex and non-polymedicated patients who were divided into 2 groups: with and without AWS (AWS/No AWS). Demographic, clinical, laboratory and image variables were collected. We performed a descriptive, univariate and multivariate data analysis with SPSS.

Results

Sample n=81 patients, median age (years): 54.0 (SD 10.5), women: 19 (23.5%), CLD: 25 (30.9%).

Comparisons between the two groups (AWS / No AWS) are shown below:

Univariate analysis:

Nominal variables [n (%): Age (<50): 24(46.2)/3(10.3) p = 0.001, gender (Female): 16(30.8)/3(10.3)

p=0.032, CLD: 9 (17.3) / 16 (55.2) p=0.001.

Quantitative variables [Mean (SD)]: Age (years): 52.2 (9.4) / 62.5 (9.1) p <0.001, Alanine amino transferase (ALT, mg/dl): 82.3 (87.4) / 44,2 (25.3) p = 0.008, direct bilirubin(mg/dl): 2.9 (3.3) / 1.7 (0.56) p = 0.037. Glucose(mg/dl) 124 (5.5) / 105.3 (25.3) p = 0.022.

Multivariate analysis: there was association between AWS and: Age (B= -1.28 OR = 0.880, 95% CI 0.81-0.95 p=0.001), gender (female) (B= 4.13 OR = 62.14, 95% CI 2.23-1725.66; p=0.015), CLD (B= -3.77 OR = 0.023, 95% CI 0.002-0.222, p=0.001), Total bilirubin (B=1,93 OR 6,94 95%IC 1,03-46,90 p=0,047) mean corpuscular volume (MCV) (B=0,116 OR = 1.12, 95% CI 1.03-1.24, p=0.005)

Conclusion

Our study suggests that patients with AWS may have less CLD than patients with another alcohol-related diagnosis. Being younger than fifty and woman could be an added risk factor for development of AWS. Higher MCV and total bilirubin were associated with more AWS. Further evidence is needed.

#1279 - Abstract

THE ROLE OF SPLEEN STIFFNESS IN PREDICTING ESOPHAGEAL VARICES IN PATIENTS WITH VIRUS-RELATED CIRRHOSIS

Razvan Peagu, Sararu Roxana, Carmen Fierbinteanu

University Emergency Hospital Bucharest, Bucharest, Romania

Background

Current guidelines recommend that all patients with cirrhosis undergo upper gastrointestinal endoscopy (UGE) screening for esophageal varices (EV). Unfortunately, UGE is an expensive, time consuming method that is not well tolerated by patients. We evaluated if spleen stiffness measured using Acoustic Radiation Force Impulse (ARFI) is a viable technique in diagnosing EV.

Methods

We recruited 178 patients with virus-related cirrhosis who underwent biochemical tests, abdominal ultrasound, UGE, liver stiffness (LS) and spleen stiffness (SS) measurements using ARFI elastography.

Results

Patients with EV had lower platelets (p=0.005), higher values for spleen diameter (p=0.001), portal vein (p=0.003), LS (p=0.006) and SS (p<0.001). However, ARFI SS was the only non-invasive parameter associated with the presence of EV (2.7±0.30 vs. 3.4±0.52, p<0.001) after multivariate logistic regression (p<0.001). ARFI SS for predicting EV showed an AUROC of 0.872 (CI 95%: 0.799-0.944).

Conclusion

SS is a good method for predicting EV in patients with virus-related cirrhosis.

#1287 - Case Report

THE ONCOLOGIC DISEASE THAT WAS, AFTER ALL, A ZENKER DIVERTICULUM

Marisa Brochado¹, Maria Ines Santos², Helena Dias²

¹ Internal Medicine Department - Hospital Distrital de Santarém, E.P.E., Fafe, Portugal

² Internal Medicine Department - Hospital Distrital de Santarém, E.P.E., Santarém, Portugal

Introduction

The Zenker Diverticulum is a rare finding of the upper digestive tract. The dysfunction of the hypopharyngeal muscle associated

with the reduction of muscle tone, when the pressure is increased, may be the origin of the formation of this pharyngeal pouch. Thus, it is characterized by a higher prevalence in the countries of northern Europe and has an incidence in more advanced age groups, especially above 60 years, and in males.

Case description

Male patient, 86 years old, with no relevant personal history. He was recruited to the Emergency Department for a clinical picture, with an evolution of approximately 12 months, characterized by weight loss of 20 kg, dyspepsia, halitosis and nocturnal predominance of food regurgitation.

Discussion

Of the complementary diagnostic tests: analytically with normochromic normocytic anemia; Chest X-ray normal; Thoraco-abdomino-pelvic CT "...a large diverticular image originating from the paramedian pharyngo-esophageal transition and posterior to the esophagus trajectory in the lower cervical region and the beginning of the upper mediastinum, with around 7X4cm, a voluminous Zenker diverticulum being probable." During the hospitalization, prokinetics were initiated with a clear improvement in nocturnal regurgitation. The patient had high medication and with referral for external consultation of Gastroenterology and Cardiothoracic Surgery.

Conclusion: This clinical case alerts us to the fact that not all elderly patients with a history of constitutional syndrome are based on an oncological etiology. Thus, studies comparing the surgical and endoscopic treatment of Zenker's diverticulum do not show significant differences in efficacy in the approach.

#1303 - Abstract

INFLAMMATORY BOWEL DISEASE (IBD) – CAN WE FORESEE A WORSE OUTCOME IN HOSPITALIZED PATIENTS?

Marta Andrade Moreira, Rosana Maia, Francisca Silva Cardoso, Miguel Romano, Ana Sofia Costa Matos, Edgar Torre, Luís Lopes, Diana Guerra

ULSAM-Hospital Santa Luzia, Viana Do Castelo, Portugal

Background

In recent years the management of the Inflammatory Bowel Disease (IBD) has undergone important modifications. The vast majority of patients are now followed in an ambulatory setting. However, there is a subset of patients requiring hospital admissions. These inpatients' prognosis is heterogeneous and appears to depend on several factors. In Portugal, there are few studies addressing this topic. We aim to assess the predictors of a worse outcome during hospitalization.

Methods

We conducted an observational cohort retrospective study, between 2012 and 2018, at Hospital Santa Luzia, ULS Alto Minho.

All patients with IBD (n=337), followed in the IBD clinic were included, and patients with at least one admission (n=54) during the study period were selected for analysis. The main indications for admission were categorized in two groups: flare (included diarrhoea and sub-occlusion) and fistulae/abscesses. The main outcome evaluated was admission prognosis defined as a binary variable, according to three dimensions: length of stay, need for biologics and surgery. A qualitative response regression analysis with a logit model was performed using multiple clinical and laboratory predictors.

Results

44 patients (81%) had Cronh's disease (CD) and 10 patients (19%) had Ulcerative Colitis (UC). 44 patients (81%) were admitted with flares and 10 patients (19%) with fistulae/abscesses. An unfavourable outcome was observed in 24 patients (54.5%) and 7 patients (70%), in the flare and fistulae subgroups respectively. In the severe cases the mean haemoglobin level was lower than the non-severe cases (11.5 g/dL vs 13.0 g/dL, $t=3.25$; $p=0.0027$). In the regression analysis, the only predictor of a worse outcome was the haemoglobin value at admission. For each 1 g/dL decrease of haemoglobin at admission, the probability of having a less favourable hospital stay increases by 9.8% ($p=0.0033$), all other predictors constant.

Conclusion

The value of haemoglobin at admission is a key predictor of the prognosis of the admitted IBD patients. Further studies are needed with larger samples to confirm our findings.

AEROPORTIA AS AN INDIRECT SIGN OF MESENTERIC ISCHEMIA

Luís Monteiro Dias, Marta Braga, Rosa Carvalho, Vânia Gomes, Céu Rodrigues, António Oliveira E Silva
Hospital de Braga, Braga, Portugal

Clinical summary

A 66-year-old male, with type 2 diabetes mellitus, arterial hypertension and stage 5 chronic kidney disease, presented to the Emergency Room (ER) with a 2 day history of abdominal pain, asthenia and nausea with onset after a hemodialysis session. The day he came to the ER, the hemodialysis session was interrupted due to hypotension. At physical examination he had low blood pressure, abdominal discomfort and fecaloid vomit. Abdominal CT revealed gastric and jejunoileal distension, associated with intestinal pneumatosis (Image). There were visible marked signs of intra-hepatic aeroportia and gas across the superior mesenteric blood vessels, suggesting mesenteric ischemia. A segmental bowel resection of nearly 30 centimeters was performed, with a good outcome.

Figure #1331. Marked signs of intra-hepatic airoportia.

#1339 - Abstract

DIET AND NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD): IMPACT ON CLINICAL PRESENTATION AND VASCULAR DISEASE IN LEAN AND OVERWEIGHT PATIENTS

Federica Iuculano, Rosa Lombardi, Giuseppina Pisano, Sibilla Maria Spreafico, Silvia Tiraboschi, Erika Fatta, Silvia Fargion, Anna Ludovica Fracanzani

Ca' Granda IRCCS Foundation, Policlinico Hospital, University of Milan; Department of Pathophysiology and Transplantation, Milan, Italy

Background

Dietary macronutrient composition plays a key role in the onset of NAFLD and an inverse correlation between Mediterranean diet and cardiovascular events has been shown. Aim: To evaluate the role of diet on clinical presentation and cardiovascular alterations in patients with non-alcoholic fatty liver disease (NAFLD).

Methods

We enrolled 154 newly diagnosed, consecutive untreated NAFLD patients (M/F 112/42 mean age 49±12 ys), who were administered with a semi-quantitative food-frequency questionnaire (dietary record including 118 food items covering seven days) to calculate energy and nutrients intake. Steatosis, carotid intima-media thickness (IMT) and plaques were evaluated by ultrasonography; diastolic dysfunction (E/A), left ventricular mass, and epicardial adipose thickness (EAT) by echocardiography.

Results

Mean BMI and waist circumference were 28.8±5.2 and 103±11

cm; prevalence of hypertension 45%, dyslipidemia 49%, obesity 34%, diabetes 10% and metabolic syndrome 35%. Twenty-three (15%) patients had "lean" NAFLD (BMI <25 kg/m²). Moderate to severe steatosis was present in 61%, IMT >0.9 mm in 13%, carotid plaques in 28%, and E/A <1 in 39%; mean EAT was 5.8±4 mm. Three patients (2%) had a history of cardiovascular events. Total calories and macro-nutrient intake (g/day) were: 1705±5 750 kcal; proteins 98±46, fat 65±32 (saturated 23±14; PUFA 10±5; monounsaturated 25±12), carbohydrates 164±75 (simple sugar 64±35), fiber 23±14. No difference in nutrient daily dietary composition and total Kcal between lean and overweight patients was observed, despite a higher prevalence of metabolic comorbidities and moderate-severe steatosis in the latter. Among nutrients, fructose was significantly higher in patients with plaques (p=0.03) and vitamin E lower in those with E/A<1 (p=0.01). At multivariate analysis adjusted for age, sex and BMI, diet fat content was significantly associated with dyslipidemia (OR 1.2, 95% CI 1-1.4, p= 0.04), fat and carbohydrate with moderate-severe US steatosis (OR 1.2, 95% CI 1.03-1.5, p=0.01). No independent association was found between nutrients and carotid IMT, plaques and E/A.

Conclusion

Nutritional intake does not differ between lean and overweight NAFLD suggesting a genetic predisposition to NAFLD in lean subjects. Different diet composition may influence the onset of metabolic alterations and the severity of liver steatosis, while the role on cardiovascular damage remains to be defined.

#1348 - Case Report

EOSINOPHILIC GASTROENTERITIS: ABOUT A CASE

Miguel Alexandre Alves¹, Sergio Alves¹, Rafael Velho², José Mariz², Elsa Gonçalves², Jorge Teixeira²

¹ ULSN, Bragança, Portugal

² Hospital de Braga, Braga, Portugal

Introduction

Eosinophilic gastroenteritis (EG) is a rare and heterogeneous disorder, with a variable clinical spectrum ranging between the presence of common gastrointestinal symptoms and occlusive pyloric or intestinal disease. The symptomatology is relatively unspecific, dependent on the eosinophil infiltration of different sections within the gastro-intestinal tract. Little is known about its etiology despite this it seems multifactorial. Chronic inflammation of the digestive mucosa is triggered by exposure to potential food allergens and inhalant allergens in previously predisposed individuals.

Case description

A 36-year-old female, no pathological history. Went to emergency department (ED) complaint of diarrhea with 15 days of evolution, without blood or mucus, with general malaise and an increase

in the abdominal perimeter and reduction in food intake with weight loss. Negative epidemiological environment. No history of consumption of foods other than usual. She was hemodynamically stable, apyrética, with a soft, globular, depressible abdomen with sign of the ascitic wave. Analytically with leukocytosis, neutrophilia and a 45% eosinophilia (7000 μ l) and discrete hepatic cytolysis with high C-reactive protein. Abdominal ultrasound with "moderate volume ascites. Some enteric loops with a discrete and diffusely thickened wall are observed". Performed TC Toraco Abdomino Pelvic, confirming "moderate volume ascites and diffuse parietal thickening of the distal esophagus. Diffuse parietal thickening of jejuno-ileal loops". Paracentesis was performed with Eosinophils 89% (8337) no other alterations. Probable eosinophilic gastroenteritis. Patient started corticotherapy, initially methylprednisolone 30mg / day being changed to prednisolone 40mg / day with favorable evolution. From the extended analytical study, negative serologies, negative autoimmune study, increased IgE. Performed High Endoscopy and Colonoscopy with biopsy, revealed inflammatory infiltrate in the lamina propria, with some eosinophils.

Discussion

EG presents great clinical diversity. The response to treatment of the disease in general is good. The diagnosis is suspected by the presence of gastrointestinal symptoms, peripheral eosinophilia present in 50 to 100% of cases, and exclusion of other pathologies that occur with eosinophilia. Confirmation is made by the histopathology of the compromised intestinal wall whose eosinophilic infiltration is pathognomonic.

RECTORRHAGIES AND DIARRHOEA: UN UNUSUAL PRESENTATION OF CLOSTRIDIUM DIFFICILE-ASSOCIATED PSEUDOMEMBRANOUS COLITIS.

Olga Cristina Pires, Joana Morais, Ana Isabel Andrade Oliveira, Inês Burmester, Paulo Gouveia, Maria João Regadas, António Oliveira Silva

Hospital de Braga, Braga, Portugal

Clinical summary

A 72-year-old man, presented to the emergency department with complaints of rectorrhagies, anorexia and diarrhoea. He denied antibiotic use in the last months. Presented elevated inflammatory parameters and a severe anaemia, requiring transfusion with two unities of red blood cells. A high digestive endoscopy was performed, that revealed a duodenal ulcer, with no signs of bleeding. Low digestive endoscopy revealed an endoscopic pattern of numerous small, yellowish or whitish plaques diffusely distributed, which compromises the rectum extending to proximal colon, typically compatible with pseudomembranous colitis. Results of *C. difficile* testing were positive. He fulfilled 14 days of oral Vancomycin and intravenous Metronidazole with a good clinical response.

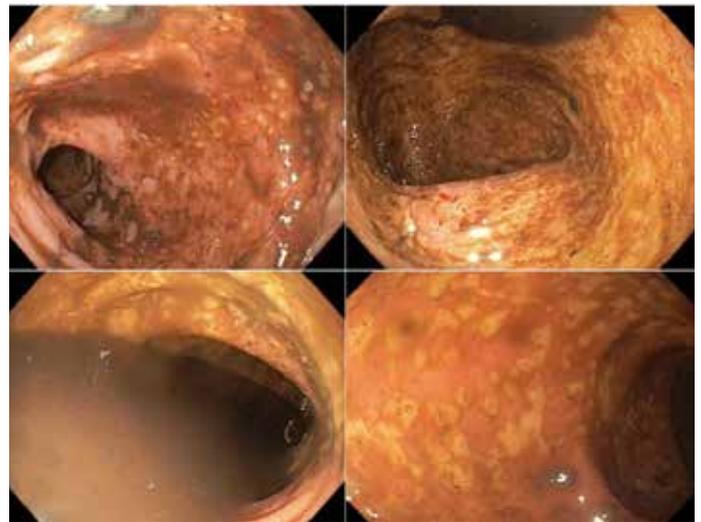

Figure #1372. Pseudomembranous colitis.

#1375 - Case Report

ACUTE PANCREATITIS WITH NEGATIVE AMYLASE AND LIPASE: A CASE REPORT

Sofia Guerreiro Cruz, Bruno Ferreira, Ana Rita Gomes, Ana Isabel Oliveira, Patrícia Ramos, Marta Quaresma, José Barata
Hospital Vila Franca de Xira, Vila Franca De Xira, Portugal

Introduction

Acute pancreatitis (AP) is caused by intracellular activation of proteolytic enzymes (PE) with destruction of pancreatic parenchyma and peripheral tissues. Biliary lithiasis and alcoholism are the most common etiological factors (80%), followed by hypertriglyceridemia, hypercalcemia and drugs. Almost all patients have abdominal pain at presentation and nausea/vomiting are also frequent. Diagnosis is made when two of the following three criteria are met: suggestive abdominal pain; characteristic imaging findings; and increased PE serum level (serum amylase [SA] and lipase [SL]), at least three times the normal level. Although normal AL levels have been reported, AP with normal SL is rare because of its negative predictive value of 94-100%. Treatment usually consists in intravenous fluid hydration, analgesia and oral feeding restriction. Without major complications, prognosis is often good, but 10-20% of cases are severe, with a mortality rate of 30%, that worsens with age.

Case description

The authors report a case of a 92-year-old female, with a good performance status and no relevant medical history, presenting with a 3-day history of abdominal pain, nausea and vomiting, without fever or other systemic symptoms. She denied history of alcohol consumption, lithiasis or introduction of new drugs. On admission, vital signs were normal and in the observation stood out diffuse abdominal pain, without peritoneal signs. Laboratory findings showed: leukocytes 28x10⁹/L; neutrophils 92,4%; C-reactive protein 49.81 mg/dL; normal liver-associated enzymes; SA 123 U/L and SL 116 U/L. Abdominal ultrasound and first

abdominal computed tomography (CT) indicated no significant anomalies. There was a clinical worsening during the first days of hospitalization, with elevation of inflammatory markers (despite negative PE values) and a reevaluation CT revealed densification of the peripancreatic fat planes and mesentery root, suggesting an edematous pancreatitis. Despite the supportive treatment, we witnessed a clinical deterioration and the patient died suddenly.

Discussion

This case intends to highlight the importance of clinical and imaging evaluation when AP is highly suspected, despite a non-significant elevation of PE (specially SL, which is rare) and how that early recognition and treatment can impact both prognosis and outcome.

#1381 - Abstract

ELASTOGRAPHY VARIATIONS IN CIRROHTIC PATIENTS OF VARIOUS HEPATIC ETIOLOGIES PRE AND POST TREATMENTS.

Obinna Kevin Kenechukwu Onwuteaka

Ternopil National medical university, Ternopil, Ukraine

Background

To evaluate elastographic variations of liver cirrohtic patients of different etiology at the ternopil regional hospital before treatment and dynamic comparison of the effects of the therapeutic regimes to the disease progression after treatment using transient elastography.

Methods

102 patients from a 2 year period was included in this study with (33) had HCV infection, (15) chronic HBV infection, (37) liver cirrohsis with alcohol etiology, (11) autoimmune hepatitis, (6) chronic idiopathic hepatitis with transformation to cirrhosis,consideration of various bias such as age, with mean age of 53.8 +/- 7.6 years, sex, (59 males, 43 females),therapeutic modalities EASL etiotropic guidelines;

GT1a, treatment experienced viral copies more than 100,000, Fibrosis grade >F3, LDV\SOF 400 mg daily PO\12 weeks.

GT1a,treatment naive, viral copy < 100,000, subcompensated F2-F3, LDV\SOF 400 mg\dailyPO\8 weeks.

GT1a,treatment naive,decompensated (child-pugh B-C) + thrombocytopenia and resistant ascities, F3-F4, LDV\SOF400mg +RBV\daily PO\ 16 weeks.

GT1b,treatment naive,decompensated (child-pugh B-C) + thrombocytopenia and resistant ascities, varices F3-F4, LDV\SOF400 mg +RBV\daily PO\ 24 weeks.

GT2, treatment experienced, decompensated with portal hypertension F4, LDV\SOF400mg +RBV\daily PO\ 12 weeks.

Prednisolone 15 mg tapered by 0.2mg every week for 8 weeks +USDA weight adjusted at 75kg for autoimmune hepatis F3.

Prednisolone 30 mg\5 days\alcoholic hepatitis. Pathogenic treatment included glutargine, hepatoprotectors,

L-glutathione,antioxidant and detoxification therapies, ursodeoxycholic acid,Proton pump inhibitors,diuretics,vitamin B complex. Liver fibrosis degree was estimated using elastography before comencement of treatment and was reevaluated after 3 months and liver enzymes assay after 1 month for assesment of organ response.

Results

At 3 months all patients had follow up investigations. The range shear wave elastography values were 7.14-16.7 kPa (F2- F4). With respect to fibrosis, shear wave elastography did not change significantly in patients F4 (0.327); a significant difference was observed between the F2-F3 and F3-F4 groups (P-0.002). Corrolation between ALT levels (Rs=0.287,p=0.804). Patients with resistant ascites had to undergo TIPS before elastographic measurements was recorded.

Conclusion

Positive dynamics is seen in F2-F3 stages in response to therapy than F3-F4 stages. With significant improvements with clinical syndromes but slow response on organ level.

#1407 - Case Report

AN UNUSUAL CAUSE OF ABDOMINAL PAIN

Joana Rua, Daniela Viana, Guilherme Assis, Nuno Silva, Cristiana Pinto, Paula Vaz Marques

CHTMAD, Vila Real, Portugal

Introduction

Splenic infarct is a rare cause of acute abdominal pain and it is associated with several diseases, including hematologic or embolic disorders, autoimmune diseases, infections and others. It can be asymptomatic but the most common clinical presentation is left upper quadrant abdominal pain, with fever, nausea, vomiting and left shoulder pain. Complications include bleeding, abscess and fistula. Treatment is mostly symptomatic and preventive.

Case description

A 73-years-old women with chronic kidney disease and non-anticoagulated paroxysmal atrial fibrillation presented to the emergency service with acute pain on the epigastric region and upper left quadrant. The pain started six days before, after dinner, associated with vomiting and nausea, with no other symptoms nor history of previous trauma. She had already been medicated with pain killers with no clinical improvement. Physical examination showed abdominal tenderness on the epigastric region and upper left quadrant. The analytic study revealed elevated LDH, myoglobin and CRP. CT scan showed severe abdominal atherosclerotic disease, structural liver changes suggesting chronic liver disease and splenomegaly with a bulky area of splenic acute infarct. Treatment with enoxaparin was initiated and she was admitted for symptom control and investigate the etiology of the splenic infarct. The autoimmune and pro-thrombotic studies,

blood cultures and infectious serology's were all negative. The echocardiogram showed no vegetation or thrombus, and ECG monitoring showed sinus rhythm. During hospital stay the patient had an episode of lower gastrointestinal bleeding, requiring transfusional support and interruption of the anticoagulation therapy. Endoscopic study of the gastrointestinal tract was performed and several polyps were biopsied. After careful restart of anticoagulation and successful pain control, the patient was discharged completely asymptomatic.

Discussion

We cannot yet exclude a paraneoplastic cause but the described patient has several risk factors to a thromboembolic etiology to the splenic infarct, including the paroxysmal atrial fibrillation, atherosclerotic disease of the aorta and the chronic liver disease. High suspicion levels are needed for diagnosis but should always be part of the differential diagnosis of abdominal pain, especially when risk factors are present. Treatment and preventive measures are very important to avoid complications.

#1412 - Case Report

PLANNING A PREGNANCY IN AGGRESSIVE AUTOIMMUNE HEPATITIS

Francisca Silva Cardoso, Miguel Romano, Francisco Teixeira Silva, Rogério Corga Silva, João Andrade, Alfredo Pinto
ULSAM - Hospital Santa Luzia, Viana Do Castelo, Portugal

Introduction

Autoimmune hepatitis (AIH) is a chronic inflammatory disease characterized by increased transaminases, hypergammaglobulinemia, presence of autoantibodies and classical histological findings. It is a rare and heterogeneous entity with a highly variable antibody pattern that makes diagnosis difficult but permits severity prediction. Pregnancy in these patients should ideally be preceded by an accurate diagnosis and effective therapy.

Case description

A 36-year-old woman, with no previous personal and family history, on oral contraceptives was referred to the Internal Medicine consultation for sustained elevation of AST and ALT, without other analytical changes. The patient presented with a one-year history of abdominal discomfort and distension, without any stigmas of chronic liver disease on physical examination and expressed a desire to conceive.

For the patient's best interest, pregnancy was delayed until a study of liver disease was performed. Serum tests showed, ALT and AST elevation (10x UNL) (ALT > AST), normal IgA and IgM, increased IgG, ANA, anti SLA/LP and Anti-Ro52 positive. ANCA (p and c), AMA, Anti Sm, Anti LKM were negative. Serologies (HIV, HCV, HBV) were also negative. Hepatic biopsy was performed with a result compatible with moderate chronic hepatitis with hepatic interphase lesions. The diagnosis of Autoimmune Hepatitis (previously designated type

3) was made. Considering the desire to become pregnant, a plan was prepared together with the obstetric physician, and the patient was put on immunosuppressive therapy with azathioprine, with full response. Term pregnancy was achieved without interurrences but a slight increase in post-pregnancy transaminases. Patient keeps follow up in consultation and maintains disease remission.

Discussion

Subclassification of AIH has been a subject of debate. However, some authors consider AIH-3 to be a more aggressive disease, with recurrent exacerbations and requiring lifelong immunosuppression.

Effective immunosuppression allows safe pregnancy in young women with AIH, and it should be maintained during pregnancy, usually with good clinical outcomes, as seen in the case presented. Nevertheless there are non-negligible risks such as disease flares and prematurity.

If diagnosis is performed during pregnancy, AIH is more difficult to manage, this is why the disease must be pre-emptively monitored and controlled.

THE TOXIC LEMONGRASS

Ruben Guerreiro Raimundo, Ana Catarina Rodrigues, André Mendes, Joana Cochicho, Ana Neves, Maxim Suleac, Adriano Pacheco Mendes, José Silva, Sócrates Vargas Naranjo, Augusto Mendonça, Isabel Lavadinho, Isabel Soles
Unidade Local de Saúde do Norte Alentejano, Portalegre, Portugal

Introduction

Nowadays there are a lot of different teas and homemade remedies and its use by population is increasing. Although they are natural products, they are able to cause a metabolic imbalance in the human body, especially when they are uncontrolled and its origin is dubious.

Case description

We present a 41-year-old woman with gastritis and medicated with sucralfate that comes to the emergency department with acute right hypochondrium pain, without fever, nausea, jaundice, choluria or acholic stool.

After investigation we found high cytolysis enzymes (AST 1768 and ALT 1328) and a slight bilirubin increase (total bilirubin 1.92 and conjugated bilirubin 1.70). Abdominal CT scan revealed a regular size liver with heterogeneous uptake of iodinated contrast. Routine questioning showed that she didn't try any new drugs, drank water from wells or had any contact with animals but she planted lemongrass in her yard and drank lemongrass tea the previous week.

Discussion

She was hospitalized for hydration and diary surveillance in order to evaluate liver enzymes, bilirubin, lactate and pH. Other

investigation excluded autoimmune disease, viral infection (HIV, HAV, HBV and HCV), zoonosis (leptospirosis) and hemocromatosis.

The patient improved and the analytical parameters evolved positively. She was discharged without any signs or symptoms, with the diagnosis of toxic hepatitis caused by regular consumption of homemade planted lemongrass tea. This clinical case shows the risk of planting and consuming food of unknown origin and the importance of buying and purchasing packaged and controlled products.

#1417 - Case Report

PRIMARY BILIARY CHOLANGITIS: THE CHALLENGE OF DIAGNOSIS AND THERAPY

Francisca Silva Cardoso, Miguel Romano, Francisco Teixeira Silva, Rogério Corga Silva, João Andrade, Alfredo Pinto
ULSAM - Hospital Santa Luzia, Viana Do Castelo, Portugal

Introduction

Primary Biliary Cholangitis (PBC) is a rare disorder that predominantly affects women over the age of 40. It is a chronic cholestatic autoimmune liver disease characterized by progressive destruction of the intrahepatic bile ducts, which in the absence of effective therapy, progresses with fibrosis, cirrhosis and liver failure.

Case description

A 36-year-old woman, with a previous known history of difficult-to-control dyslipidemia, treated with oral contraceptive, was referred to the Internal Medicine consultation for elevation of transaminases (AST 88 UI/L, ALT 321 UI/L), cholestasis parameters (GGT 224 UI/L) and an alterations in abdominal ultrasound showing hepatomegaly and 2 hyperechoic images (probable hepatic hemangiomas). The patient had no relevant family history presents with scattered hyperpigmented skin lesions at physical examination. She complained of lower limbs pruritus for the 4 previous months. Serum tests highlighted positive values of ANA, AMA, Anti M2 and AntiGp210. Abdominal CT revealed an enlarged liver and 2 nodular images in segment VII and V/VI of the liver. MRI showed a heterogeneous hepatomegaly and nodularities that may correspond to hepatic hemangiomas, without an aggressive appearance. A liver biopsy was performed which did not rule out the diagnosis of CBP at an incipient stage. Once the diagnosis of CBP was established, ursodeoxycholic acid therapy was initiated. After 1 year of therapy, hepatic markers continued worsening and due to difficult control of the disease (corroborated with a GLOBE Score of 2.42), confirmed indication to start the patient on obeticholic acid. Patient keeps follow up in consultation.

Discussion

Early identification of CBP is crucial in initiating treatment and slowing the progression of the disease. In responding patients,

Ursodeoxycholic acid offers a life expectancy similar to the general population and cirrhosis development is rare. Patients who don't respond to this therapy have new options available. The approval of the expensive obeticholic acid is a current validated alternative, but it requires the use of validated risk assessment tools, able to accurately stratify PBC patients to high and low risk, after one year of conventional therapy. It is argued that in more severe cases (more aggressive, refractory and in young people) we should wait less time. Data on CBP in Portugal are scarce, but its impact isn't ignoble.

#1432 - Case Report

NON-ALCOHOLIC STEATOHEPATITIS AFTER LONG-TERM CORTICOSTEROID THERAPY

Andrea Silva, Carina De Sousa, João Madaleno, Catarina Canha, Adélia Simão, Armando Carvalho
Coimbra Hospital and University Centre, Coimbra, Portugal

Introduction

Corticosteroids may have major effects on the liver, particularly when given long term and in higher than physiologic doses. Glucocorticoid use can result in hepatic enlargement and steatosis or glycogenosis. Hepatic complications of corticosteroids usually represent the worsening or triggering the hepatic disease like non-alcoholic steatohepatitis (NASH), and rarely are the result of drug hepatotoxicity.

Case description

We present a case of a 56-year-old man with sarcoidosis with neurological involvement, hypertension, dyslipidemia, obesity and alcohol consumption of 15g/day, who was admitted for asymptomatic elevation of liver enzymes (aspartate transaminase 435U/L, alanine transaminase 540U/L, alkaline phosphatase 688U/L, gamma-glutamyltransferase 6792U/L), without liver failure. He was chronically medicated with prednisolone 8mg/day for 3 years, azathioprine, atorvastatin and metoprolol. Before initiating treatment for sarcoidosis the liver enzymes were normal. He denied consumption of illicit or over-the-counter drugs. He was asymptomatic and had no stigmata of chronic liver disease or alcohol abuse. Blood tests revealed total cholesterol of 457 mg/dL and triglycerides of 362 mg/dL. Serology for hepatotropic viruses and immunological markers for immune-mediated liver disease were negative. Abdominal ultrasound and computed tomography revealed steatosis. Non-alcoholic fatty liver disease fibrosis score was 2. Liver biopsy was compatible with steatohepatitis. Dietary alterations were made and the patient remained asymptomatic with progressive regression of analytical alterations.

Discussion

This is an early, but well documented report of NASH arising during corticosteroid therapy. The increased of serum aminotransferase and exclusion of other causes led to a hospital admission and liver biopsy. An issue is whether the liver disease was due to

corticosteroid therapy directly or was the result of weight gain and insulin resistance caused by the therapy.

#1442 - Abstract

ALCOHOL INTAKE AMONG PATIENTS WITH VIRAL C HEPATITIS

Elena Cristina Rezi

Lucian Blaga University, Medical Faculty, Sibiu, Romania

Background

Ethanol intake is an independent predictor of liver cirrhosis in subjects with chronic hepatitis C virus (HCV) infection. Viral infections favor the development of alcoholic liver diseases; these two factors, alcohol and virus, potent themselves. Our aim was to study the prevalence and some consequences of alcohol consumption among patients chronically infected with HCV.

Methods

We have considered all the patients who were hospitalized in the medical departments of the County Hospitals from three major cities from Transylvania during ten weeks, and who were ultrasonographically examined. We have studied the prevalence of HCV and the association of these diseases with alcohol consumption.

Results

A total number of 1377 patients were examined. The prevalence of the infection with HCV was of 7.5% (104 patients). 13.88% of them were also alcohol consumers. There were analyzed the patients with HCV who did not consume alcohol, as compared with those who are also consuming alcohol. At the last ones, there were found significantly higher values of the next parameters: the degree of liver steatosis ($p=0.02$), the spleen diameter ($p=0.05$), TGO ($p=0.00037$), TGP ($p=0.0062$), GGT ($p=0.00016$), total bilirubine level ($p=0.027$). The patients with viral C hepatitis who are also alcohol consumers, are, generally younger than those with viral C hepatitis who do not consume alcohol (54.42 years, compared with 57 years, $p=0.02$). Also, the Forns index of liver fibrosis was higher in patients with HCV who were also alcohol consumers, as compared with those with HCV who do not consume alcohol (5.56, as compared with 5.11, $p=0.22$).

Conclusion

The alcohol consumption among patients chronically infected with HCV is pretty high, this fact being also involved in the response to the antiviral treatment. The patients who are infected with HCV and also consume alcohol have a higher steatosis grade and a higher degree of cytolysis and cholestasis.

GASTRIC MALIGNANCY PRESENTING AS INTERNAL JUGULAR VENOUS THROMBOSIS

Ana Inês Ponciano, Joana Raquel Monteiro, Sónia Santos, Fernanda Pinhal, José Leite, Célio Fernandes

Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

Jugular venous thrombosis is unusual and usually associated with central venous catheterisation, intravenous drug abuse and head and neck sepsis. However, is seldomly associated with malignancy. Gastric carcinoma is the second most common cause of cancer-related death worldwide. Advanced gastric carcinoma commonly presents with outlet obstruction, dyspeptic symptoms, and features of metastasis. Jugular vein thrombosis is an uncommon presentation.

Case description

A 31-year-old female presented to the emergency department with pain and swelling of the left side of her neck of four days duration, in association with a sore throat and chest tightness. There was no history of fever, night sweats or weight loss. She had no cough, and no relevant past medical or surgical history and was not taking any medications. On examination, there was diffuse tender swelling on the left side of neck with marked engorgement of the superficial veins over this area. The remainder of clinical examination was normal.

Ultrasound examination of the neck which demonstrated extensive thrombosis of the left internal jugular and subclavian veins. The patient was admitted for further study and started anticoagulation with low molecular weight heparin. She underwent body computed tomography (CT) which confirmed venous thrombosis. Coagulation tests were normal. CT also showed multiple lymphadenopathies especially on the celiac trunk and an incisional biopsy was performed. The histology was diagnostic of carcinoma. In order to find out the primary site she underwent upper endoscopy revealing an ulcer of the gastric body and biopsy confirmed the final diagnosis of gastric adenocarcinoma. She started chemotherapy but showed rapid progression of disease and died after 6 months.

Discussion

Venous thrombosis usually affects the legs. The veins in the head and neck are less susceptible to thrombosis as they are mostly valveless and their drainage is aided by gravity in the upright position.

Jugular venous thrombosis may be first manifestation of an occult malignancy and may be due to the hyper coagulated state of the patient secondary to a metastatic malignancy. In the absence of an obvious head and neck pathology or haematological disorder, disseminated malignancy should be suspected and further investigations initiated.

#1491 - Case Report

HEPATOCELLULAR-CHOLANGIOCARCINOMA AND NON-CIRRHOTIC PORTAL HYPERTENSION: WHICH CAME FIRST?

Carolina Teles¹, Carlos Dias Da Silva¹, Teresa Vaio^{1,2}, Rui Santos^{1,2}, Armando Carvalho^{1,2}

¹ Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

² Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal

Introduction

Combined hepatocellular-cholangiocarcinoma (CHC) is a rare and aggressive primary liver cancer, sharing unequivocal elements of both hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (ICC). The etiologic factors behind CHC development are still poorly understood but its presence in a normal liver is uncommon. On the other hand, it has been suggested an association between liver cancer and non-cirrhotic portal hypertension, a condition of unclear natural history.

Case description

A 51-year-old female patient with a two-month history of epigastric discomfort, nausea, asthenia, and unexplained weight loss (14%). Physical examination showed epigastric tenderness and hepatomegaly, with no other changes. She had no personal history of diabetes, dyslipidemia or hypertension, and denied chronic medication use. No smoking or alcohol habits. No family history of liver neoplasms. Laboratory studies revealed hypochromic microcytic anemia, thrombocytopenia and liver enzymes elevation (AST 63 U/L, ALT 40 U/L, ALP 259 U/L, GGT 206 U/L), with normal bilirubin, alpha-fetoprotein, ferritin, alpha-1 antitrypsin and ceruloplasmin levels, and negative serologies for hepatotropic viruses and liver autoimmune disease. Abdominal ultrasound showed a hypoechoic nodule with 10 cm of greater axis, with no evidence of liver steatosis or cirrhosis. This finding was confirmed by Thoracoabdominal Computed Tomography and liver Magnetic Resonance Imaging, which also identified 5 liver nodules compatible with metastases, abdominal and mediastinal adenopathies, as well as signs of portal hypertension (splenomegaly, perisplenic collateral circulation and peritoneal effusion). Liver biopsy revealed a carcinoma with morphology and phenotype consistent with hepatocellular origin but immunohistochemical overlap with cholangiocarcinoma. Upper Gastrointestinal Endoscopy demonstrated esophageal varices and hypertensive gastropathy.

Discussion

This case reports the coexistence of CHC and non-cirrhotic portal hypertension, in a patient with no risk factors, supporting the possible relevance of this association, not yet completely understood. Given its mixed characteristics and lack of specific manifestations, CHC represents a real diagnostic challenge, resulting in delayed diagnosis and worse prognosis, emphasizing the importance of a high index of suspicion for CHC in the case of liver nodule detection.

CODEINE-INDUCED ACUTE PANCREATITIS: A CASE REPORT

Ricardo Ambrosio Rodrigues¹, Inês Farinha², Ana Rita M. Gomes³, Telma Alves¹, Mariana Guerra¹, João Pina Cabral¹, João Rocha Gonçalves¹, Armando Carvalho¹, Ana Figueiredo¹

¹ Department of Internal Medicine, Coimbra Hospital and University Center, Coimbra, Portugal

² Department of Pulmonology, Coimbra Hospital and University Center, Coimbra, Portugal

³ Department of Cardiology, Coimbra Hospital and University Center, Coimbra, Portugal

Introduction

Acute pancreatitis is a sudden inflammation of the pancreas that can vary from a mild to a life threatening condition. The most common causes are gallstones, representing 40-70% of cases, followed by alcohol (25-35%), hypertriglyceridemia and others. Medication induced pancreatitis is rare, representing less than 5% of cases.

Case description

A 78-year-old woman presented to the Emergency Room with coffee ground vomiting that started during the night, accompanied by epigastric pain and abdominal distention. The patient mentioned having started acetaminophen/codeine association the previous day. Physical examination showed abdominal defense, more pronounced in the epigastric region, with no other significant findings. Blood work showed an increase, more than 3 times the upper limit, of both amylase and lipase. Abdominal ultrasound was shown to be completely normal, with no gallstones or any other changes to report.

Diagnosis of acute pancreatitis was assumed (Ranson criteria of 2 and BISAP of 1) and the patient was admitted to the Internal Medicine infirmary for conservative therapy.

During the period of hospitalization all other causes were ruled out, including alcohol abuse, hypertriglyceridemia and others (including auto-immune). Abdominal CT scan was also performed and revealed no changes as well.

Codeine-induced acute pancreatitis was assumed as the diagnosis and the patient had a complete recovery after a few days of fasting and supportive therapy only.

Discussion

Codeine has already been associated with acute pancreatitis in published cases, most of them in patients that have undergone cholecystectomy.

This case highlights the importance of carefully monitoring and being aware of possible drug side effects, particularly when they are first prescribed.

#1514 - Case Report

THE OTHER CAUSE

Ana Cláudia Antunes, Ana João Carvalho, Cátia Santos, Adélia Miragaia

Centro Hospitalar de Leiria, Leiria, Portugal

Introduction

One of the possible consequences of gastrectomy is anemia, either due to vitamin B12 deficiency (VB12D) caused by the resection of the parietal cells or iron deficiency, due to increased gastric pH. Autoimmune gastritis (AIG) is a chronic inflammatory disease that affects the gastric parietal cells so, VB12D with pernicious anemia is a known consequence of this entity. These patients are usually asymptomatic but may present dyspepsia with late gastric emptying, intestinal infections, weight loss, muscle weakness, diarrhoea or neurological manifestations such as paresthesia.

Case description

80-year-old male, with history of psoriasis, psoriatic arthritis, arterial hypertension, splenectomy, partial gastrectomy due to ulcers of the great curvature of the stomach, who was referred to the internal medicine consultation due to weight loss of approximately 10 Kg in two months and dyspepsia with delayed gastric emptying. Thoracic, abdominal and pelvic computed tomography were normal. The pathological anatomy study of gastric biopsies by upper digestive endoscopy (UDE) revealed mild grade chronic gastritis, severe atrophy with extensive pseudopyloric metaplasia suggestive of autoimmune aetiology and were negative for *Helicobacter pylori*. Blood tests showed anemia 12.9 g/dL, with MCV 103.7 fL and MCH 34.1 g/dL, decreased ferritin 15.2 ng/mL, without iron deficiency 15.2 μ mol/L, VB12D 64 pg/mL, Hb A1c 5.3%, elevated IgG and IgA of 1752 and 570 mg/dL respectively, intrinsic factor antibody and gastric parietal cells antibody were positive. Thyroid, renal and hepatic function without alterations.

Discussion

This case emphasises the importance of a thorough diagnosis approach even when in the presence of an already known potential cause for anemia, as multifactorial causes may be present, and the discovery of other factors may lead to different patient management. The gold standard for the diagnosis of AIG is the UDE with fundus and gastric body biopsy that reveals typical findings such as presence of polyps, endocrine cell hyperplasia in early stages and, with the progression of the disease, intestinal metaplasia with marked glandular atrophy. An additional importance of this diagnosis is the risk of developing gastric adenocarcinoma.

THE COFFEE-BEAN SIGN

Mafalda Miranda Baleiras, Cristina Gouveia, Inês Ferreira, Carolina Gouveia, Patrícia Vicente, Luis Campos

Hospital São Francisco Xavier, Lisbon, Portugal

Clinical summary

Sigmoid volvulus is the fourth leading cause of large bowel obstruction. The diagnostic accuracy of plain-X rays ranges from 30-90%. If left untreated, it may result in bowel ischemia, gangrene and perforation.

A 90-year-old woman presented to the emergency department with a 1-week history of abdominal pain and constipation. She had no record of abdominal surgery. Her vital signals were normal. Physical examination revealed diffuse abdominal tenderness and distension. Abdominal radiograph showed a distended sigmoid loop with an inverted U-shape, the classic "coffee-bean sign", suggestive of sigmoid volvulus. The patient underwent a successful transrectal endoscopic decompression.

Awareness of the coffee-bean sign helps to prevent life-threatening complications from sigmoid volvulus.

Figure #1554. Abdominal radiograph showing dilated sigmoid loop (arrows) with an inverted U-shaped appearance (coffee-bean sign).

#1615 - Case Report

COLIC HAEMOLACRIA IN MICROSCOPIC COLITIS, A RARE CONDITION THAT MAKES MUCOSA CRY BLOOD

Elena Creanga¹, Sebastian Dobos², Monica Nechita Ferreira³

¹ CHU Brugmann, Gastroenterology Department, Bruxelles, Belgium

² CHU Brugmann, Surgery Department, Bruxelles, Belgium

³ CHU Brugmann, Internal Medicine Department, Bruxelles, Belgium

Introduction

Patients with microscopic colitis present chronic watery diarrhea, normal endoscopy and inflammatory abnormalities of the

colorectal mucosa detected on biopsies. The diagnosis is based on histological findings, exclusion of other causes of diarrhea and analyses of effects of all treatments used over a 6-month period. Because of the inflammatory abnormality, the diagnostic assessment is frequently associated with increased iatrogenic complications at a higher rate than one encountered during screening colonoscopy.

Case description

An 89-year-old female patient was referred for total colonoscopy due to chronic diarrhea without rectorragias or fever. Weight loss was reported but not quantified. The patient had a medical history of hypothyroidism and hypertension and her medication include l-thyroxine, ramipril and aspirin. During the colonoscopy the mucosa of transverse and right colon presented edema, erythema, high friability and tore easily- all of these characteristics of colic haemolacria. Two tears in the right colon were closed by endoscopic clips. For developing progressive abdominal pain, she realized an abdominal scanner which showed pneumoperitoneum. A colic perforation after colonoscopy was diagnosed and the patient underwent a right hemicolectomy extended to the transverse colon with ileocolic anastomosis. Diarrhea disappeared progressively with a complete and permanent remission of symptoms during the follow-up period. The anatomopathologic exam confirmed the presence of collagen colitis with thickening of the subepithelial collagen band and infiltration of the lamina propria by lymphocyte-containing plasma.

Discussion

The authors discuss the therapies generally adopted in microscopic colitis: avoidance of drugs that might induce symptoms, symptomatic treatment or surgical treatment if resistance to medical treatment, iatrogenic complications or associated malignancy. Surgery involves excision procedures from ileostomy to proctocolectomy.

This case illustrate the importance of considering the diagnosis of microscopic colitis in patients with watery diarrhea. Early recognition of endoscopy findings, like the presence of mucosal erythema, edema, linear colonic mucosal defects or mucosal scarring could suggest the diagnosis and impose a more careful approach during and after endoscopy.

We draw attention that in the presented case the surgical act undertaken to resolve the complication of colonoscopy was therapeutic.

#1616 - Case Report

NON-HODGKIN LYMPHOMA IN A PATIENT WITH CELIAC DISEASE

Pablo Segovia-Alonso¹, Julio Dávila¹, Sara Hernández², Antonio Gracia¹, José Hernández¹, María Antonia Gonzalo¹

¹ Complejo Asistencial de Ávila, Ávila, Spain

² Complejo Asistencial de Salamanca, Salamanca, Spain

Introduction

Celiac disease (CD) is characterized by a T-cell-mediated response to gluten intake. This immune response leads to a chronic inflammation of the small intestinal mucosa that results in malabsorption, diarrhea, abdominal distension and pain, malnutrition and weight loss. Since 1937, it has been recognized that CD is associated with an increased risk of developing T-cell non-Hodgkin lymphoma (T-cell NHL), defined as enteropathy-associated T-cell lymphoma (EATL). We present a case of EATL in a 61-year-old man with celiac disease.

Case description

A 61-year-old man with celiac disease was admitted at the emergency department. He was diagnosed seventeen years ago of his pathology, but he does not conduct gluten free-diet although he regularly attended to schedule check-ups. At present, he referred fever up to 38.5°C, asthenia and weight loss during the last three weeks. He came from a rural area with consumption of unpasteurized dairy products and he referred occasional tick bites. Baseline laboratory evaluation with inflammatory markers was normal. Liver function tests showed mild elevation of transaminases and mild cholestasis with an elevated value of lactic dehydrogenase (more than three times over the upper limit of normality). Brucella microagglutination test and serologic test for Rickettsia, Coxiella and Borrelia spp were performed and the results were negative. A full body CT revealed a gastric neoplasia with multiple liver metastases. Upper endoscopy with biopsy was conducted compatible with high-grade enteropathy-associated Non-Hodgkin's T lymphoma. Ki-67 index showed high proliferation rate (95%). Hematology consultants evaluated the patient and started CHOP chemotherapy with poor response, then switched to IVE-MTX achieving partial response.

Discussion

EATL is a rare tumor that involves less than 5% of all gastrointestinal lymphomas and less than 1% of all non-Hodgkin lymphomas. Several studies verify that the risk of T-cell NHL is considerably greater in patients with CD than in the unaffected population. The T-cell-mediated immune response induced by the ingestion of gluten it is thought to be the main cause of the lymphomagenesis among CD patients. Management of celiac disease with a gluten-free diet effectively prevents the development of EATL. Consequently, it is important to reassure the compliance to the strict gluten-free diet for life.

#1620 - Case Report

SINUSOIDAL OBSTRUCTION SYNDROME INDUCED BY MEDICINAL HERBS

Pablo Segovia-Alonso¹, Sara Hernández², Francisco Díaz¹, María Pilar Delgado¹, Rosana Villanueva¹, Juan Manuel Blanco¹, Antonio Gracia¹, José Hernández¹, María Antonia Gonzalo¹, Raquel Tur¹, Beatriz Segovia¹

¹ Complejo Asistencial de Ávila, Ávila, Spain

² Complejo Asistencial de Salamanca, Salamanca, Spain

Introduction

The sinusoidal obstruction syndrome (SOS) is a disease secondary to a blockage of the venous drainage of the liver. This disorder is produced by the damage caused in the hepatic sinusoidal endothelium by the intermediate metabolites of different toxic substances inducing rapidly progressive ascites, painful hepatomegaly and jaundice. Typically, SOS is a serious complication of hematopoietic cell transplantation (HCT) but hepatotoxic effects of pyrrolizidine alkaloids found in herbal medicines have also been described as cause of this syndrome.

Case description

A 56-year-old woman was admitted at the emergency department. She was diagnosed one year ago with low risk essential thrombocythemia but she did not require medical treatment. At the present time, she referred abdominal pain, hyporexia and weight increase for two weeks. One month ago, she started a therapy with medicinal herbs for acid reflux by her naturopath. Baseline laboratory evaluation showed a normal serum aminotransferase levels with mild cholestasis, slight direct hyperbilirubinemia (1,7mg/dL, normal < 0,5 mg/dL), prothrombin activity curtailment (61%, normal 70-115%) and slight thrombocytosis ($475 \times 10^3/\text{mm}^3$, normal < $450 \times 10^3/\text{mm}^3$). A full body CT was performed ruling out hepatic vein thrombosis or neoplastic disease but revealing the presence of important ascites. Liver biopsy was performed illustrating sinusoidal congestion and endovenular fibrosis. Those findings were suggestive of SOS. The patient was treated with an adequate management of water retention but a week later she referred worsening of its basal state with increasing ascites. A new CT was conducted revealing thrombosis of the suprahepatic veins (Budd-Chiari syndrome). Haematology consultants evaluated the patient and started low molecular weight heparin and hydroxycarbamide with clinical improvement but with frequent evacuation paracentesis needed. Four months after the diagnosis, a new CT was executed proving partial permeability of the suprahepatic veins. The patient underwent porto-systemic shunt with no further needs of paracentesis.

Discussion

SOS is frequent among patients underwent HCT but there is a long list of drugs and toxic agents related to this syndrome. The increasingly use of natural remedies, including those derived from pyrrolizidine alkaloids, could lead to major drug-induced liver toxicity and SOS. Due to the severity of the disease and the lack of an effective treatment, a prompt and accurate diagnosis is essential.

#1626 - Case Report

INFLAMMATORY BOWEL DISEASE IN A PATIENT WITH PSORIATIC ARTHRITIS TREATED WITH SECUKINUMAB

Pablo Segovia-Alonso¹, Carmen Torres¹, Marta Lumbreras¹, Sara Hernández², Juan Manuel Blanco¹, José Manuel Hernández¹, María Antonio Gonzalo¹

¹ Complejo Asistencial de Ávila, Ávila, Spain

² Complejo Asistencial de Salamanca, Salamanca, Spain

Introduction

Psoriatic arthritis (PsA) is a chronic immune-mediated inflammatory disease that shows significant correlation with inflammatory bowel disease (IBD). Patients with PsA are two to four times more likely to develop IBD. Secukinumab is a human monoclonal antibody that inhibits IL-17A, showing significant efficacy in the treatment of PsA but has not shown effectiveness in the treatment of IBD. Moreover, detection of IBD has been reported in patients being treated with IL-17 inhibition. We present a case of IBD-unclassified (IBDU) following treatment with secukinumab in a 56-year-old woman with PsA.

Case description

A 56-year-old woman with PsA was referred from Rheumatology for diarrhea. He was diagnosed of PsA twenty years ago and she has performed multiple treatments with partial response (methotrexate, leflunomide, infliximab, etanercept, adalimumab, golimumab, ustekinumab and ciclosporine). Two months ago her rheumatologist started secukinumab 300 mg subcutaneous with usual initial dosing, followed by monthly maintenance dosing. She described bloody diarrhea (three-four times per day), abdominal pain and intermittent mild fever with no other signs of infection or extraintestinal manifestations. Baseline laboratory evaluation included normal values of renal and liver functions with mild C-reactive protein elevation and sedimentation rate four times its normal rank (with significant increase since the beginning of secukinumab where it was twice times its normal value). Stool cultures were negative for both bacteria and viruses. Colonoscopy with biopsy was conducted revealing pancolitis with chronic colitis and mild inflammatory activity compatible with idiopathic inflammatory bowel disease. Secukinumab was discontinued and salazopyrin was started with cessation of the diarrhea and normalisation of the inflammatory markers.

Discussion

While the association between PsA and IBD is well recognized, IBD pathogenesis is still under study. Dysregulation of mucosal cytokines, including interleukins and tumour necrosis factor alpha, seems to promote IBD pathogenesis. Nevertheless, IL-17A inhibition appears to increase the risk of IBD in some patients. Murine studies implicate that IL-17A is an important contributor to the gastrointestinal homeostasis and tissue repair, rather than enhance pathogenic inflammation. Patients treated with secukinumab should be assessed for IBD during treatment with withdrawal of the drug if specified.

#1646 - Abstract

NAFLD AND HEPATIC FIBROSIS BY TRANSIENT ELASTOGRAPHY ARE HIGHLY PREVALENT IN DIABETIC PATIENTS: NEED FOR A SYSTEMATIC SCREENING OF LIVER DISEASE

Annalisa Cespiati¹, Rosa Lombardi¹, Lorena Airaghi¹, Giovanni Targher², Giovanni Serviddio³, Gabriele Maffi¹, Cristina Bertelli¹, Giuseppina Pisano¹, Erika Fatta¹, Federica Iuculano¹, Luca Rinaldi⁴, Emanuela Orsi⁵, Silvia Fargion¹, Anna Ludovica Fracanzani¹

² Division of Endocrinology, Diabetes and Metabolism, Department of Medicine, University Hospital of Verona, Verona, Italy, Verona, Italy

³ Centro C.U.R.E., Dept. of Medical and Surgical Sciences, University of Foggia, Foggia, Italy

⁴ Department of Medical, Surgical, Neurological, Metabolic and Aging Sciences, University of Campania Luigi Vanvitelli, Naples, Italy, Napoli, Italy

⁵ Department of Medical Science, Endocrinology and Diabetes Unit, Ca' Granda IRCCS Foundation, Policlinico Hospital, University of Milan Italy, Milano, Italy

Background

Type 2 diabetes mellitus (T2DM) is a risk factor for the onset and progression of non-alcoholic fatty liver disease (NAFLD) to liver fibrosis, but this issue is often neglected. Liver biopsy is the gold standard for staging NAFLD, but it is not routinely applicable to wide cohorts of T2DM patients. We aimed at estimating non-invasively prevalence and predictors of NAFLD and liver fibrosis in a multi-center cohort of T2DM patients.

Methods

Three-hundred nineteen T2DM patients attending the diabetes outpatient clinic in five Italian centres were enrolled. Secondary causes of liver disease were excluded. All patients underwent liver ultrasound (steatosis grading 1-3) and FibroScan®. Controlled attenuation parameter (CAP) ≥ 248 Db/m and liver stiffness measurement (LSM) ≥ 8.7 kPa for M probe and ≥ 7.2 kPa for XL probe defined steatosis and advanced fibrosis, respectively.

Results

Among the 319 T2DM patients included (mean age 69 ± 9 years; 49% males) hypertension was present in 78%, dyslipidemia in 84% (79% of whom on statins) and obesity in 36%; almost all the cohort (96%) was on antidiabetic therapy (mean HbA1c $7 \pm 1.1\%$); elevated levels of AST, ALT and GGT were present in only 8%, 12% and 13% of patients, respectively. The overall prevalence of US hepatic steatosis was 89% (severe in 17%), confirmed in 72% of cases by CAP (available in 238 cases). CAP values significantly correlated with US steatosis grades (p for trend < 0.001). CAP ≥ 248 Db/m was associated at multivariate analysis with waist circumference (WC) (OR 1.07, 95% C.I. 1.0-1.15, $p=0.05$) and

triglycerides (OR 1.02, 95% C.I. 1.0-1.04, $p=0.01$). Presence of severe fibrosis (LSM $\geq 8.7/7.2$ kPa) was detected in 51 (13%) and correlated at multivariate analysis with serum GGT (OR 1.03; CI 95% 1.01-1.05; $p=0.001$), hyperuricemia (OR 9.1; CI 95% 1.9-41.6; $p=0.004$), BMI (OR 1.2; CI 95% 1.1-1.4; $p=0.03$), severe steatosis (OR 14; CI 95% 2.4-79.1; $p=0.003$).

Conclusion

NAFLD is highly prevalent in T2DM patients (89%), advanced liver fibrosis is detectable in 13% of them, despite normal transaminases in the majority of cases. Therefore, we suggest a careful non-invasive screening for liver disease in diabetics in primary care, especially if severe steatosis, obesity and hypertriglyceridemia also coexist. In addition, hyperuricemia and GGT may be useful markers to detect liver damage in this category of patients.

PERSISTENT CHOLESTASIS DUE TO TERBINAFINE

Ana Castro Barbosa, André Mendes Martins, Inês Machado Leite, Marina Duque Fonseca, Rui M. M. Victorino
Centro Hospitalar Universitário Lisboa Norte, EPE, Lisboa, Portugal

Introduction

Terbinafine is an oral antifungal agent that is commonly used to treat superficial fungal infections of the skin and nails. It's associated with mild liver biochemistry abnormalities in about 1% of treated patients. However, the incidence of clinically significant liver injury attributed to terbinafine is unknown. The liver injury may be hepatocellular at initial presentation but usually evolves into a cholestatic profile over time. Additionally rare instances of severe hepatitis, acute liver failure and fatalities have been described with terbinafine use.

Case description

A 53-year-old man from Sacavém, Portugal, construction worker, presented with abdominal pain, vomiting and dark urine. His medical history was remarkable for onychomycosis treated with terbinafine during about one month until three days before onset of abdominal pain. On physical examination no abnormalities except for jaundice were found. Laboratorial tests showed a cyto-cholestatic pattern (aspartate aminotransferase 324 U/L; alanine aminotransferase 615 U/L; gamma-GT 581 U/L; alkaline phosphatase 460 U/L; total bilirubin 6.91 mg/dL; direct bilirubin 5.12 mg/dL). Ultrasonography of the upper abdomen showed normal non-dilated bile ducts and no gall stones. Hepatitis A, B and C were serologically excluded and no autoantibodies were demonstrated. A biopsy, performed nine days after terbinafine was discontinued, showed a moderate inflammatory infiltrate in the portal areas and several foci of necroinflammatory activity and intrahepatic cholestasis of predominantly centrilobular distribution. Laboratory tests for cholestasis remained in ascending profile until four weeks after drug withdrawal (aspartate

aminotransferase 261 U/L; alanine aminotransferase 461 U/L; gama-GT 404 U/L; alkaline phosphatase 461 U/L; total bilirubin 24.97 mg/dL; direct bilirubin 18.90 mg/dL). He was started on prednisolone however laboratory values began to decrease only six weeks after this treatment was initiated. The patient remained asymptomatic and without evidence of liver failure.

Discussion

The liver function abnormalities in the patient described were probably due to treatment with terbinafine because of the temporal relationship between the drug intake and the occurrence of symptoms, and because extrahepatic cholestasis, viral hepatitis and autoimmune disease were excluded. Another important fact is that hepatic injury was confirmed by liver biopsy.

#1648 - Abstract

TYPE 2 DIABETES MELLITUS AND CHRONIC HEPATITIS C - A CASE STUDY OF A HEPATOLOGY CONSULTATION

Maria Pacheco, Ana Teresa Moreira, Nuno Rodrigo Maia Alves, Adriano Cardoso

Hospital de Sousa Martins, Guarda, Portugal

Background

Several recently published studies suggest Hepatitis C Virus (HCV) infection as a risk factor for Type 2 Diabetes Mellitus (T2DM), either by the inflammatory cascade triggered by the virus or by its molecular characteristics. On the other hand, T2DM accelerates the clinical and histological progression of liver disease, with an increased incidence of cirrhosis and hepatocellular carcinoma and increased of hepatic decompensation. The degree of hepatic fibrosis, cirrhosis and HCV infection are considered independent risk factors for T2DM. At the same time, it is assumed that the prevalence of T2DM in patients with HBV infection is similar to that of the so-called healthy population. The purpose of this study is to determine the incidence of T2DM in patients with viral hepatitis from the hepatology department of a medium size General Hospital.

Methods

Review of the medical records of patients with viral hepatitis, followed in the hepatology department between 2017 and 2018. For each patient, we analyzed the presence of the viral agent; the treatment and the response to it; clinical evolution; HBA1C value, and other cardiovascular risk factors such as arterial hypertension, obesity and dyslipidemia.

Results

This study included 177 patients with a 57-year-old mean age, 61% where male. Ninety-two had chronic Hepatitis C, of which 34% had hypertension, 57% had dyslipidemia, and 8% (n=7) had T2DM. The presence of T2DM did not imply a significant difference in the response to treatment. Of the eighty-two patients with

chronic hepatitis B, 46% had arterial hypertension and 43% had dyslipidemia. The prevalence of T2DM in the population with HBV infection was 19%. The presence of the virus also showed no influence on therapeutic outcome.

Conclusion

This study results, clearly didn't meet the results obtained in the different study's published until now. In this cohort, patients with HCV infection weren't more prone to develop T2 DM. This may be due to the small number of participants, and also by the fact that the patients only source was the liver disease consultation, and many where under the new direct antivirals treatment. Despite of what has been described, there were also no worse outcomes of Hepatitis C patients with T2 DM, and this may be justified by the short follow-up time and by the fact that the patients were in early disease stages. As result of this, we started a prospective study, to evaluate this interaction, as well as with other cardiovascular risk factors, over time.

ATYPICAL FINDINGS IN HEPATOBILIARY SICKLE CELL DISEASE

Raquel Lopes Brás¹, Maria Ribeiro Cunha², Ana Brázio^{1,3}, João Meneses Santos^{1,3}, Helena Cortez-Pinto^{4,5}, Rui M. M. Victorino^{1,3}

¹ Department of Internal Medicine II, North Lisbon University Hospital Center - Santa Maria Hospital, Lisbon, Portugal

² Department of Infectious Diseases, North Lisbon University Hospital Center - Santa Maria Hospital, Lisbon, Portugal

³ Medicine II University Clinic, Faculty of Medicine - University of Lisbon, Lisbon, Portugal

⁴ Department of Gastroenterology and Hepatology, North Lisbon University Hospital Center - Santa Maria Hospital, Lisbon, Portugal

⁵ Gastroenterology University Clinic, Faculty of Medicine - University of Lisbon, Lisbon, Portugal

Introduction

Sickle-cell liver disease can have very diverse presentations. Acute manifestations have been divided into acute sickle cell hepatic crisis, acute hepatic sequestration and acute intrahepatic cholestasis. However, some patients exhibit atypical forms of hepatobiliary disease, which can present a diagnostic and therapeutic challenge.

Case description

We describe the case of a 64-year old Angolan African male with history of sickle cell disease. He presented with general malaise, diarrhea with the occasional blood, and upper respiratory symptoms. Physical examination revealed jaundice, and abdominal examination revealed ascites and hepatomegaly. Laboratory studies revealed a predominantly cholestatic pattern (ALT 34 U/L, AST 60 U/L, γGT 227 U/L, ALP 254 U/L total bilirubin 8.78 mg/dL, direct bilirubin 5.18 mg/dL and LDH 760 U/L). Imaging studies revealed an enlarged heterogenous liver with no dilated

biliary ducts. Fibroscan was suggestive of advanced fibrosis, with no steatosis. Endoscopy revealed incipient esophageal varices. Etiologic investigation excluded active viral hepatitis, cardiac cirrhosis (no right-sided cardiac failure), harmful alcoholic consumption past or present, secondary hemochromatosis (normal serum ferritin and no signs of iron overload on MRI), autoimmune hepatitis (negative immunologic tests) or alpha-1-antitrypsin deficit. Alpha-fetoprotein was normal. He was then presumed to have sickle cell cholangiopathy. While awaiting liver biopsy, he developed sudden worsening of jaundice (bilirubin rising from 5 to 27 mg/dL). The absence of upper quadrant pain or worsening of anemia and lack of resolution after treatment of infection and supportive measures makes it difficult to categorize these changes into acute sickle cell hepatic crisis or acute hepatic sequestration. He did not fulfill criteria for acute intrahepatic cholestasis (no elevated transaminases; alkaline phosphatase and bilirubin not elevated enough). Liver biopsy revealed moderated fibrosis and nodular hepatocellular regeneration and signs of chronic cholestasis.

Discussion

Sickle-cell hepatic disease can be multifactorial and hard to characterize or divide into clear distinct syndromes. This and other atypical cases call forth the need to review our current understanding of sickle cell liver disease.

ZENKER'S DIVERTICULUM: A RARE CAUSE OF DYSPHAGIA

Fabiana Gouveia, Diogo Raposo André, Rafael Nascimento, Helena Freitas Luís, Rita Vieira, João Miguel Freitas, Luz Brazão
Hospital Central do Funchal, Funchal, Portugal

Introduction

The Zenker's Diverticulum (ZD) emerges from increased chronic pressure in an area of weakness of the hypopharynx known as the Killian triangle, formed by the cricopharyngeus and inferior pharyngeal constrictor. It is a rare entity, which occurs predominantly in males and is more frequent in the seventh and eighth decades. The most common symptom is dysphagia and may be associated with weight loss, heartburn or regurgitation. Diagnostic gait begins in the clinical history and is confirmed by Barium Contrast Radiography (BCR), as an initial test before esophagogastroduodenoscopy (EGD). Manometry can be performed if there is suspicion of an associated esophageal motility disorder. The treatment of symptomatic DZ evolved from an open surgical approach to endoscopic techniques.

Case description

A 73-year-old man, with a history of hypertension and dyslipidemia, who attended Internal Medicine appointments due to a predominantly solid upper dysphagia, with a 5-year evolution. He also reported regurgitation, sialorrhea, halitosis, globus

pharyngeus, and unproductive coughing, with worsening in the last months. He denied weight loss or dysphonia. The objective examination showed no changes.

Analytically, there were no changes and a radiographic study with barium suspension ingestion showed a large diverticular formation in the cervical esophageal lumen, with superior communication and about 5 cm in diameter suggestive of ZD, causing a slight mass effect on the esophageal lumen and surrounding tissues. Then, it was requested an esophageal manometric study (no alterations) and an EGD that revealed a pharyngeal pouch with alimentary remains and apparently normal-looking mucosa. Computed tomography of the neck confirmed the diverticulum without significant irregularities of this cavity. Endoscopic treatment was suggested, which the patient awaits at the date of submission of this work.

Discussion

ZD is an acquired pulsed pseudo-diverticulum and its diagnosis is suspected based on the patient's complaints and confirmed by BCR or EGD. Manometry is generally not necessary, however, may help to clarify the pathogenesis of the diverticulum. However, as symptoms usually appear in the seventh and eighth decades of life, minimally invasive endoscopic approaches have gained popularity in recent years because of the surgical risk inherent in this age group.

EOSINOPHILIC GASTROENTERITIS IN A YOUNG WOMAN

Bárbara Saraiva, Francisco Lopes Morgado, Celestina Blanco Torres, Luis Manuel Sanchez
ULS- Guarda, Guarda, Portugal

Introduction

Eosinophilic gastroenteritis (EGE) is a rare and heterogeneous disease, defined by eosinophilic infiltration and peripheral eosinophilia. It can be seen anywhere in the gastrointestinal tract (GI). The pathogenesis is not well understood, but hypersensitivity is a major factor. The diagnosis is based on upper gastrointestinal endoscopy (GE) followed by histopathological examination of the biopsies, which shows eosinophilic infiltration in different layers of GI tract.

Case description

A 32-year-old woman admitted with the complaint of an abdominal pain of 3 weeks of evolution, nausea, diarrhea, sensation of postprandial fullness and increased abdominal perimeter. Diagnostic exams include laboratory confirmation of severe eosinophilia (36.5% of total leukocytes 13360 / mm³). Rx of abdomen with airfluids in the right quadrant. An Abdominal CT with diffuse parietal thickening of the lower 2/3 of the esophagus, moderate ascites, and distention of the thin loops in the left quadrants. GE with 40 cm peptic ring and hyperemia of the body and mucosal antrum. The colonoscopy (CP) showed congestive and petechial ileocecal valve and colon mucosa with

evidence of submucosal circulation. Biopsies of the colon showed mucosa with hyperplasia and an increased number of eosinophils. In the paracentesis guided by ultrasound the presence of 6912 leukocytes/mm³, of which 93.3% were eosinophils. After the results of the exams, the diagnosis of EGE was established; the patient was given prednisolone 40 mg/die orally (vowel) with clinical and analytical improvement. Currently, no corticosteroid is being used, being asymptomatic.

Discussion

In the EGE the heterogeneity is determined by the site of the eosinophilic infiltration, so the involvement of the different layers gives enlargement to distinct symptomatology. In this case the important characteristic is the high number of eosinophils in the peripheral blood, besides the muscular layer compromise with common manifestations in the involvements of the mucous membranes (abdominal pain and vomiting) and serous (ascites). EGE presents a large number of diversities regarding its clinical manifestations and is generally a devalued condition, which requires a clinical evaluation focused on the investigation of the patients. The GE, along with CP and the histological examination are of paramount importance for the diagnostic confirmation, which allows the settlement of the specific therapy for the clinical condition of each patient.

#1740 - Case Report

USE OF HALO CATHETER IN ANTRAL VASCULAR ECTASIA. ABOUT A CASE.

Andrea Gonzalez Pascual, Marta Esles Bolado, Cristina Limia Vita, Lucia Paz Fajardo, Esther Hierro Ciria
Hospital Sierrallana, Torrelavega, Spain

Introduction

Gastric antral vascular ectasia (GAVE) or watermelon stomach is an uncommon cause of upper gastrointestinal bleeding (4% of non-variceal bleeding). It is more common in women older than 70 years and is associated with cirrhosis (31% of patients with GAVE) and with some autoimmune diseases, such as systemic sclerosis. It usually manifests as chronic iron deficiency anemia.

Diagnosis is established by the endoscopic image which shows vascular ectasias in the mucosa and submucosa, distributed longitudinally from the pylorus to the antrum.

Treatment is based on the correction of anemia with ferrotherapy and transfusions. Endoscopic coagulation techniques help to reduce the degree of bleeding. Antrectomy is reserved for cases refractory to previous treatments.

Traditionally, the most commonly used endoscopic hemostasis technique has been electrocoagulation with argon. However, its effectiveness is limited by the size of the lesions.

Case description

We present the case of an 86-year-old woman, with antecedents of hypertension and good functional situation. She is admitted

to our service in 2014 for severe iron deficiency anemia, being diagnosed with GAVE. Since then she is being followed in our consultation.

During this time, she has received medical treatment with tranexamic acid and octreotide and several sessions of endoscopic electrocoagulation with argon. Despite the treatment, she keeps maintaining high transfusion requirements of approximately two weekly red blood cell concentrates.

In November 2017, it was decided to perform a first radiofrequency ablation session with a HALO 90 catheter. Five months later, in April 2018, a second session was held. From then on, there is a reduction in the frequency of transfusions until reaching the current situation, in which the patient requires an average of 2 red cell concentrates per month.

Discussion

HALO catheter is a radioablation system consisting of an energy generator and two different catheters: HALO360 for the circumferential lesions and HALO90 for the focal ones.

By radiofrequency it produces the destruction of the entire epithelial layer, lamina propria and part of the muscularis mucosae, without injuring the submucosa. Its most widespread use is the treatment of dysplasia in Barrett's esophagus.

Recently, studies show good results in patient with refractory GAVE, with lower rate of recurrence of bleeding, after the use of this technique.

GASTRO-HEPATIC FISTULA: A RARE COMPLICATION OF GASTRIC ULCER

Vasco Tiago, Raquel Sousa, Fernando Aldomiro
Fernando Fonseca Hospital, Amadora, Portugal

Clinical summary

A 73-year-old male, with known peptic ulcer disease and not on any medication, came to the emergency room after a first episode of haematochezia presenting as hypovolaemic shock, recovering after fluid challenge and blood transfusion. He had tarry stools for more than a year, along with non-quantified weight loss and anorexia. His admission haemoglobin was 5.8 g/dL. Upper endoscopy revealed a nonbleeding gastric ulcer, highly suggestive of malignancy. While awaiting results from biopsy, a CT scan for staging of presumed cancer demonstrated a gastro-hepatic fistula with liver abscess. He underwent Billroth II gastrectomy and surgical abscess drainage. Biopsy samples from both upper endoscopy and surgical resection specimen were compatible with chronic gastritis and negative for cancer.

#1762 - Case Report

NON-BLOODY CHRONIC WATERY DIARRHEA IN AN ELDERLY PATIENT - WHAT IS THE DIAGNOSIS?

Miguel Borges Da Silva, Albina Moreira

Hospital Pedro Hispano, Unidade Local de Saúde de Matosinhos, Matosinhos, Portugal

Introduction

Microscopic colitis (MC) is a common cause of chronic non-bloody diarrhea. The CM examines two histological entities: lymphocytic colitis (LC) and collagenous colitis (CC) and has as its diagnostic triad: (1) non-bloody aqueous diarrhea; (2) absence of macroscopic changes in colonoscopy; (3) and typical LC or CC histology. This entity is more frequent in the female sex (20:1), with a peak incidence in the 6th-7th decade, with no defined etiologic cause. Morbidity and mortality are related to the consequences of diarrhea and are generally not life-threatening.

Case description

We report the case of an 83-year-old female patient with a history of dyslipidemia and hypertension. Interned in August / 2018 due to diarrhea, non-bloody aqueous with 2 months of evolution and weight loss. Exhaustively investigated (endoscopic studies with normal colon biopsy, negative coprocultures), was discharged without diagnosis even with episodes of some episodes of diarrhea. Reintroduced in September 2018 for diarrhea, weight loss, dehydration and hypokalemia (2.4 mEq/L). Among the 2 hospitalizations, there were asymptomatic periods alternating with periods of watery diarrhea, without blood. Significant weight loss. From the study, we highlight: coprocultures and parasitological of negative stools, positive leucocyte leucocytes. Abomino-pelvic computed tomography without abnormalities, colonoscopy and normal upper digestive endoscopy; biopsies of the colon and duodenum showed "mild lymphoplasmacytic inflammatory infiltrate and some eosinophils." Suspected microsomal colitis, as likely to trigger drugs (reported in the literature): omeprazole and simvastatin, suspended this therapy initiated loperamide with significant improvement in diarrhea.

Discussion

The case described above demonstrates the need to pursue a diagnosis and to repeat endoscopic studies and biopsy in the suspicion of microscopic colitis until a diagnosis can be made.

#1769 - Case Report

BLACK ESOPHAGUS, A RARE DISEASE

Ivo Castro, Ana Filipa Matos, Adelaide Figueiredo, Maria Cristina Esteves

Hospital Distrital de Santarém, Santarém, Portugal

Introduction

Acute esophageal necrosis, more frequently mentioned as "black esophagus", is a rare disorder, whose diagnosis is obtained

on endoscopy. The etiology of acute esophageal necrosis is multifactorial, and usually develops when several ischemic offences are combined, particularly hypoperfusion, corrosive injury from gastric contents, gastric outlet obstruction and/or poor nutritional status. It is more frequent in older males with comorbidities.

Case description

We present a case of a 90-year-old male patient with a history of chronic obstructive pulmonary disease, heart failure, hypertension, dyslipidemia and Parkinson disease, who was admitted for acute onset of community-acquired pneumonia. On the third day after admission, the patient presented an upper gastrointestinal bleeding and, after an esophagogastroduodenoscopy, the diagnosed of black esophagus was established. The patient was exclusively medically treated, i.e., no surgery was performed. The placement of a nasogastric tube was required in order to protect the esophageal mucosa and allow to safely feed the patient. The medical approach was essentially based on proton pump inhibitor, sucralfate suspension and corticoid. After a sixteen days hospitalization the patient was referred for external consultation and died after one year due to cardio-respiratory failure.

Discussion

The acute esophageal necrosis is a rare diagnostic that need to be made by esophagogastroduodenoscopy. For the prognosis look to be more important the comorbidities of patient than the esophageal complications.

ARIADNE'S THREADGiulia Francesca Manfredi¹, Mattia Bellan¹, Rachele Rapetti¹, Stefano Fangazio¹, Carlo Smirne¹, Sergio Gentilli², Giordana D'Aloisio², Giuseppe Guzzardi³, Mario Pirisi¹¹ Division of Internal Medicine, "AOU Maggiore della Carità", Novara, Italy² Department of Surgery, "AOU Maggiore della Carità", Novara, Italy³ Interventional Radiology, "AOU Maggiore della Carità", Novara, Italy**Introduction**

As in the myth of Theseus and Princess Ariadne, who helped the hero defeat the Minotaur, also in this patient we had to retrace the thread to find the way out of the labyrinth.

Case description

A 75-year-old man was admitted to our hospital complaining persistent and widespread abdominal pain from 5 days; except for inappetence, no other symptoms were reported. He had a history of acute lithiasic pancreatitis, ischemic and valvular heart disease treated with CABG and mitral valve plastic, chemoembolization of pseudoaneurysm at the mesenteric artery, performed approximately 8 months earlier, with application of three metal spirals. On physical examination the abdomen was soft but widely painful. Laboratory tests showed only a modest neutrophilic

leukocytosis and a slight rise in C-reactive protein, hepatic transaminases and pancreatic enzymes levels were normal. Abdominal ultrasound revealed the presence of gallstones and biliary sludge, pancreas was not evaluable. A plain abdominal X-ray was normal except for signaling the presence of multiple metal wires in the abdomen. Despite the therapy, the abdominal pain remained unchanged. An EGDS was performed that was negative for ulcers or other injuries. The CT scan reported the presence of a radiopaque wire 2 mm-thick that extends from the III portion of the duodenum to the hepatic flexure. This wire was referable to the slinking of one of the spirals previously used for the embolization procedure.

Discussion

The slinking of spirals used in these procedures is a rare complication. In this case, the decubitus first occurred and then the foreign body entered the small intestine; gradually it has been extended by the intestinal peristalsis. A second extended EGDS confirmed the duodenal entry of the wire, with concomitant mucosal ulceration. This case shows the importance of a precise past medical history and how a non-surgical presentation of abdominal pain can hide a real surgical problem. The cooperation between Internists and Surgeon allowed the management of this unique case.

#1783 - Case Report

A CASE OF DRUG INDUCED LIVER INJURY

Joana Milho, Ana Rita Lambelho, Sofia Guerreiro Cruz, Ana Pinheiro Sá, José Barata

Hospital Vila Franca de Xira, Vila Franca De Xira, Portugal

Introduction

Drug induced liver injury (DILI) accounts for about 10% of all cases of acute hepatitis.

Lamotrigine is an anti-epileptic drug that rarely can cause hypersensitivity reactions with liver injury with a wide range of severity, from mild liver enzyme elevation to fulminant hepatic failure.

Case description

A twenty four year old woman presented to the hospital with fever, myalgia, and macular rash for 4 days. She had a history of bipolar disorder and 3 weeks previous to this episode was started on lamotrigine.

The initial evaluation showed liver enzyme elevation with a hepatocellular pattern: aspartate aminotransferase (AST) 544 U/L, alanine aminotransferase (ALT) 460 U/L, gamma-glutamyl transpeptidase (GGT) 36 U/L. INR 1, normal renal function, C-reactive protein 2 mg/dL, Leucocytes 4.2x10³/μL without eosinophilia. Serologies for hepatitis were negative. Abdominal ultrasound and CT didn't show masses or biliary tract obstruction. She was admitted to further investigation.

We assisted to deterioration of liver function - AST 7779 U/L, ALT

4363 U/L, bilirubin: total 2.12 mg/dL, direct 1.5 mg/dL, INR > 1.5, hypoalbuminemia, factor V 7%, thrombocytopenia 109 x 10³/μL but with no signs of encephalopathy, which led to admission in the intensive care unit.

A drug reaction was suspected so all potential hepatotoxic drugs were stopped.

A hepatic biopsy was performed and showed apoptosis and an inflammatory infiltrate constituted predominantly by eosinophils, characteristic for drug hypersensitivity reaction

With the withdrawal of lamotrigine and supportive care we assisted to an improvement of hepatic function tests. The patient was discharged one week later.

Discussion

Lamotrigine hypersensitivity reactions are not dose dependent and are impossible to predict. With this case the authors pretend to demonstrate that, although rare, lamotrigine hepatic injury can be severe so it's important a high level of suspicion.

The treatment consists on discontinuation of the offending drug with the majority of patients experiencing complete recovery.

#1792 - Case Report

AUTOIMMUNE HEPATITIS – AN OVERLOOKED ENTITTY

Ana Rita Lambelho, Luísa Gomes Silva, Joana Milho, Leuta Araújo, Ana Pinheiro Sá, José Barata

Hospital Vila Franca Xira, Vila Franca De Xira, Portugal

Introduction

The differential diagnosis of acute hepatitis is broad and often includes viral hepatitis, drug-induced liver injury, and alcoholic liver disease. Autoimmune hepatitis has an incidence of only 2.5% in the general population, which makes it a diagnosis often overlooked in the initial evaluation of acute hepatitis.

Case description

The authors present the case of a 46-year-old woman who went to the Emergency Department reporting a 2 day course of jaundice, choloria and abdominal pain. This was accompanied by a worsening asthenia, nausea and myalgias that started 3 weeks prior to its onset. She denied alcohol or drugs consumption. At observation she was icteric and presented with hepatalgia. The analytical evaluation showed elevated serum aminotransferase levels (AST 1713 IU/L, ALT 2273 IU/L), bilirubin (total 8.53 mg/dL, conjugated 6.86 mg/dL), GGT 411 IU/L and AP 213 IU/L elevation, as well as an INR of 1.32. An abdominal ultrasound was performed and excluded lithiasis or obstruction. The patient was hospitalized for further investigation. An abdominal CT scan was performed and did not reveal any significant changes. The viral serology markers were all negative along with the VDRL test. During hospitalization, a progressive improvement of the clinical status was observed with supportive therapy and she was discharged with normalized hepatic function. At the follow-up, a floating pattern of elevation of serum

aminotransferase levels were observed and a liver biopsy was performed. It revealed aspects of chronic hepatitis with fibrosis and inflammatory activity. ANA were present (1:640) and the remaining autoantibodies were negative (AMA, ASMA, ALC-1 and ALKM-1). A diagnosis of autoimmune hepatitis was made and the patient was referred to the Gastroenterologist where immunosuppression using glucocorticoid and azathioprine was initiated with progression to normal serum aminotransferase levels.

Discussion

Autoimmune hepatitis is a chronic inflammatory disease of the liver characterized by circulating autoantibodies. The disease may start as an acute hepatitis and progress to chronic liver disease and cirrhosis with high morbidity. This diagnosis is suspected when both characteristic serologic or histologic findings and the elevation of serum aminotransferase levels are present in the absence of other forms of chronic liver disease. As a result autoimmune hepatitis is a diagnosis often neglected in the initial management of acute hepatitis despite its serious consequences.

#1806 - Case Report

MULTIPLE RISK FACTORS FOR HEPATOCELLULAR CARCINOMA

José Da Cunha Marques, José Faria Costa, Catarina Vilaça Pereira, Fernando Miranda Nogueira, José Ribeirinho Soares, Diana Seixas Ferrão, António Jorge Almeida

Centro Hospitalar Universitário São João, Porto, Portugal

Introduction

Hepatocellular carcinoma (HCC) has no specific manifestations. It is often an incidental finding in imaging studies.

We present the case of a patient with multiple risk factors that show synergism for the development of HCC.

Case description

55 years old, male. History of alcoholism (60 grams/day), smoking (56 PY) and alcoholic cirrhosis.

Followed by Neurology due to parkinsonism secondary to hepatocerebral degeneration. No chronic medication. Referred to Internal Medicine department due to changes in liver tests. Patient denies fever and other constitutional symptoms. No history of previous gastrointestinal bleeding, ascites or encephalopathy. On physical examination with bilateral gynecomastia, cutaneous hyperpigmentation, digital clubbing and edema of the lower limbs. Total alcohol withdrawal counseling. Abdominal ultrasound shows a 49x39mm nodular lesion in the right hepatic lobe and 15cm splenomegaly. Analytically with thrombocytopenia and leukopenia, albumin 27.3 g/L, AST 103 U/L, ALT 80 U/L, GGT 133 U/L, alkaline phosphatase 154 U/L, total bilirubin 1.93 mg/dL, DHL 205 U/L, seric iron 172 g/dL, ferritin 1384 ng/mL, transferrin saturation 83%, betagama fusion on proteinogram and negative alpha-fetoprotein. Immune to hepatitis B virus, serology is negative for hepatitis C.

Chest-abdomen-pelvis CT revealed a liver with a dysmorphic aspect suggestive of chronic liver disease, a 46mm nodule suspected of HCC accompanied by a cavernomatous transformation of the portal vein.

Hepatic MRI demonstrates nodular lesion in the hepatic segment 8 of 47x42 mm, with washout compatible with HCC, chronic portal vein thrombosis with cavernomatous transformation, as well as iron overload raising suspicion of hemochromatosis. A genetic study was carried out with heterozygosity of the H63D gene.

Discussion

Patient in alcohol withdrawal for more than 6 months, good performance status, Child-Pugh B stage, without extrahepatic metastization, with chronic portal vein thrombosis. The case was discussed with the Oncology Group, that decided to perform radioembolization of the hepatic lesion. This is an illustrative case where the synergism between multiple risk factors culminated in the development of HCC.

THE CONJUGATION OF TWO RARE ENTITIES...

Ana Oliveira Costa, Pedro Pereira, Nuno Silva, Pratima Isvarlal, Paulo Carrola

Centro Hospitalar de Trás os Montes e Alto Douro, Vila Real, Portugal

Introduction

Pylephlebitis is a septic thrombophlebitis of the portal vein. Its clinical presentation may be highly variable requiring a high clinical suspicion for its diagnosis. Although a rare phenomenon, it is still associated with high mortality rates therefore, early aggressive interventions play an important role predicting their outcomes.

Case description

51-year-old woman, obese, medicated with oral contraceptive, presented to ED with progressive abdominal pain for 5 days, fever and anorexia. On physical examination hemodynamically stable but with tenderness in the right upper quadrant and lumbar percussion. Laboratory data revealed leukocytosis and elevation of CRP, mild cholestasis and hyperbilirubinemia. Abdominal CT revealed signs of acute thrombosis and pylephlebitis of the left portal and inferior mesenteric branches, without other intraabdominal focus, and no permeability of the right branch with right lobe atrophy and left lobe hypertrophy suggesting chronicity. Gynecology identified trichomoniasis without signs of pelvic infection. Additional questionnaire revealed mild abdominal trauma 2 years before. The patient was admitted with parenteral antibiotic therapy and hypocoagulation and carried out complementary investigation: no microbial isolation or septic focus identified; negative screening for solid and haematological malignancy; small varicose veins in the oesophagus and negative auto-immune study. However acute phase pro-thrombotic study revealed negative antiphospholipid antibodies, it also revealed heterozygous G20210A prothrombin

gene mutation and homozygous MTHFR C677T polymorphism, despite no hyperhomocysteinemia. Antibiotic therapy was maintained for 5 weeks and hypocoagulation to date (7months). MRI 5 months later still revealed thrombosis of the splenoportal axis with extension to the superior and splenic mesenteric veins and signs of portal cavernomatous transformation.

Discussion

This case meets 2 rare entities: a chronic noncirrhotic nontumoral portal vein thrombosis (PVT) and a pylephlebitis with no identifiable primary focus that did not recanalize. Regarding PVT in up to 80% the underlying cause is identified when exhaustively researched. In this case, the conjugation of prothrombotic susceptibility, obesity, oral contraception, and previous abdominal trauma may be the etiology of chronic thrombosis. Given prothrombotic disorder, recurrence and extent of thrombosis as well as the absence of recanalization, ad eternum hypocoagulation may be unavoidable.

#1812 - Case Report

RIBOCICLIB: FROM BREAST CANCER TREATMENT TO DEATH BY LIVER FAILURE

Ana Realista Pedrosa, Leila Barrocas, Sofia Moura, Conceição Barata

Hospital do Espírito Santo - Évora, Évora, Portugal

Introduction

Acute liver failure is a rare syndrome, characterised by an acute abnormality of liver blood tests in an individual without underlying chronic liver disease. Ribociclib is used in the treatment of postmenopausal women with metastatic breast cancer. It is associated with a moderate rate of serum aminotransferase elevations during therapy and to clinically apparent liver injury in some patients. Experience with ribociclib is limited, but it appears to be capable of causing significant liver injury. To the extent of our knowledge, acute liver failure associated with ribociclib has not been documented in the literature.

Case description

In this case report, we describe the evolution of acute liver failure in a 69-year-old woman with breast cancer stage IV (invasive carcinoma) with bone metastasis, treated with letrozole and ribociclib (suspended at admission), admitted with the diagnosis of febrile neutropenia. We objected a significant derangement in liver function, associated with jaundice, pruritus and hepatic encephalopathy. We rolled out liver metastasis, thrombotic events, compression of the biliary tree and viral infection. No other causes of acute liver failure were identified, leading to the presumptive diagnosis of hepatic toxicity secondary to ribociclib. Given the patient's history of metastatic cancer, she was not a candidate to liver transplant. Although supportive management and treatment with N-acetylcysteine were instituted, it was observed a poor outcome, neither biochemical test, nor encephalopathy were reversed, leading to death.

Discussion

This case report highlights the possibility that ribociclib can cause significant liver injury, leading to acute liver failure. We point out the importance of early recognition of liver injury and pharmacological toxicity since evolution to acute liver failure, though rare, is associated with a significant morbimortality.

#1815 - Abstract

AUTOIMMUNE GASTRITIS, A FREQUENTLY UNDERDIAGNOSED CAUSE OF IRON DEFICIENCY ANEMIA

Mafalda Ferro Teixeira¹, Inês Santos², Ana Sousa², Ricardo Paquete Oliveira¹, Bruno Grima¹, José Delgado Alves¹

¹ Hospital Professor Doutor Fernando da Fonseca, Lisboa, Portugal

² Hospital do Espírito Santo de Évora, Évora, Portugal

Background

Iron deficiency anemia occurs in 2-5% of adult men and postmenopausal women in the developed world and is a common cause of referral to Internal Medicine consultation. Autoimmune gastritis (AIG) is a chronic progressive inflammatory condition encountered in 20-27% of patients with obscure, or refractory iron deficiency. Although it is estimated to be 4 to 6 times more common than celiac disease it is frequently underdiagnosed and its association with other autoimmune endocrinopathies and gastric cancer is therefore overlooked. Aim: To characterize clinical, laboratorial and endoscopical profile of a population with iron deficiency anemia secondary to AIG.

Methods

A descriptive, observational study including 14 patients with a diagnosis of autoimmune gastritis (positive parietal cell antibody and gastric corpus atrophy) in the setting of refractory iron deficiency anemia and requirement for intravenous iron therapy, after exclusion of other potentially contributing causes of anemia. Data were retrospectively collected from clinical files, including: demographic age (age, gender), laboratorial evaluation (Hb, serum ferritin, B12 vitamin, folic acid, intrinsic factor autoantibodies, parietal cell autoantibodies, thyroid antibodies) and endoscopic findings. Descriptive statistical analysis was performed (mean, median and standard deviation).

Results

The mean age of all 14 patients was 54±18 years and 86% of the patients were female. 29% had concomitant vitamin B12 deficiency (pernicious anemia). 21% of the patients with AIG also had autoimmune thyroiditis. During iron deficiency anemia investigation, upper GI investigation (UE) was performed in 86% of the patients but only 50% were submitted to colonoscopy and an even lower percentage (7%) to videocapsule endoscopy. 58% of the patients submitted to UE had a macroscopically normal exam and only 17% had macroscopic evidence of corpus gastric mucosa atrophy. Gastric biopsies were performed in 83% of these patients.

Conclusion

We highlight autoimmune gastritis as a diagnosis to be considered when investigating refractory iron deficiency anemia particularly in women between the third and fifth decades of life. About one third of the patients with AIG have autoimmune thyroiditis. The initial pre-atrophic stages of AIG are not associated with substantial macroscopic changes, therefore the diagnosis may not be suspected endoscopically and the acquisition of mucosal samples are mandatory.

ACUTE HEPATITIS IN DRESS SYNDROME

Ana Mestre¹, Ana Oliveira¹, Filipe Damião², Sofia Carvalhana²

¹ Hospital Distrital de Santarém, Santarém, Portugal

² Centro Hospitalar Lisboa Norte - Hospital de Santa Maria, Lisboa, Portugal

Introduction

Dress syndrome (DS - Drug Reaction with Eosinophilia and Systemic Symptoms) is a severe and potentially life-threatening hypersensitivity reaction to drugs, with up to 10% mortality rate. It is characterized by a mild exanthem to extensive macular erythema, fever, eosinophilia, lymphadenopathy and systemic involvement. Hepatic injury is frequent but generally mild, with

Clinical summary

A 78-year-old woman goes to the emergency department due to cough and dyspnea for small efforts with two weeks of duration. Without fever or other organ/system-specific complaints. On physical examination: hemodynamically stable, no fever, labial cyanosis and scattered crackles in both lung fields. Arterial gasometry with respiratory insufficiency. Analytically: high PCR (231 mg/L), without leukocytosis, BNP 1369.1 pg/mL, urinary antigen tests negative for *Streptococcus pneumoniae* and *Legionella pneumophila*. Chest X-ray with hydro-aerial level in the lower 1/3 of the left hemithorax (pulmonary abscess?).

CT scan of the thorax revealed a hiatal hernia with the entire stomach localized in the thoracic cavity and the patient was directed to General Surgery.

transaminases elevation not greater than 10 times the normal value. Hepatic insufficiency is rare.

Case description

A 45-year-old woman presents to the emergency department with a 7 days history of a non-pruritic cutaneous rash, that started 3 weeks after the introduction of sulfasalazine for seronegative arthritis. On physical examination she was febrile (38°C) and presented an extensive maculopapular eruption with erythema and edema of the face. Laboratory studies revealed normal white blood cell count (5900 cell/ μ L) with absolute eosinophil count of 2000 cell/ μ L, with no atypical lymphocytes. Liver enzymes were mildly elevated: aspartate transaminase (AST) 54 IU/L; alanine transaminase (ALT) 235 IU/L; alkaline phosphatase (AP) 234 IU/L; gamma-glutamyl transferase

(gGT) 216 IU/L; total bilirubin 1.40 mg/dL, with normal prothrombin time (PT). Renal function was normal at presentation. The patient was admitted to the dermatology ward and started on 1mg/Kg/day dose of prednisolone with clinical improvement. A skin biopsy was performed showing superficial dermal perivascular lymphocytic inflammatory. Five days after the admission she was started on cefuroxime, for urinary tract infection, with recurrence of rash and fever after 3 days. There was a sudden and severe rise in liver enzymes (AST 6364 IU/L; ALT 3133 IU/L; AP 291 IU/L; gGT 481 IU/L) total bilirubin was elevated (10.03 mg/dL) and PT slightly prolonged. Other causes of hepatitis were excluded, and a liver biopsy was performed revealing acute hepatitis confluent bridging necrosis, suggestive of toxic etiology. After withdrawal of all the drugs, with the exception of prednisolone, there was a progressive improvement.

Discussion

DS pathogenesis, is to this day, not completely understood, however, drugs like antibiotics are known triggers, specially in patients previously exposed to sulfasalazine. Treatment is based on the discontinuation of the culprit drug and administration of corticosteroid. Although rare, acute hepatitis is a potentially fatal complication of DS.

A HIDDEN FOE - A CASE OF CHRONIC LIVER DISEASE

José Pereira, Juliana Magalhães, Inês Antunes, Ivone Barracha, Rosa Amorim

Centro Hospitalar do Oeste - Hospital de Torres Vedras, Torres Vedras, Portugal

Introduction

Hemochromatosis is a recessive autosomal hereditary disease. Its mutations impact the function and production of hepcidine, consequently unregulating iron homeostasis and allowing the accumulation of iron on the organ tissues. Despite being a notorious etiology of liver disease, when in presence of another, more common, cause, its investigation is often overlooked, resulting in significant underdiagnosis. Late onset of treatment might allow disease progression, with development of chronic liver disease (CLD) and severe impact on prognosis.

Case description

We report the case of a 57 year old male fisherman, with a history of type-2 diabetes, hypertension, smoking and drinking habits, the latter spanning over 4 decades. He had a presumptive diagnosis of alcoholic liver disease, and was sent by his family doctor to a diabetology appointment due to worsening metabolic control. Initial laboratory assessment revealed macrocytosis (104 fL), thrombocytopenia (94,000) and hyperbilirubinemia (2.1 mg/dL), with mild cytolysis (TGO 78U/L, TGP 67U/L) and cholestasis (AF 156 U/L, GGT 60 U/L). Abdominal ultrasound revealed only moderate hepatomegaly and upper GI endoscopy was unremarkable. The

patient was classified as a Child-Pugh A (Score 6). Iron studies revealed serum iron levels of 237 mcg/dL and a 14532 ng/mL ferritin. AFP was 4 ng/mL and viral serologies were negative. The patient presented a greyish skin tone, initially ignored given the patient's job and subsequent heavy sun exposure. An MRI revealed important hepatic and splenic iron overload and HFE gene testing identified the c.845G>A (p.Cys 282Tyr) mutation.

Discussion

The authors present this case report given the presence of a concurrent frequent and obvious cause of hepatic disease, which delayed clinical suspicion and diagnosis of hemochromatosis. The patient's skin tone and the presence of high ferritin led to further investigation, which culminated in a diagnosis. The authors would also like to emphasize the need for a thorough approach of CLD patients, even in alcoholics, given the potential prognosis impact of early treatment in some cases.

CROHN'S DISEASE: A DIAGNOSTIC CHALLENGE

Isabel Maria Pinheiro

Hospital Santa Maria, CHLN, EPE, Lisboa, Portugal

Introduction

Crohn's disease is an inflammatory, chronic, idiopathic disease that can affect any segment of the digestive tract and may evolve with periods of activity and remission, including abdominal pain and diarrhea with mucus and blood, fistulas, obstruction, malnutrition and several extra-intestinal manifestations, namely genito-urinary, musculo-skeletal, dermatological, ophthalmologic and hypercoagulable states.

Case description

69-year-old white male, retired accountant, married, with previous tonsillectomy 20 years ago; laparoscopic cholecystectomy; smoking; pulmonary emphysema; benign prostatic hypertrophy and ureteral meatus stenosis; thrombosis of the mesenteric artery recanalized (of unclear etiology). Recently admitted with pyelonephritis due to *Enterococcus faecalis*, balanitis due to *Candida albicans* and external hemorrhoid thrombosis. He also complained of diarrhea in the last year, 4 daily dejections, sometimes with mucus but without blood. At the physical examination he was pale, without jaundice, emaciated, abdomen was diffusely painful to palpation but without pain at decompression or other alterations, without palpable adenopathies. Analytically: Hb 12.6g/dL; normal B2-microglobulin and serum electrophoresis; negative serology for cytomegalovirus, hepatitis B and C and HIV1, negative antibodies anti-gliadin and anti-endomysial, interferon gamma release assay (IGRA) was negative. *Clostridium difficile* toxin, stool culture and parasitological examination of feces were negative.

The colonoscopy showed 5 cm of ileum, with 2 deep linear ulcers and an irregular mucosa. Biopsies were inconclusive. The capsule

endoscopy revealed deep ulcers in jejunum, one of which occupied 2/3 of the circumference and was responsible for secondary stenosis, and mucosal aspects suggestive of active ulcer disease of the small intestine. The entero-resonance showed extensive and active ulcerated disease of the whole ileum, short bowel, non-active entero-enteric fistula and mesenteric reactive adenopathies. The upper gastrointestinal endoscopy was normal and abdominal computed tomography, revealed aspects of superior mesenteric vein thrombosis recanalised and collateral venous circulation. He was medicated with prednisolone with clinical improvement.

Discussion

This extensive disease was reasonably tolerated. We assumed that superior mesenteric vein thrombosis occurred in the context of hypercoagulability associated with Crohn's disease.

AEROPORTIA – SIGNAL OF ADVANCED BOWEL ISCHEMIA

Anilda Barros, Elena Pirtac

Hospital Garcia de Orta, Almada, Portugal

Clinical summary

A 93-year-old woman with previous history of chronic atrial fibrillation requiring the reversal of anticoagulation therapy due to spontaneous abdominal wall hematoma. She presented with acute abdominal pain and a diagnosis of mesenteric ischemic was made. Toraco-abdomino-pelvic CT scan showing exuberant aeroportia and intestinal pneumatosis.

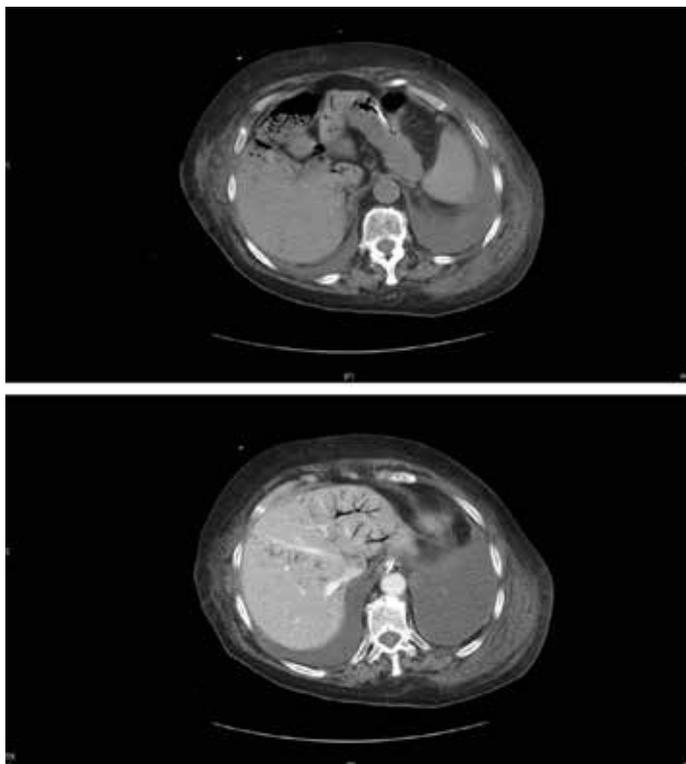

Figure #1959.

#2005 - Abstract

PROTEIN PUMP INHIBITORS IN A MEDICAL WARD

Estefânia Turpin, Rita Valente, Filipa Cardoso, Inês Lopes, Maria Amaral

Centro Hospitalar Universitário de Lisboa Central, Lisboa, Portugal

Background

Protein pump inhibitors' (PPI) prescription is widely disseminated. Although according to the current guidelines, published by the American Society of Healthsystem Pharmacists SHP, there is no indication for prescribing PPI for stress ulcer prophylaxis (SUP) in patients admitted to the hospital outside intensive care units the reality is most patients are medicated with these drugs.

Methods

In this study we selected all patients hospitalized in three different internal medicine wards during the same 24 hours and checked if they were medicated in that moment with PPI. We then used the proposed risk stratification score by Herzig SJ et al to classify them in to low risk (LR) (score ≤ 7), low-medium risk (LMR) (score 8-9), high-medium risk (HMR) (score 10-11) or high risk (HR) (score ≥ 12) for digestive haemorrhage. Only the HMR and HR patients have indication for PPI. We also took in account history of dyspepsia, gastritis, esophagitis, gastric reflux disease and gastric or duodenal ulcer as these diseases may cause symptoms that could have indication for treatment with PPI, and upper intestinal bleeding.

Results

Of the 132 patients hospitalized, 67 corresponding to 50,8% were medicated with PPI but only 38 (28,8%) had indication for SUP. Among the LR and LMR patients 9 had gastro-oesophagi pathology that could justify treatment with PPI. Surprisingly among the 38 patients who had indication for SUP, only 17 were prescribed PPI. There were 8 cases of upper gastrointestinal bleeding, 5 among patients with score ≥ 10 , and 3 among LR and MLR patients, and they were all medicated with PPI. 53 patients (40.2%) were medicated with PPI before being admitted, 35 with LR and MLR, of which 26 were medicated with PPI in the hospital, and 18 with HMR and HR, 15 of these medicated medicated with PPI in the hospital.

Conclusion

In these medical wards PPI are overprescribed in patients who don't have indication for SUP and under-prescribed in those who do have. Some of the perceived overprescription could be explained by other indications for PPI like symptoms of dyspepsia or heartburn. The fact that patients were previously medicated with PPI could also incline doctors to continue this prescription in the hospital. This shows the importance of further studies to validate a risk score and its uniformed use. PPI have known side effects in the intestinal flora and potentially cognitive impairment. Like any other drug they are not innocuous and their prescription should be carefully considered.

#2029 - Case Report

PORTAL HYPERTENSION: WHEN THERE IS NO EVIDENT CAUSE

Joana Borges¹, Carolina Teles², Teresa Vaio², Rui Santos², Armando Carvalho²

¹ Respiratory Medicine Service, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

² Internal Medicine Service, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Introduction

Portal vein obstruction (PVO) that leads to portal hypertension (PH) is classified based upon the site of obstruction. PVO can occur due to a disturbance in any one of the Virchow triad components: reduced flow, hypercoagulable state or endothelial disturbance.

Case description

A 39-year-old woman was seen in the Emergency Department with upper quadrant abdominal pain as well as nausea, fatigue, and anorexia for a month. She denied fever. No other symptoms were recorded. Besides being obese, she had no relevant past medical history. She had been taking Desogestrel with Ethinylestradiol. She had had no recent surgery, hospital admission or trauma. She had no smoking or alcoholic habits. On admission, she had leucocytosis and raised C-reactive protein, aminotransferases (AST 48 U/L, ALT 86 U/L) and γ glutamyltransferase (152 UI/L). Ultrasound with Doppler flow study showed absent flow in the portal vein. She was admitted, the oral contraceptive was stopped and anticoagulation was initiated. Endoscopy revealed oesophageal varices. Contrast-enhanced abdominal computed tomography revealed thrombosis of the inferior vena cava, portal vein (with cavernous transformation of it), splenic vein and superior mesenteric vein. Serological testing for viral hepatitis was negative. Levels of lipid panel, immunoglobulins, iron saturation, serum ferritin, ceruloplasmin, copper, and α -1-antitrypsin levels were normal. Tests for antinuclear, antimitochondrial, anti-smooth muscle, anti-liver cytosol, anti-liver/kidney microsomal, anticardiolipin and anti-beta2-glycoprotein I antibodies and lupus anticoagulant were negative. She had no antithrombin or protein S or C deficiencies and no factor V Leiden and JAK2 V617F mutations. Paroxysmal nocturnal haemoglobinuria (PNH) was excluded by the absence of PNH white blood cells. She had homozygosity for MTHFR c.665C->T but not an increase in plasma homocysteine that would increase the thrombophilic risk. Anticoagulation was initiated with enoxaparin (1 mg/kg twice a day) and then changed to warfarin (dose-adjusted). Upon clinical and analytical improvement the patient was discharged from the hospital.

Discussion

This case report highlights the importance of the identification of the cause of PVO, as it can imply different management approaches. No apparent cause is found in 25% of patients and many of these patients probably have an underlying hypercoagulable state. Clinical presentation is often non-specific, which makes a PVO diagnosis extremely difficult.

#2054 - Case Report

COMPLICATED PANCREATIC PSEUDOCYST

Catarina Jorge¹, Tânia Gago², Bruno Peixe², Tatjana Mihailovic¹, Sérgio Silva¹, Domingos Sousa¹, Sara Duarte¹, Diana Reis¹

¹ Algarve's University Hospital Centre - Faro Unit, Internal Medicine Department, Faro, Portugal

² Algarve's University Hospital Centre - Faro Unit, Gastroenterology Department, Faro, Portugal

Introduction

The pseudocyst is defined as a fluid collection that result from pancreatic inflammation and necrosis. It's commonly associated with alcoholic etiology and occurs in 20 to 40% of cases of chronic pancreatitis. Infection, hemorrhage and rupture are examples of complicated pseudocysts.

Case description

A 47-year-old woman is brought to the Emergency Department (ED) by a generalized tonic-clonic seizure, lasting 30 seconds, with sphincter incontinence, without tongue biting. New seizure was observed in the ED that subsided with diazepam. The family reported that the patient had fever and abdominal pain with 3 days of evolution associated with vomiting the day before. History of alcohol habits for about 6 years (192 g/day) and smoking. No history of epilepsy. No other organ or system focusing symptomatology. At admission, the patient was vigilant, disoriented, hypertensive, eupneic, febrile, without cardiopulmonary alterations. Soft and depressible abdomen, with palpable mass in epigastric and periumbilical region, about 8 cm in diameter, elastic consistency, painful, with signs of peritoneal irritation. Negative meningeal signs. Analytically, elevation of inflammatory markers, hyperglycemia, cytocholestase pattern and elevation of amylase (721 U/L) and lipase (771 U/L). Abdominal ultrasound revealed a well-defined lesion, heterogeneous, 15x7cm, difficult to visualize if there was communication with a part of the pancreas. For better characterization, abdomen CT scan was performed, showing a well-defined, encapsulated collection in the pancreatic body and tail, suggesting a pancreatic pseudocyst with an internal hemorrhagic area (pseudoaneurysm rupture). Pancreatitis of alcoholic etiology was admitted with pancreatic pseudocysts complicated with hemorrhage and infection. Seizures in the context of alcohol withdrawal syndrome.

Discussion

The present case report pancreatic pseudocyst complicated by infection and hemorrhage, which is a rare condition. In addition, the clinical presentation as a seizure was an initial confounding factor, reinforcing the primordial value of the complete anamnesis in the establishment of the diagnosis.

#2060 - Medical Image

FROM OLGIVIE'S SYNDROME TO RESPIRATORY FAILURE

Francisca Santos, Daniela Félix Brigas, Eugénio Dias, Susana Marques

Centro Hospitalar de Setúbal, Setúbal, Portugal

Clinical summary

A 90-year-old man was admitted at the Emergency Department after being found fallen at home. Upon the objective examination, it should be highlighted the presence of a very voluminous abdomen with marked tympanism at percussion. Rectal examination showed a normotonic sphincter, without stenosis. Analytically, there were no major changes. An abdominal x-ray was performed and suggested a megacolon and the abdominal-pelvic computed tomography confirmed an important distension of the colonic frame, with no significant distention of the thin loops, with presence of fecaloma in the sigmoid and rectal ampulla. It appeared to be a case of megacolon in the sequence of Olgivie's syndrome. Despite the medical measures, the patient died in a respiratory failure sequence.

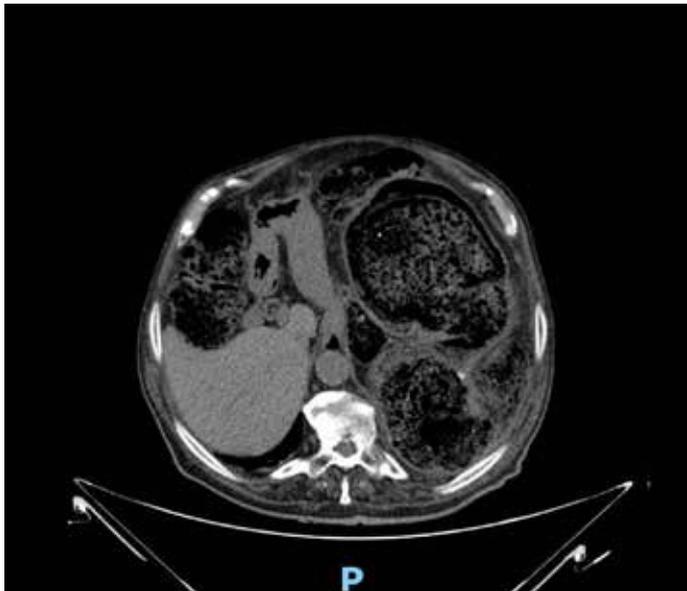

Figure #2060. Computed tomography findings of a case of megacolon associated with Olgivie's syndrome.

#2098 - Case Report

PRIMARY SCLEROSING CHOLANGITIS AND ULCERATIVE COLITIS IN A YOUNG WOMEN

Cristina Moreira Marques, Ana Francisca Pereira, Carina Costa Silva, João Pedro Abreu, Márcia Ribeiro, Ana Ogando, Carlos Oliveira

Hospital Santa Maria Maior, Barcelos, Portugal

Introduction

Primary sclerosing cholangitis (PSC) is the cholestatic hepatobiliary disorder more common in males and usually presents at 40 years of age. It is a chronic immune-mediated disease of intra and

extrahepatic bile ducts, primarily affecting large ducts. Is usually common in patients with inflammatory bowel disease (IDB), particularly those with ulcerative colitis (UC) with a phenotype involving rectal sparing, right colonic disease with backwash ileitis; and generally, its diagnosis is posterior to the IBD.

Case description

18-year-old female, without previous relevant medical history or medication, presented in the ER with abdominal pain in the right hypochondrium, pruritus and diarrhea without blood or mucus, without fever, with two months of evolution. She had a normal physical exam. Blood work was done, with normal blood count, AST 193 IU/L; ALT 668 IU/L; AP 485 IU/L; GGT 1165 IU/L, normal bilirubin and CMV, HBV, HCV and HIV negative serologies. Due to the alterations, a CT scan was performed that showed a "mild dilatation of the intrahepatic biliary tract". She was then directed to the Internal Medicine Consultation to continue the study. A MRI showed "mild ectasia of the intrahepatic bile ducts, which alternate with areas of mild stenosis". The colonoscopy showed typical signs of ulcerative colitis, in particularly cecal patch. The autoantibody test performed revealed ANA; ANCA; LC1 and anti-ML positive. The patient was diagnosed with primary sclerosing cholangitis and ulcerative colitis, started on ursodeoxycholic acid with improvement of the liver function and symptoms.

Discussion

The diagnosis and management of PSC presents itself with several challenges. Many times patients are asymptomatic or present with mild symptoms. In this case, the diagnose of PSC prior to that of the IDB, which should alert us to the importance of the diagnosed of the associated diseases that sometimes do not have the most common presentation. The treatment of this entity is of vital importance once our goal is to achieve delay or reversal of the disease and its complications.

#2106 - Case Report

GASTRIC OUTLET OBSTRUCTION- FIRST MANIFESTATION OF DUODENAL ULCER SUCCESSFULLY TREATED WITH DRUG THERAPY

Federica Parlato¹, Pedro Silva Gaspar^{1,2}, Manuel Silvério António³, Maria Margarida Andrade¹, Sandra Braz^{1,2}, Rui Victorino¹

¹ Serviço de Medicina 2, Hospital de Santa Maria (Director: Prof. Doutor Rui M. M. Victorino), Centro Hospitalar Lisboa Norte, Lisboa, Portugal

² Faculdade de Medicina, Universidade de Lisboa, Lisboa, Portugal

³ Serviço de Reumatologia e Doenças Ósseas Metabólicas (Director: Prof. Doutor João Eurico da Fonseca), Hospital de Santa Maria, Centro Hospitalar Lisboa Norte. Unidade de Investigação em Reumatologia, Instituto de Medicina Molecular, Centro Académico de Medicina de Lisboa, Faculdade de Medicina, Universidade de Lisboa, Lisboa, Portugal

Introduction

The prevalence of peptic ulcer disease (PUD) has significantly

decreased over the past several decades due to treatment of *H. pylori* infection and the development of drugs such as proton pump inhibitors (PPI). However, complications such as hemorrhage, perforation and obstruction still occur. Gastric outlet obstruction (GOO) is the least frequent complication occurring in 3% of the cases. Definitive treatment may include endoscopic balloon dilatation or surgery.

Case description

A 81-year-old male patient, with prior medical history of primary hemochromatosis, arterial hypertension and type 2 diabetes mellitus, was admitted with a 1-week history of nausea, epigastric pain and bloating relieved by vomiting. He denied hematemesis or melena. On physical examination he was dehydrated and had abdominal distension with tenderness over epigastrium and left hypochondrium. Laboratory findings were as follow: hemoglobin 15 g/dL, urea 148 mg/dL, serum creatinine 2.14 mg/dL, Na⁺ 141 mmol/L, K⁺ 3.7 mmol/L. Abdominal x-ray showed exuberant gastric distension and computed tomography scan revealed parietal thickening of the gastric antrum-pyloric region and duodenal bulb of about 2.5cm in length. Upper endoscopy showed intense edema and hyperemia of the bulbar mucosa and a severe stenosis at that level. Biopsies were taken and a nasogastric tube was placed. Histopathology revealed intense chronic antral and pyloric inflammation, mucosal ulceration and the presence of *H. pylori*. There was no evidence of fibrosis or malignant tissue. *H. pylori* infection eradication therapy (intravenous amoxicillin, metronidazole and high dose PPI) was started. On the second week of therapy, liquid diet was initiated and tolerated. Upper endoscopy was repeated on the third week of high dose PPI and showed partial resolution of the stenosis. The feeding tube was removed and soft diet was initiated. Three months after the diagnosis of GOO the patient tolerates normal diet.

Discussion

PUD, both acute and chronic, can lead to GOO and accounts for about 5% of the cases of obstruction. In this case GOO was the inaugural manifestation of DUP. The sudden onset of the clinical picture, the intense hyperemia and edema of the duodenal mucosa, the presence of an inflammatory infiltrate and absence of fibrosis in the tissue supports this diagnosis. In these cases, drug therapy is a reasonable, safe and efficacious option. Endoscopic dilatation and/or strictureplasty should be reserved for patients who fail to respond to drug therapy.

#2116 - Case Report

VON MEYENBURG COMPLEX AS DIFFERENTIAL DIAGNOSIS OF SOLID LIVER LESION.

Pedro Manuel Reis Pereira, Patrícia Chow Liu, Joana Liz Pimenta, Paula Vaz Marques, Sandra Alves Morais
Centro Hospitalar de Trás-os-Montes e Alto Douro, Vila Real, Portugal

Introduction

Hepatic lesions are a common finding in clinical practice. The aetiology of solid liver lesions is diverse, dividing mainly into benign and malignant lesions. Patients with chronic liver disease have a higher risk of malignant lesions, therefore, a close screening and detailed investigation of new solid liver lesions should be performed.

Case description

We present the case of a 58-year-old male with an alcoholic liver disease at a compensated cirrhotic stage, followed at the hepatology outpatient clinic. During an abdominal ultrasound screening an hypoechoic nodule was found on the right hepatic lobe, with a diameter of 19 mm. Hepatic MRI described the presence of a nodule with a diameter of 16 mm of which the unspecific imagiological features resembled a colangiocarcinoma or an hyalinized hemangioma (atypical hepatic hemangioma). Given the doubts raised by the imaging exams, a nodule biopsy was performed, and the histological examination described the presence of lesions suggestive of bile ducts hamartomas. Based on the benignity of the diagnosis, this compensated cirrhotic patient remained on a biannual screening regime, and maintains a stable evolution.

Discussion

Bile ducts hamartomas, also known as Von Meyenburg complex, are rare, benign and asymptomatic hepatic malformations, with variable imagiological findings that may sometimes resemble malignant lesions. The radiological presentation demonstrate multiple small lesions scattered throughout the liver, or more rarely an isolated nodule, thus, imaging exams are not reliable methods for the differential diagnosis. Biopsy of the liver lesion remains the gold standard for a definitive diagnosis of Von Meyenburg complex. In the present case, we intend to demonstrate an atypical presentation of a rare benign entity, in which radiological similarities with malignant lesions may lead to a incorrect and inconclusive interpretation of the findings. We highlight the importance of histologic evaluation, especially in cirrhotic patients in order to diagnose a rare and not frequently considered entity in clinical practice.

#2122 - Abstract

MORTALITY AFTER VARICEAL HEMORRHAGE IN CIRRHOTIC PATIENTS: IDENTIFYING RISK FACTORS

Margarida Viana Coelho¹, Pedro Campelo², Claudia Camila Dias^{3,4}, Isabel Jesus Pereira^{5,3,4}

1. Internal Medicine Department, Hospital de Faro, Centro Hospitalar Universitário do Algarve, Faro, Portugal
2. Gastroenterology Department, Hospital de Faro, Centro Hospitalar Universitário do Algarve, Faro, Portugal
3. Department of Community Medicine, Information and Health Decision Sciences-MEDCIDS, Faculty of Medicine of the University of Porto, Portugal, Porto, Portugal
4. CINTESIS – Center for Health Technology and Services Research, Porto, Portugal, Porto, Portugal
5. Emergency and Intensive Care Department, Hospital de Faro, Centro Hospitalar Universitário Do Algarve, Faro, Portugal, Faro, Portugal

Background

Variceal hemorrhage in cirrhotic patients is a medical emergency with an estimated mortality of 15– 20% during the first episode. Risk classification can be assessed by Child-Pugh class, Model for End Stage Liver Disease (MELD) score, variceal size, and endoscopic findings.

Our aim was to identify factors associated with mortality in patients with esophageal and gastric variceal hemorrhage.

Methods

A retrospective observational study was conducted between 1 January and 31 December 2017. All cirrhotic patients admitted with acute variceal hemorrhage were included. Clinical records were revised for data retrieval on end stage liver disease related complications (hepatic encephalopathy, ascites, spontaneous bacterial peritonitis and hepatocellular carcinoma (HCC)), and for scores of severity and prognosis (Child-Pugh and MELD). The course of hospitalization was investigated through the presence of hemodynamic instability, hemoglobin values, active bleeding at the initial endoscopy and subsequent episodes hemorrhage. Statistical analysis was performed according to the collected variables and objectives and data was analyzed using SPSS v25.

Results

A total of 57 cirrhotic patients with esophageal and gastric variceal hemorrhage on admission were included, of whom 87,7% were male (n=50) with a mean age of 60,5 years; 91,2% had alcoholic etiology. The mean MELD score was 19,1; 57,9% of patients had Child-Pugh class B (n=33) and 33,3% Child-Pugh class C (n=19). In-hospital mortality was 15.8% (n=9); and 42.1% (n=24) at 30-days

In-hospital mortality was strongly associated with hepatic encephalopathy (p=0.002), hemodynamic instability (p=0.008), ascites (p=0.012), active bleeding at the initial endoscopy (p=0.048) and relapsing hemorrhage (p=0.022).

Mortality at 30 days was strongly associated with hepatic

encephalopathy (p=0.000), ascites (p=0.024), Child Pugh Class B and C (p=0.001), relapse bleeding (p=0.004) and HCC (p=0.005).

Conclusion

Attention should be addressed towards the prevention of major cirrhosis complications. As described in other series, mortality was strongly influenced by hepatic encephalopathy, ascites and relapse bleeding. When considering 30-day mortality, Child-Pugh class and HCC were also strongly associated with increased mortality.

In the acute setting, hemodynamic resuscitation and hemorrhage treatment must be concomitant with the identification and treatment of cirrhosis complications, as these are predictors of mortality.

AN ATYPICAL PRESENTATION OF AN ASYMPTOMATIC PANCREATITIS WITH A LATE COMPLICATION: WON

Marta Sáenz De Tejada López, Gloria Rojano Rivero, Maria Elena Mansilla Rodriguez

Hospital Infanta Elena, Huelva, Spain

Clinical summary

A 53-year-old patient with a history of hypertension, dyslipidemia and smoking.

Admitted for 4-days-evolution of a biliary colic with a lipase in 208 mg/dl and PCR 72, without leukocytosis and normal hepatic profile. Diabetes not previously known with HbA1c 7.5%. We found a suspect image in US of a cystic lesion in the head of the pancreas. In the abdomen scan, we see an image of a large imprecise multicystic lesion in the head/uncinate process of 43x38x43 mm, impressing of pancreatic cystic tumor. USE-PAAF, describes an encapsulated necrotic collection, suggesting WON (Walled-off necrosis) and the biopsy of the lesion dismiss malignancy. It was made a necrosectomy and cholecystectomy, due to bad evolution. It's an atypical late complication of acute pancreatitis, asymptomatic in this case.

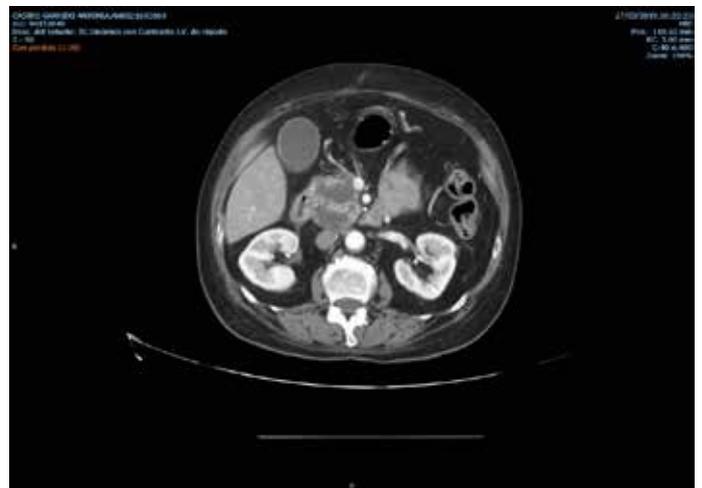

Figure #2134. Scan of the pancreatic lesion.

#2152 - Case Report

RETROPERITONEAL LIPOSARCOMA – A RARE ENTITYMiguel Alexandre Alves¹, Sergio Alves¹, Filipa Lucas²¹ ULSNE, Bragança, Portugal² Hospital de Cascais, Cascais, Portugal**Introduction**

Retroperitoneal sarcomas are rare tumors, with incidence around 2.5 cases / million inhabitants. Within these, the liposarcomas represent about 20% of cases. They are usually slow growing, oligosymptomatic tumors, reaching large sizes at diagnosis.

Case description

We present a case of a man of 69 years of age, with marked alcoholic / smoking habits that reported a progressive increase in abdominal perimeter, with weight loss of 12 kg during the last year. He had na abdominal voluminous mass that occupied the right quadrants. Abdominal ultrasound was not enlightening and therefore an abdominal CT was performed, revealing a heterogeneous mass measuring 24x18x21 cm, which occupied almost all of the abdominal cavity. MRI showed good cleavage planes with adjacent structures and confirmed the retroperitoneal location of the lesion. The complementary study did not show any secondary lesions. He underwent surgery for removal of the retroperitoneal tumor and complementary appendectomy due to adhesion. The main piece weighed 5.220 kg and the surrounding retroperitoneal fat about 1.360 kg. The postoperative period was uneventful. The anatomical-pathological study revealed a predominance of adipocyte cells with nuclear and abundant atypia connective septa, compatible with a well differentiated liposarcoma. Currently the patient is being treated with Radiotherapy.

Discussion

Clinically it presents, in the great majority of cases, as an asymptomatic abdominal mass, not painful to palpation. When symptoms are present, they are responsible for the effect of local tumor invasion, such as: early satiety, gastrointestinal occlusion, lower limb or abdominal edema. The first-line treatment is surgical, with block resection of the tumor and adjacent structures or organs with direct evidence of invasion, since the negative histological margins represent the main prognostic factor.

A FEVER KEPT IN A POCKET

Mafalda Corrêa Figueira, Margarida Lopes Madeira, Goncalo Amaral Mendes, Bárbara Lobão, José Pedro Villa De Brito, Ermelinda Pedroso

Centro Hospitalar de Setúbal, Setúbal, Portugal

Clinical summary

A 72-year-old male patient was admitted due to progressive and worsening dysphagia accompanied by severe weight loss and intermittent fever.

During the first evaluation he was found to have a giant zenker diverticulum.

He had a relapsing-remitting fever so that infectious, autoimmune and neoplastic etiologies were investigated and excluded. After surgical intervention to remove zenker diverticulum he stopped having fever.

It was hypothesized that the debris that accumulated in esophageal pouch, probably with some component of lung microaspirations, could explain the recurrence of fever.

Figure #2204. Giant Zenker diverticulum.

GERIATRICS AND MULTIMORBIDITY

#31 - Abstract

ASSESSING COMORBIDITY AND QUALITY OF LIFE IN EXTREMELY ELDERLY PEOPLE

Laisa Socorro Briongos Figueroa¹, Marta Cobos Siles¹, Jessica Abadía Otero¹, Miriam Gabella Martín¹, Ana Aguado De La Fuente², Juan Carlos Martín Escudero¹

¹ Internal Medicine Service, Rio Hortega University Hospital, Valladolid, Spain

² Nursing Care Department, Rio Hortega University Hospital, Valladolid, Spain

Background

Spanish population life expectancy is one of the longest in the world. Moreover, it's known that elderly people have less chronic illnesses associated to aging. Our aim was to analyze interactions between comorbidities and health related quality of life (HRQoL) in extremely elderly patients

Methods

Cross-sectional study including Internal Medicine in-patients over 80 years-old without diabetes mellitus during 2018. Clinical information was obtained from medical records. Comorbidity was evaluated using Charlson index (CI) and HRQoL with EuroQoL (EQ-5D-3L). Data analyzed using SPSS v.15.0

Results

We identified 305 patients, 59% women. Mean age was 88±5, 38% were aged over 90 and 64% were living in family home. For the previous year, mean number of visits at primary care system were 5.5±3.3 and 2.4±1.8 at the emergency department. Most common comorbidities were hypertension (78%), hypercholesterolemia (37%), atrial fibrillation (31.5%), dementia (23.6%), chronic respiratory disease (19.7%) and heart failure (6%). Corrected CI mean score was 6.2±1.7, without comorbidity in 51% and high comorbidity in 28.5% of patients (higher in men: 33.6% vs 25%, $p=0.049$). Estimated HRQoL was 0.43±0.33 on a scale between 0 and 1 for index value and 55.7±19 for visual analogue scale with a CI correlation of -0.171 ($p=0.003$) for EQ-5D-3L index value

Conclusion

As a novelty, present study showed that about half of our non-diabetic-patients have no comorbidities. Furthermore, weak negative correlation between IC and HRQoL was detected: as CI

increased a worse subjective HRQoL appeared. This fact matches with the high prevalence of absence of comorbidities in our extremely elderly population.

#34 - Case Report

A DEADLY FORM OF DELIRIUM

Xin Zhang, Bernard Aoun

Mayo Clinic, Rochester, United States

Introduction

Acute onset mania is rare in the older adults and should raise suspicion for delirium or dementia. Delirious mania is a rare and potentially deadly etiology of acute onset mania in hospitalized patients.

Case description

A 62-year-old woman, with psychiatric history of major depression, was hospitalized for urinary tract infection. During her hospitalization, she exhibited unusual behaviors consisting of paranoia, disinhibition, and pressured speech. Interestingly, she did not have fluctuations in orientation or alertness suggestive of acute delirium. Because of the manic symptoms, she was started on risperidone and haloperidol. Unexpectedly, she developed hallucinations and signs of catatonia. She had extensive evaluation for somnolence and was found to have pneumonia. CT head showed mild leukoaraiosis. EEG demonstrated diffuse slowing and intermittent runs of generalized triphasic waves consistent with delirium. Risperidone was discontinued without improvement in her mental status. Despite aggressive medical therapy, she developed multiorgan failure and passed away after 30 days in the hospital.

Discussion

Delirious mania is a highly fatal, acute, rapidly progressive and under recognized syndrome of alternating delirium, mania, catatonia and psychosis. In 1 study, 75% of patients with delirious mania died while hospitalized. Unlike in acute delirium, antipsychotics may worsen symptoms. Benzodiazepines and electroconvulsive therapy are the recommended treatments.

#134 - Abstract

HOSPITAL READMISSIONS IN ELDERLY PATIENTS WITH HEART FAILURE. A RETROSPECTIVE STUDY

Rita Vieira Alves, Marília Andreia Fernandes, Diogo Drummond Borges, Inês Rego Figueiredo, Ana Margarida Antunes, Heidi Gruner

Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

Background

Heart failure (HF) is a major cause of morbidity and mortality worldwide. The prevalence increases with age and usually progresses, leading to repeated hospital admissions and significant symptom burden for patients. The correct management of these patients may decrease readmissions and increase quality of life.

Methods

Retrospective study, consulting patient's clinical records, population over 65 years of age with HF, hospitalized in 2017, in an internal medicine ward in a tertiary hospital. Patients were divided into 2 groups with (wR) and without (woR) readmission within 1 year and were compared regarding the patient's gender, age, level of autonomy, comorbidities and reason for hospitalization. The etiology of heart disease, BNP assay and echocardiogram were characterized. The primary outcome was death at 12 months.

Results

Eighty-nine patients were included, 60 woR and 29 wR, mean number of readmissions within a year was 2.6. There was no gender difference between groups; the wR group had older patients (77.3 years woR/79.5 years wR) with no difference in independence in activities of daily living (35.0% woR/34.5% wR). The most frequent comorbidities included atrial fibrillation (46.6% wo / 1.7% wR) and hypertension (41% woR/40% wR). The most frequent cause of hospitalization was HF due to insufficient therapy or progression of the disease (45.0% woR/72.4% wR), or an infectious process as decompensating factor (16.6% woR/20.7% wR). The etiology of HF was mainly hypertensive (51.0% woR/41.4% wR) and ischaemic (21.0% woR/37.9% wR). The wR group had more patients classified as NYHA >III (16.6% woR / 31.0% wR). Seventy-five patients had an echocardiogram, all with structural changes and 10% woR vs 48% wR had decreased ejection fraction (EF). No difference between groups in BNP quantification (941 pg/mL woR / 807 pg/mL wR). 57 patients were taking beta-blocker, 52 were on angiotensin converting enzyme inhibitors or angiotensin receptor blockers and 69 were taking a diuretic at admission. Mortality at 12 months was higher in the group with repeated admissions (16.6% woR/31.0% wR)

Conclusion

HF is a progressive disease, which causes repeated hospitalizations, especially in more advanced stages of the disease, in patients with decreased EF and is associated with higher mortality, as was the case in our small sample. The characterization of this population

allows us to highlight the causes of decompensation and to review medication in order to increase the quality of life.

#142 - Abstract

CLINICAL ADVERSE EVENTS IN A MEDICAL WARD - A PROSPECTIVE STUDY

Rita Vieira Alves, Marília Andreia Fernandes, Diogo Drummond Borges, Inês Rego Figueiredo, Ana Margarida Antunes, Heidi Gruner

Centro Hospitalar Universitário Lisboa Central, Lisboa, Portugal

Background

Adverse events (ADEs) are a significant problem and may particularly affect the elderly population, which constitutes a significant part of hospitalized patients. In clinical practice, fewer than 5% of ADEs are reported, even when reporting is mandatory.

Methods

A prospective study, consulting patient's electronic clinical notes over 6 months (June to December 2017) in an Internal Medicine ward of a tertiary hospital. ADEs reported in the clinical notes were selected and the drug or intervention responsible noted. Patients were grouped by age; group A <65 years, group B 65-80 years, group C >80 years and compared in terms of gender, autonomy status, comorbidities, diagnosis at admission and readmission rate within one year. Primary outcomes included mean length of stay and mortality.

Results

Sixty-two episodes, equivalent to 61 patients (8% of the 706 admitted) with ADEs were included. Autonomy decreased with increasing age; 100% independent in A, 65% B and 47% C. 30% had hypertension, 30% atrial fibrillation, 18% diabetes and 17% ischemic heart disease. In 56% of the cases, the ADE was the cause of admission. Readmission rate was 54% (61% A, 61% B, 47% C). The most frequent ADEs included analytical changes including acute renal failure and electrolyte imbalance (30% total; 30% A, 23% B, 39% C), anemia and blood loss (28% total; 23% A, 23% B, 34% C), infection (18% total; 38% A, 19% B, 0.5% C) and altered state of consciousness (15% total; 0% A, 19% B, 17% C). The most commonly implicated therapies were drugs; anticoagulants (23%), antihypertensives and diuretics (17%), immunosuppressive therapy (16%), beta-blockers (1%) and insulin (1%). Mean length of stay was 17 days (16.0 days A, 17.5 B, 18.3 C), considerably longer than the average length of stay of 11 days for the same period. Mortality within one year of hospitalization was 30%, again significantly higher than the 9% mortality rate calculated for the same period (10% A, 27% B, and 43% C).

Conclusion

Pharmacovigilance is a clinical responsibility, particularly in the polymedicated and increasingly elderly population in hospital. Length of stay and mortality are increased in patients with ADE,

as is the case in our small sample, which reflects findings in recent literature. A limitation in this study is that the collected data included only the ADE reported in the clinical notes, furthermore only drug related ADE were found; it is likely that this study will significantly underestimate the prevalence of ADE in hospital settings.

#159 - Abstract

CLINICAL PROFILE OF HYPERTENSIVE PATIENTS WITH HEART FAILURE IN A COUNTY HOSPITAL

Julio Osuna Sánchez¹, Antonio Ubiña Carbonero²

¹ Hospital Comarcal Melilla, Melilla, Spain

² Centro de Salud San Andrés-Torcal, Málaga, Spain

Background

Carry out a retrospective descriptive study of hypertensive patients admitted for heart failure in the Internal Medicine service of our hospital during 2017.

Methods

This is a transversal descriptive analysis of patients admitted to internal medicine for heart failure (HF) in 2017 who were hypertensive. A detailed study was carried out of all the risk factors presented by patients, the associated comorbidities, as well as personal history. We have analyzed the discharge reports of our service along with the review of medical records. A descriptive study of the characteristics of patients using frequency measurements has been carried out, analysing the type of sample to see whether or not they remained normal.

Results

There were a total of 120 patients hospitalized for HF, of which 62.5% were hypertensive. 58.7% were women. The mean age was 80.69±10.07 years. 8% of the patients were institutionalized, 18.7% were dependent for all the basic activities of daily life. 57.3% were of Caucasian ethnicity and 42.7% were Berber. 89.3% had social security.

Regarding personal history: 26.7% previous ischemic heart disease; 61.3% HBP; 36% A-fib; 13.3% COPD; 34.7% dyslipidemia; 9.3% sleep apnea; 12% anemia; previous stroke 8% and 14.7% neoplasia (active or not). The most frequent causes of admission were the ischemic cause with 38.5% and the valvular heart disease with 38.5%. As an important finding, 10.7% of the patients presented cognitive impairment to some degree. 100% of patients had 2 or more pathologies at the time of admission. The medication prescribed was as follows: ACE inhibitors 30.7% (enalapril (77.8%)); beta-blockers 45.3% (bisoprolol (8.8%)); ARBs 32% (valsartan (27.3%)) and calcium antagonists 18.7%. The mean stay of hospital admission was 10±8.77 days, being exitus 10,7% of the patients.

Conclusion

Heart failure is a problem for both public health and the doctor who must face it daily. Once diagnosed the prognosis becomes

ominous as approximately 50% of patients die within the next 5 years. Early diagnosis and treatment of HF is important to prevent its complications, slow its evolution, decrease its symptoms and avoid the need for hospitalizations once the diagnosis is confirmed. This picture worsens when as a comorbidity we add HBP, making it harder to manage and the morbidity and mortality is higher. Patients admitted for acute HF with HBP have a multi-pathological profile with multiple diseases so we should do a closer follow-up if possible due to the high mortality rate.

#250 - Case Report

RAOULTELLA PLANTICOLA INFECTION AND WHEN TO STOP

Flávio Pereira, Joel Pinto, Mariana Da Silva Leal, Viktor Malyarchuk, Jorge Henriques, Susana Cavadas
Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

Introduction

Raoultella planticola is a Gram negative bacillus that is present in the soil and water. It rarely causes infection in immunocompetent hosts. This microorganism has aroused interest in the scientific community due to the increasing number of identifications. As a member of the Enterobacteriaceae family, it has a huge potential to develop multi-resistance.

Case description

87-year-old woman, bedridden, with severe functional dependence (Barthel Scale 20 points) and severe sarcopenia presents to the emergency room with vomiting and decreased urinary output. Two days before she had initiated flucloxacillin for left lower limb cellulitis. She presented with temporo-spacial disorientation and inflammatory signals in pre-tibial region of the left lower limb at admission. Complementary study revealed leukocytosis ($20.3 \times 10^9/L$) with neutrophilia ($17.00 \times 10^9/L$), elevated C reactive protein (15.89 mg/dL), acute kidney injury (Urea 182.5 mg/dL; Creatinine 5.93 mg/dL), hepatic cholestasis (alkaline phosphatase 1068 U/L; gamma-GT 1061 U/L) and urine dipstick with leukocyturia. Abdominal ultrasonography revealed a nodule of 35 mm near the hepatic hilum in the right hepatic lobe. Blood and urine cultures were done and patient started ceftriaxone and clindamycin. Body computed tomography revealed a nodule in the right hepatic lobe, near the hilum and multiple micro nodules in right lung, suggestive of metastasis. Patient exhibited good clinical and analytic evolution of the septic condition. Urine culture revealed positivity for *Raoultella planticola* resistant to ampicillin and fosfomicin. Pulmonary and hepatic metastization by an unknown occult neoplasia was assumed. Given the previous functional state and after discussion of the clinical condition with the patient's family, it was decided to stop the etiological study.

Discussion

Raoultella planticola infection is frequently associated with immunosuppression. In this case, there was an elevated suspicion

of advanced oncologic disease, beyond immunosenescence. This case highlights the importance of avoiding the diagnostic and therapeutic rampant and adjust the degree of investment to the patient general state. Patient and family should be included in the decision making process.

#352 - Abstract

THE INFLUENCE OF COGNITIVE FUNCTION ON OUTCOME AFTER HIP FRACTURE IN OLDER PEOPLE

Cristina Carvalho Gouveia¹, Ana Lopes Santos¹, Sofia Duque¹, Luís Campos¹, Rosana Andrade², Fátima Falcão²

¹ Hospital de São Francisco Xavier, Centro Hospitalar de Lisboa Ocidental, Lisbon, Portugal

² Centro Hospitalar de Lisboa Ocidental, Lisbon, Portugal

Background

Hip fracture (HP) is associated with considerable morbidity and mortality, especially in older people. Cognitive impairment, which has been found in 31-88% of older patients experiencing HP, has been demonstrated to be associated with poorer functional recovery after HP surgery. We aim to study the cognitive function in this population and its possible association with adverse outcomes after hospital discharge for HP.

Methods

Retrospective study of older outpatients previously admitted to an Orthogeriatric Unit for HF. We included patients whose follow-up consultation was between May and December 2018. The population was separated accordingly to the Global Deterioration Scale (GDS) at hospital admission: group A – no cognitive impairment (GDS 1 and 2), B – mild cognitive impairment (GDS 3), C – moderate to severe cognitive impairment (GDS 4-7).

Results

42 patients were included. 40.5% (n = 17) had cognitive impairment. The follow-up evaluation was performed 201 days (mean) after hospital discharge. Patients in group C had worse functional status before hospital admission, as demonstrated by a lower Barthel index (57.2 vs A: 90.2 vs B: 90 points), lower Holden classification (2.8 vs A: 4.2 vs B: 4.3 points) and higher Charlson index (5.7 vs A: 4.0 vs B: 4.4 points). Group C had also more institutionalized patients (44.4 vs A: 4.0 vs B: 12.5%). The preoperative time was longer in group C (6.0 vs A: 4.6 vs B: 4.9 days). At discharge, the majority of patients was able to walk with support (A: 88.6, B: 87.5 and C: 88.9%) and none of the patients, of any group, was bedridden or able to walk without support. Almost all patients started physiotherapy for gait rehabilitation after discharge (A: 97.1, B: 100 and C: 100%). Patients in group C had a more pronounced deterioration in functional status, as demonstrated by a higher decline in the Barthel index (23.3 vs A: 15.2 vs B: 0.15 points). Also, group C had significantly less patients able to walk independently (0 vs A: 40 vs B: 50%) and more bedridden patients (22.2 vs A: 8.0 vs B: 0%).

Conclusion

Cognitive impairment is prevalent in this population. In this study, moderate to severe cognitive dysfunction seemed to be associated with worse functional outcomes after hospital discharge for HP, regarding the ability to walk and perform the activities of daily living. These results may justify a more thorough approach to cognitive impaired patients, in order to provide them a better quality of life.

#356 - Abstract

POTENTIALLY INAPPROPRIATE MEDICATIONS IN OLDER ADULTS - PREVALENCE IN THE WARD ACCORDING TO UPDATED AMERICAN GERIATRICS SOCIETY 2019 BEERS CRITERIA

Mariana Da Cruz, Nuno Zarcos Palma, Gisela Vasconcelos, Ligia Santos, Margarida Cruz, Catarina Couto, Ricardo Meireles
Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal

Background

Prescription and polypharmacy are extremely important topics in the geriatric population due to their weakness and multiple comorbidities. The American Geriatrics Society reviewed in 2019 the criteria of Beers attempting to detail potentially inappropriate medications (PIM) in order to avoid the use of these as first-line therapy in the elderly. The aim of this study is to estimate the prevalence of PIM using the Beers criteria in the elderly population hospitalised in the medical department and general surgery ward.

Methods

Retrospective, cross-sectional study. Eligibility criteria were: patients with 65 years old and over, admitted under the care of the medicine department: internal medicine and pneumology (6 wards) and general surgery services (2 wards). Patients in the ICU and with a palliative care setting were excluded. At the prescribed drugs were applied the 2019 updated Beers criteria and thus observed its prevalence.

Results

A total of 324 clinical processes were analyzed, of which 201 met the inclusion criteria, 56% (n=112) female, 44% (n=89) male, with a mean age of 80.6±7.9 (65-96) years. The length of hospital stay was, on average, 12.9±16.1 (1-42) days. The sample had a moderate dependence according to an average Katz score of 4, and a high risk of falling, with a Morse scale greater than 45 points in 58% (n=118). The most frequent reason for hospitalisation was community acquired pneumonia (n=56) followed by acute cerebral vascular disease (n=35). A median of 9 drugs per patient were prescribed, with the most common being acetaminophen (n=198), proton pump inhibitors (n=190), low molecular weight heparin (n=193) and rapid insulin (n=184). When the Beers criteria were applied, 66% of the patients had PIM prescriptions, corresponding to 428 drugs. The most common drugs were: PPI (n=198) typical

and atypical antipsychotics (n=60), metoclopramide (n=53) and benzodiazepines (n=43). Drugs targeting the central nervous system account for 53% of PIM.

Conclusion

In the literature there is a strong association between the drugs included in the Beers criteria and a worse prognosis in patients, despite this preponderant information, PIM are still frequently prescribed. It is noteworthy that the medical prescription should always be individualized considering a multiplicity of factors. Training is needed for rational drug use and polypharmacy in the elderly population. The authors emphasize the importance of training in geriatrics.

#443 - Abstract

SUPPLEMENTATION WITH VITAMIN E IN ELDERLY PATIENTS WITH CARDIOVASCULAR DISEASE

Eugenia Corina Zorila¹, Liana Mioara Mos¹, Eva Mera²

¹ "V. Goldi" Western University, Arad, Romania

² S.C.Clinical Laboratory SRL, Arad, Romania

Background

It is known that Vitamin E protects cell membranes from damage by oxygen free radicals. Low plasma levels of Vitamin E has been associated with a risk factor of 2.6 times higher of early vascular disease.

Objectives. We studied the effect of supplementation with vitamin E on oxidative stress using markers of lipid peroxidation in a group of elderly people with known cardiovascular disease.

Methods

We studied a group of 33 patients over 65 years with ischemic cardiovascular disease and/or hypertension (Group I) hospitalized in our clinic. We administered 600 mg alpha-tocopherol/day (Vitamin E) for 7 days in capsules. The vascular damage was evaluated using intimal media thickness of the common carotid artery by ultrasonography in lying supine. In order to determine the oxidative stress we have determined Thiobarbituric Acid (TBA)-reactive substances by Satoh method in peripheral venous blood, prior to administration of vitamin E and the after supplementation treatment. We compared this group (Group I), with another group of patients with symptomatic vascular disease (Group II) without nutritional supplementation

Results

Group I characteristics was : hypertension was present in 54.4% of studied patient, myocardial ischemia (angina or equivalents) in 38.5% of cases, aortic valve disease in 6.06%, patients with cardiomegaly and those with left ventricular hypertrophy represented 63.6% of the group I and only 36.4% of patients had normal sized heart. Baseline average level of TBA-reactive substances was similar in the two groups, but was significantly

lower in group I after nutritional supplementation with alpha-tocopherol, 4.54 ± 0.62 nmol/l vs 2.69 ± 0.54 nmol/l ($p < 0.001$).

Conclusion

Vitamin E (Alpha-tocopherol) supplementation in patients with chronic cardiovascular disease, over 65 years, revealed a significant decrease in oxidative stress evaluated by markers of lipid peroxidation, with possible protective effect on endothelial dysfunction

#446 - Abstract

THE INCREASING BURDEN OF AGING ON ADMISSION, HOSPITAL STAY AND TARIFF IN AN ACADEMIC DIVISION OF INTERNAL MEDICINE IN SOUTHERN ITALY

Marina Nuzzo¹, Michela Capurso¹, Anna Belfiore¹, Paolo Buonamico¹, Francesco Minerva¹, Vincenzo Ostilio Palmieri¹, Stefania Pugliese¹, Emilio Molina-Molina¹, Francesco Albergo², Piero Portincasa¹

¹ Clinica Medica "A. Murri", Department of Biomedical Sciences and Human Oncology, University of Bari "Aldo Moro" Medical School, Bari, Italy

² School of Management, Università LUM "Jean Monnet", Bari, Italy

Background

In 2015, subjects older than 65 years in Italy were 21.7% and figures are growing, with enormous burden on national health systems, also worldwide. We describe the impact of aging on the hospitalization profiles and diagnosis-related group (DRG) tariff in an Academic Division of Internal Medicine, in Southern Italy.

Methods

We included data from hospital registry of elective and emergency admissions on three consecutive years (2016-2018) of patients aged 15-100.

Results

Admitted were 2586 patients (1255 F, 1331 M, mean age $69.6 \pm SE0.3$ yrs. Median 73); 1786 patients (69.1%) aged ≥ 65 . Patients from Emergency Room (ER) were 1924 (74.4%) of total admissions, were older than elective patients (mean age 71.5 ± 0.4 vs. 64.1 ± 0.6 yrs, $P=0.0000$), had longer hospital stay (9.3 ± 0.2 vs 4.6 ± 0.2 days, $P=0.0000$) and higher DRG tariff ($\text{€}2,992 \pm 38$ vs $2,594 \pm 73$, $p=0.0000$). Hospital stay ($r=0.14$; $P=0.0000$) and DRG tariff ($r=0.17$; $P=0.0000$) increased significantly with age. The impact of aging on hospital stay and DRG tariff was further evaluated on four age groups, i.e., <65 , 65-74, 75-84 and ≥ 85 yrs (30.9%, 22.6%, 29.7% and 16.7% of total, respectively). A progressive increase at each age group occurred for both mean hospital stay (6.9 ± 0.3 , 7.9 ± 0.3 , 8.9 ± 0.3 , 9.1 ± 0.3 days respectively, $p=0.0000$) and mean DRG tariff ($\text{€}2525 \pm 70$, 2943 ± 70 , 3111 ± 59 , 3103 ± 67 respectively, $p=0.0000$).

Conclusion

In an Academic Division of Internal Medicine in Southern Italy opened to ER, geriatric patients account for 69% of total admissions. This population drains major clinical and economic efforts. Geriatric expertise and cost-effective strategies are urgently required to cope with elderly and fragile patients' management.

#460 - Abstract

THREE-MONTH MORTALITY IN PERMANENTLY BEDRIDDEN MEDICAL NON-ONCOLOGIC PATIENTS: THE BECLAP STUDY

Luca Matteucci, Valeria Giosia, Antonio Luca Brucato

University of Milan, Milan, Italy

Background

Nowadays bedridden status is a major problem and it may have a role in increasing mortality among patients hospitalized in medical wards. The aim of BECLAP study (permanently BEdridden, creatinine CLearance, Albumin, Previous hospital admissions study) is to predict the three-months mortality in permanently bedridden medical non-oncologic inpatients.

Methods

2788 consecutive patients admitted in 5 Italian Internal Medicine units from January 2016 through January 2017 were prospectively screened; 644 oncologic patients were excluded; 2144 non-oncologic patients (1021 female) were followed-up for mortality for 6 months. The main outcome was 3-months mortality in permanently bedridden inpatients with at least 2 of creatinine clearance <35 ml/min; albumin <2.5 mg/dl; at least 2 hospital admissions in the previous 6 months. Advanced dementia and dysphagia were also recorded.

Results

Mean age of the 2144 patients was 73.9 (SD, 14.9) years; 374 (17%) were permanently bedridden, 435 (20%) had a creatinine clearance <35 ml/min, 217 (10%) albumin <2.5 mg/dl, 112 (5%) at least 2 hospital admissions in the previous 6 months. Seventy-seven (4%) patients were permanently bedridden with at least 2 of the above-mentioned items, and 48 of them died within 3 months (62%) ($p < 0.001$; 95% CI 51-73%). Regression coefficients of the variables associated with 3-months mortality in multivariate analysis in 998 patients of unit 1 (training cohort) were used to create a simple score, which was validated in the 1146 patients of the other units (validation cohort) and performed well in predicting the 3-months mortality.

Conclusion

Approximately two out of three non-oncologic medical patients permanently bedridden having 2 of the abovementioned items are dead 3 months after index admission; a simple score including bedridden status, creatinine clearance, albumin, dysphagia, age, and sex may help discuss management priorities.

ORAL HEALTH IN THE ELDERLY PATIENT HOSPITALIZED IN AN INTERNAL MEDICINE DEPARTMENT

Fatma Ben Fredj¹, Thabet Maissa¹, Raouaa Belkacem², Omar Marouene², Jihed Anoun¹, Anis Mzabi¹, Monia Karmeni¹, Amel Rezgui¹, Chadia Laouani¹, Nabiha Douki²

¹ Université de Sousse, Faculté de Médecine de Sousse, Hôpital Sahloul, Service de Médecine Interne, Unité de Recherche de Gériatrie et Gérontologie Clinique, Sousse, Tunisia

² Université de Sousse, Hôpital Sahloul, Service de Médecine Dentaire de Sahloul Sousse, Sousse, Tunisia

Background

The aim of this study was to evaluate the oral state of patients aged 65 years or over hospitalized in an internal medicine department.

Methods

This is a prospective study conducted at Sahloul Hospital of Sousse over a period of 1 month (March 2019) including all patients aged 65 or over hospitalized in the Sahloul Internal Medicine Department. A systematic oral examination was performed for all these patients. We examined the periodontal state (presence of tartar, plaque and bleeding index...), the examination of the mucous membranes and a dental examination (CAD index and dental formula...)

Results

Of 27 hospitalized patients, 12 were aged 65 or older. There were 5 men and 7 women (SR=0.7), the mean age of our patients was 71.23 years [65-90].

Six patients had hypertension and four were diabetic, three of whom were on insulin therapy.

The mean MMS score of our patients was 21.02 [14-27]. The evaluation of their mood showed an average score of mini-GDS at 2.4 [1-3]. Mean ANM was 10.7 [7-12]. Eight of our patients were autonomous.

Oral hygiene was inadequate in all our patients. One-third of the patients included never used toothbrushes.

Periodontal examination showed poor hygiene in all patients with at least moderate periodontitis. It was generalized in 9 cases. Mucosal involvement was observed in 3 patients (maculae, whitish and purplish lesions).

The dental examination revealed that eleven patients had at least 3 missing teeth and 7 patients had untreated dental caries.

As for the therapeutic needs, eleven patients had prosthetic needs; five had surgical needs and seven has restoration needs. Whereas, periodontal therapy was indicated for all patients.

Conclusion

The results of this study show that an annual oral examination seems necessary for elderly. The oral health and hygiene of older people is not sufficient and could be improved with oral care education of caregivers and regular professional dental care to elderly.

#607 - Abstract

MULTIMORBIDITY AND OLD AGE - IMPACT OF ILLITERACY AND RESIDENCE IN RURAL AREAS

Josiana Oliveira Duarte, Isabel Taveira, Sofia Sobral, Tiago Fiúza, Rui Seixas, Ana Cláudia Vicente, Adelaide Belo

Hospital do Litoral Alentejano, Santiago Do Cacém, Portugal

Background

Thinking of the constant concerns about the use of the emergency service and avoidable hospitalizations, in January 2017 emerged the Case Management Project. This project included patients with 4 or more episodes of emergency room visits during the previous 365 days or 3 or more admissions in the previous year, with 2 or more comorbidities and 6 or more drugs, with the aim of improving patient and consequently less use of emergency services, reduction of avoidable hospitalizations and health costs. This required greater coordination of care, communication between professionals, interaction with the community and investment in training.

Methods

We present a retrospective study of the population that integrated the Case Management Project in the year 2018, whose main objectives were to assess whether the degree of illiteracy and residence in rural areas would have a statistically significant influence on the use of emergency services before and after integration in the project.

Results

It is a population with 85 patients, 47 men, average age of 78 years, of whom 15 have died. For the purposes of statistical analysis, only patients with 6 months or more of integration into the project (58 patients, min 6 months, max 22 months) were included. Regarding the data prior to integration into the project, using the Mann Whitney test, we concluded that the residence in rural areas is statistically significant for increasing the number of emergency room visits ($p=0.001$). Similarly, regarding illiteracy, we conclude that the level of schooling less than or equal to the 4th class is statistically significant for the increase in the number of emergency room visits ($p=0.013$). After 1 year of the project, we found that the fact of living in rural areas was no longer statistically significant ($p=0.094$) and that the level of education less than or equal to the 4th class remained statistically significant for the increase in the number of visits to the ER ($p=0.012$).

Conclusion

On the basis of these data, we conclude that integration into the project has made patients living in rural areas less likely to go to the emergency department, most likely by moving the case manager/health care to the patient's home. The degree of illiteracy has remained a statistically significant factor, presumably because the ability to understand the recommendations given to these patients may be compromised. This suggests that more training strategies appropriate to the degree of illiteracy are necessary.

#621 - Abstract

EFFECTIVENESS OF THALIDOMIDE IN THE TREATMENT OF RECURRENT GASTROINTESTINAL BLEEDING

Pedro J Maese Rufino, M^a Asunción Navarro Puerto, M^a Isabel Melguizo Moya, José Antonio Mira Escarti

Hospital Virgen de Valme, Internal Medicine, Sevilla, Spain

Background

Patients with recurrent gastrointestinal bleeding (onwards, GI bleeding) are a challenge to treat. According to scientific literature, the main etiology are vascular malformations (angiodysplasias). These lesions are even more frequent in elder and comorbid population (up to 8% of all GI bleeding), often a complex clinical scenario without options of endoscopic neither surgical approach. Thalidomide has demonstrated good results in controlling bleedings, as well as diminishing blood transfusions requirements.

Methods

An observational, retrospective study was developed on patients receiving thalidomide for GI bleeding in our Hospital (period 2008 - 2018). We analyzed bleeding events, blood hemoglobin evolution and transfusion requirements during 6 months of follow-up.

Results

28 patients were included (median age 76, 53% females, high comorbidity according Charlson index) receiving thalidomide for GI bleeding. Most of them (85%) did not present a major GI bleeding during follow-up.

Thalidomide demonstrated a significant reduction in transfusion requirements (81% before - 43% under thalidomide, p value=0.003). An increase in the median hemoglobin level was observed: from 7.35 g/dL at the start of treatment to 11.5 g/dL at 6 months.

Incidence of intolerances reached 25%, without dangerous side-effects.

Conclusion

Thalidomide seems a safe and effective drug for the treatment of recurrent GI bleeding in elderly comorbid patients.

#647 - Abstract

UTILITY OF THE NAURSE SCALE FOR PREDICTING IN-HOSPITAL MORTALITY IN PATIENTS OVER 90 YEARS OLD.

Magdalena Martín Pérez, Rocio Rojas Lorence, Isabel Ríos Holgado

Hospital Punta de Europa, Algeciras, Spain

Background

The current demographic trend reveals that the world population and, in particular, the Spanish population will be growing. This progressive aging implies an increase in people over 90 years of age,

with a worse social, physical and cognitive situation and, therefore, with an increase in the needs and consumption of health resources. In 2014, the results of a simple in-patient mortality prediction rule were published in nonagenarians based on 4 variables collected on admission (NaURSE score) with promising results. The objective is to use this scale in our population over 90 years old to predict in-patient mortality, which may be useful in the patient's first care, determining the need for a more aggressive immediate action or the indication of conservative / palliative measures.

Methods

Cross-sectional retrospective study of the income of patients over 90 years of age in the Internal Medicine Unit during 2018. The variables collected were: sociodemographic (age, sex), sodium concentration (>145 mEq/L), blood urea (>84 mg/dl), respiratory rate (>20 rpm) and the shock index (heart rate/systolic blood pressure >1), which constitute the acronym NaURSE, as well as the total of variables of this scale present in the subgroup of deceased patients.

Results

104 patients were analyzed. Average age was 92.4 years, predominantly women (653%); mortality was 21% and no more variables were found within the subgroup of deceased: 40% had 2 variables, 27% only one and only 4% met the 5 variables studied. The most frequent variable found was urea (> 84mg / dl) at 33.6% followed by respiratory rate (>20 rpm) at 22.1%.

Conclusion

Most studies in the nonagenarian population are descriptive, without predictive mortality scales. The classic prognostic factors (age, comorbidity, dependence) do not seem to be associated with mortality in several studies, which indicates the difficulty to find reproducible predictors in this highly heterogeneous type of population.

In our attempt to validate the NaURSE score, we have not observed that mortality increases as the variables studied are met, which reveals the physical, psychological and social complexity of this population, possibly linked to the sample size of our study. An individualized evaluation of the patient and the clinical judgment of the doctor remain irreplaceable.

#674 - Abstract

MEDITERRANEAN DIET IS INVERSELY RELATED TO ADMISSION DURATION AND MORTALITY IN ELDERLY, HOSPITALIZED PATIENTS: A 2-YEAR PROSPECTIVE STUDY

Christos E Lampropoulos, Maria Konsta, Vicky Dradaki, Irini Dri, Afroditi Roumpou, Ioanna Papaioannou
Argolidos General Hospital, Nafplion, Greece

Background

Mediterranean diet has been associated with lower incidence of cardiovascular disease and cancer. Purpose of our study was

to examine the hypothesis that mediterranean diet may reduce duration of admission in elderly, hospitalized patients and protect against long-term mortality.

Methods

Sample population included 183 patients (91 men, 92 women, mean age 80±8.4). The following data were taken into account in analysis: anthropometric and laboratory data, dietary habits (MedDiet score), patients' nutritional status [Mini Nutritional Assessment (MNA) score], physical activity (International Physical Activity Questionnaires, IPAQ), smoking status, cause and duration of current admission, medical history (co-morbidities, previous admissions). Primary endpoints were mortality (from admission until 2 years afterwards) and duration of admission, compared to national guidelines for closed consolidated medical expenses. Logistic regression and linear regression analysis were performed in order to identify independent predictors for mortality and extended hospitalization respectively.

Results

According to MNA, nutrition was normal in 83/183 (45%) of patients, 47/183 (25%) of them were at risk of malnutrition and the rest 53/183 (30%) were malnourished.

After performing multivariate logistic regression analysis we found that the odds of death decreased 22% per each unit increase of MedDiet score (OR=0.78; 95% CI:0.7-0.86; p<0.0001). Patients with cancer-related admission were 12 times more likely to die, compared to those with infection (OR=12.95% CI:2.4-58, p=0.002).

According to multivariate linear regression analysis, admission duration was inversely related to mediterranean diet, since it was decreased 0.28 days on average for each unit increase of MedDiet score (b:-0.28; 95% CI:-0.4 - -0.15; p<0.0001). Additionally, the duration of current admission increased on average 0.6 days for each previous hospital admission (b:0.6; 95% CI:0.3-0.85; p<0.0001). The admission duration of patients with cancer was on average 5 days higher than the patients who admitted due to infection (b:5; 95% CI:1.6-8.3; p=0.004).

Conclusion

Mediterranean diet adequately protects elderly, hospitalized patients against long-term mortality and reduces the duration of hospitalization.

#676 - Abstract

FULL MINI NUTRITIONAL ASSESSMENT QUESTIONNAIRE AND THE RISK OF MALNUTRITION AND MORTALITY IN ELDERLY, HOSPITALIZED PATIENTS: A 2-YEAR PROSPECTIVE STUDY

Christos E Lampropoulos, Maria Konsta, Irini Dri, Vicky Dradaki, Afroditi Roumpou, Ioanna Papaioannou
Argolidos General Hospital, Nafplion, Greece

Background

Full Mini Nutritional Assessment (MNA) questionnaire is one of the most useful tools in diagnosing malnutrition in hospitalized patients, which is related to increased morbidity and mortality. The purpose of our study was to assess the nutritional status of elderly, hospitalized patients and examine the hypothesis that MNA may predict long-term mortality and extension of hospitalization.

Methods

183 patients (91 men, 92 women, mean age 80±8.4) were included in this prospective study. The following data were taken into account in analysis: anthropometric and laboratory data, physical activity (International Physical Activity Questionnaires, IPAQ), smoking status, dietary habits, cause and duration of current admission, medical history (co-morbidities, previous admissions). Primary endpoints were mortality (from admission until 2 years afterwards) and duration of admission. The latter was compared to national guidelines for closed consolidated medical expenses. Logistic regression and linear regression analysis were performed in order to identify independent predictors for mortality and extended hospitalization respectively.

Results

According to MNA, nutrition was normal in 83/183(45%) of patients, 47/183 (25%) of them were at risk of malnutrition and the rest 53/183 (30%) were malnourished.

After performing multivariate logistic regression analysis we found that the odds of death decreased 15% per each unit increase of full MNA score (OR=0.85; 95% CI 0.8-0.9; p<0.0001). Patients who admitted due to cancer were 10 times more likely to die, compared to those with infection (OR=10; 95% CI 2.3-48; p=0.002).

As far as admission duration is concerned, according to multivariate linear regression analysis, each unit increase of full MNA, decreased the admission duration on average 0.3 days (b=-0.3; 95% CI -0.4 - -0.14; p<0.0001). Patients admitted due to cancer had on average 5 days higher duration of hospitalization, compared to those admitted for infection (b=5; 95% CI 1.6-8.3; p=0.004). Additionally, the duration of current admission increased on average 0.5 days for each previous hospital admission (b=0.5; 95% CI 0.27-0.8; p<0.0001).

Conclusion

Mortality and extension of hospitalization is significantly increased in elderly, malnourished patients. Full MNA score is a useful diagnostic tool of malnutrition.

#700 - Abstract

QUALITY OF LIFE FOR CAREGIVERS OF ELDERLY PATIENTS

Maïssa Thabet, Jihed Anoun, Najeh Adaily, Imen Saoud, Monia Karmeni, Fatma Ben Fredj, Amel Rezgui, Chedia Laouani
Université de Sousse, Faculté de Médecine de Sousse, Hôpital Sahloul
Service de Médecine Interne, Unité de Recherche de Gériatrie et Gériologie Clinique, Sousse, Tunisia

Background

With the aging of the population, the number of caregivers caring for the elderly is increasing considerably. These carers are essential partners for a best quality of life (QOL) for elderly in the perspective of a home support. The health status and QOL of these caregivers deserve to be studied.

The aim of this study is to evaluate the QOL of caregivers of non-autonomous elderly people living at home.

Methods

Prospective observational study conducted in the internal medicine department of Sahloul hospital during the month of March 2019. Elderly of over 70 years old hospitalized in the department and their caregivers were included. The QOL was assessed by the Zarit score.

Results

Ten couples of "elderly person-caregiver" were evaluated. The average age of elderly was 79 ± 6 years with 4 men and 6 women. The caregivers were spouses in 4 cases (average age 74 years, 100% women) and children in 6 cases (average age 49 years, 50% women).

Five caregivers lived at the same home of the elderly person and five spent each day between 30 minutes and 1 hour to visit their elderly parent. The average time spent with the elderly parents was more than 10 hours per day for 3 caregivers.

Seven caregivers were married and six had children in charge, two of whom had more than three children. Four caregivers worked full time and reported that taking care of their elderly relative forced them to adapt or reduce their professional activity.

Six caregivers had themselves chronic illnesses and were on long-term treatment, and four reported that caring for elderly relatives disturbed their social and family lifestyle.

The evaluation of the Zarit score in the caregivers showed that 7 caregivers had a score between 21 and 40 and therefore a light load and that three carers had a score between 41 and 60 indicating a moderate load. Any of the caregivers said that caring was a burden.

Conclusion

The QOL of elderly is closely dependent on caregivers and vice versa. Improvement of caregivers' QOL may have a direct impact on the psychotic symptoms of elderly and indirectly on their QOL. This may confirm the need for ongoing family interventions.

#725 - Abstract

THE INFLUENCE OF MALNUTRITION ON ADMISSION DURATION AND MEDICAL EXPENSES IN ELDERLY, HOSPITALIZED PATIENTS

Christos E Lampropoulos, Maria Konsta, Afroditi Roumpou, Vicky Dradaki, Irini Dri, Ioanna Papaioannou
Argolidos General Hospital, Nafplion, Greece

Background

Malnutrition of elderly, hospitalized patients is a poor prognostic factor for survival and admission duration. Many validated scores have been developed to assess patients' physical activity and the risk for malnutrition. Aim of this study is whether malnutrition increases the medical cost due to extended hospitalization.

Methods

183 patients (91 men, 92 women, mean age 80 ± 8.4) participated in the study. The following data were analyzed: anthropometric and laboratory data, dietary habits (MedDiet), nutritional status scores [Mini Nutritional Assessment (MNA) scores (screening, total), Malnutrition Universal Screening Tool (MUST), Short and Simplified Nutritional Assessment Questionnaire (SNAQ)], physical activity (International Physical Activity Questionnaires, IPAQ). The expected duration and financial costs of the admissions as well as the additional ones (due to extended hospitalization) were calculated according to national guidelines for closed consolidated medical expenses. Spearman coefficient was used for correlation between variables and Kruskal-Wallis test for group comparisons. Multivariate regression analysis was applied for independent predictors of extended hospitalization and additional cost.

Results

The additional medical cost per patient was inversely correlated to screening ($r = -0.35$, $p < 0.0001$) and total ($r = -0.4$, $p < 0.0001$) MNA, MedDiet ($r = -0.6$, $p < 0.0001$), IPAQ ($r = -0.4$, $p < 0.0001$), albumin ($r = -0.4$, $p < 0.0001$), Hb ($r = -0.14$, $p = 0.04$) and positively correlated to MUST ($r = 0.4$, $p < 0.0001$) and SNAQ ($r = 0.33$, $p < 0.0001$). The mean cost per patient increased on average 60 (0-300), 480 (180-1380) and 0 (0-450) euros for admissions due to infection, cancer and stroke respectively ($p = 0.008$).

According to multivariate logistic regression analysis, the additional cost per patient decreased on average 25 euros per each unit increase of MedDiet ($b = -24.6$; 95% CI -36, -13; $p < 0.0001$) and 118 euros ($b = -118$; 95% CI -227, -8.7, $p = 0.03$) per each unit increase of albumin.

Concerning admission duration, according to multivariate linear regression analysis, each unit increase of full MNA or MedDiet decreased the duration on average 0.2 days ($b = -0.2$, 95% CI -0.3, -0.04, $p = 0.02$) and 0.22 days ($b = -0.22$, 95% CI -0.4, -0.06, $p = 0.008$) respectively.

Conclusion

Malnutrition and poor physical activity are related to extended hospitalization and increased associated medical expenses. Higher adherence to mediterranean diet and increased serum albumin reduce the financial cost for each patient's admission.

#760 - Abstract

PROGNOSTIC FACTORS FOR MORTALITY AND DURATION OF ADMISSION IN MALNOURISHED HOSPITALIZED, ELDERLY PATIENTS: A 2-YEAR PROSPECTIVE STUDY

Christos E Lampropoulos, Maria Konsta, Vicky Dradaki, Afroditi Roumpou, Irini Dri, Ioanna Papaioannou
Argolidos General Hospital, Nafplion, Greece

Background

Malnutrition in hospitalized patients is related to increased morbidity and mortality. Purpose of our study was to assess nutritional status of hospitalized, elderly patients and detect unfavorable prognostic factors, related to increased mortality and extended duration of admission.

Methods

183 patients (91 men, 92 women, mean age 80 ± 8.4) were included in the study. Nutritional status was assessed by screening and full Mini Nutritional Assessment (MNA), Malnutrition Universal Screening Tool (MUST), short Nutritional Appetite Questionnaire (sNAQ) and mediterranean diet (MedDiet). The following data were incorporated in analysis: anthropometric and laboratory data, physical activity (International Physical Activity Questionnaires, IPAQ), smoking status, cause and duration of admission, medical history (co-morbidities, previous admissions). Primary endpoints were mortality (from admission until 2 years afterwards) and duration of admission, compared to national guidelines for closed consolidated medical expenses. Mann-Whitney two-sample statistics or t-test was used for group comparisons and Spearman or Pearson coefficients for testing correlation between variables.

Results

Normal nutrition was assessed in 84 (46%), 137 (75%) and 136 (74%) of patients, according to MNA, MUST and sNAQ respectively.

Mortality rate was 48% (88/183 patients). These patients had lower BMI (24.5 ± 4 vs 26.3 ± 5 , $p = 0.01$), albumin (3.1 ± 0.7 vs 3.6 ± 0.6 , $p = 0.0001$), screening MNA (8.5 ± 4 vs 11 ± 3 , $p < 0.0001$), full MNA (16.5 ± 6.7 vs 22.4 ± 5 , $p < 0.0001$), MedDiet (26.6 ± 5.7 vs 33.3 ± 5.4 , $p < 0.0001$) and IPAQ [$0(0-16.5)$ vs $390(0-760)$, $p < 0.0001$] compared to remaining one. In contrast, the aforementioned patients had higher MUST [$1(0-3)$ vs $0(0-0)$, $p < 0.0001$] and sNAQ [$1(1-4)$ vs $0(0-1)$, $p < 0.0001$]. These patients had extended hospitalization [$3(0-6)$ vs $0(-2, 1)$ days, $p < 0.0001$].

Duration of admission was inversely related to screening (Spearman $r = -0.32$, $p < 0.0001$) and full MNA (Spearman $r = -$

0.36, $p < 0.0001$), MedDiet (Spearman $r = -0.4$, $p < 0.0001$), IPAQ (Spearman $r = -0.34$, $p < 0.0001$), albumin (Pearson $r = -0.3$, $p < 0.0001$) and Hb (Pearson $r = -0.14$, $p = 0.05$). On the other hand, duration was positively correlated to MUST (Spearman $r = 0.37$, $p < 0.0001$) and sNAQ (Spearman $r = 0.3$, $p < 0.0001$).

Conclusion

A great proportion of elderly, hospitalized patients are malnourished or at risk of malnutrition. All nutritional scores, physical activity and albumin are significantly related to mortality and increased hospitalization.

#781 - Abstract

CHANGES IN HOSPITALIZATION AMONG ELDERLY PATIENTS FROM 2000 TO 2015: A RETROSPECTIVE STUDY USING THE SPANISH NATIONAL HOSPITAL DISCHARGE DATABASE

Sergio Palacios-Fernandez¹, Mario Salcedo¹, Jose Manuel Ramos²

¹ Valencia University, Valencia, Spain

² Miguel Hernandez of Elche University, Alicante, Spain

Background

Elderly patients are an increasing population in developed countries, which involves an augmenting number of admissions to hospitals. The aims of this study are to analyze and compare the demographic characteristics, health outcomes and costs of the population older than 65 admitted to hospitals in Spain in the years 2000 and 2015.

Methods

All patients older than 65 years discharged from Spanish hospitals in the years 2000 and 2015 were analysed using the data from the Minimal Basic Data Set (MBDS) provided by the Spanish Ministry of Health. We retrieved data related to the next variables: number of discharges each year, all cause in-hospital mortality, average stay and average cost in the studied population.

We tabulated the information and computed secondary data such as absolute or relative magnitude of the referred variables in each age group, and the ratio with respect to the total discharged population.

Finally we compared the data between the years 2000 and 2015 and elaborated a table showing the progress.

Results

The number of discharges in older than 64 patients was 1,200,016 in 2000 (37% of total discharges) and 1,721,073 in 2015 (46% of total discharges), which means 124% more discharges in that age group. The gap is much broader if we focus on those older than 84, who were 164,713 in 2000 (5% of total discharges) and 428,217 in 2015 (11% of total discharges), which means 259% more discharges, and an increase of 10% more very old patients each year.

In 2000, in-hospital mortality in patients between 64 and 74 years old was 4.9% and in patients older than 84 was 13.6%. Mortality has maintained stable in the studied years, although the ratio of mortality of patients older than 64 has increased with respect to the total discharged population.

Average stay is longest in the age group between 74 and 84 years old, decreasing in younger and older patients. Compared to 2000, average stay has decreased a 7% in patients older than 64.

Finally, cost is slightly higher in those older than 64 (5295 euros/discharge in 2015) than the average cost (4866 euros/discharge). Nonetheless, cost has decreased around a 10% between 2000 and 2015. The reduction is higher the older is the patient.

Conclusion

The burden of elderly patients in Spanish hospitals is rapidly increasing. However between 2000 and 2015 mortality has stabilized in each age group and cost and average stay have slightly decreased.

#802 - Abstract

RISK FACTORS FOR FALLS IN PATIENTS OF THE GERIATRIC HOSPITAL IN THE RUSSIAN FEDERATION

Anton Naumov, Natalia Khovasova, Viktoriya Moroz

Pirogov Russian National Research Medical University (RNRMU), Moscow, Russia

Background

Aim. To assess the structure and prevalence of risk factors of falls among people over 60 years.

Methods

In the research have been included 125 geriatric patients at the age of 75.66 ± 7.98 years (110 women, 88%) with at least one fall occurred during the last year. A general clinical study, a comprehensive geriatric assessment, as well as an assessment of the risk of falls (Morse scale, a self-assessment scale of falls) have been carried out during the research period.

Results

Before hospitalization in the Geriatric hospital, the program of prevention of falls was not been implemented in these patients. The decline Activities of daily living (IADL) is identified in 57.6%. The high risk of falls was determined in 82.4% of cases according to the self-assessment scale and in 28% of cases according to the Morse scale. The number of falls during the year was 2.42 ± 1.9 , more than 2 falls occurred among 71 people (56.8%). Consequences of falls: non-severe - 84%, severe (fracture - 11.2%, traumatic brain injury - 4.8%). The most common causes of falls are imbalances (64.8%) and unstable gait (36%), the use of mobility aids (35.2%), and diseases of the musculoskeletal system: osteoarthritis (61.6%), foot pathology (7.2%). Moreover, the significant risk factors of falls were polypharmacy (52%), single accommodation (44.8%), fear of

falling (42.4%), cognitive impairment (39.2%), depression (13.6%), incontinence (36%), dizziness (36%), orthostatic hypotension (7.2%). However, the most common factors were visual impairment (70.4%), fall during anamnesis (89.6%) and chronic pain (89.6%). In almost half (44.6%) of cases, chronic pain was constant, and moderate intensity was by (40.5±0.57 according to VAS). By every fourth person, the low back pain, in half of cases in the large joints. 62 patients used NSAIDs, of which 41.9% used it more than 1 time per week, and 17.7% used it daily. In 21 cases (18.75%), chronic pain caused a limitation of physical activity. A decrease in the quality of life was noted by every third patient.

Conclusion

More than a half of the patients had 2 or more episodes of falls during the last year. In 15% of cases, a fall resulted severe consequences. Chronic pain, polypharmacy, fear of falling and cognitive impairment are most common risk factors for falls.

#855 - Abstract

DO OLDER PEOPLE RECOGNIZE THEIR TREATMENTS?

Rezgui Amel, Maïssa Thabet, Najah Adaily, Jihed Anoun, Monia Karmeni, Fatma Ben Fredj, Chedia Laouani

Université de Sousse, Faculté de Médecine de Sousse, Hôpital Sahloul
Service de Médecine Interne, Unité de Recherche de Gériatrie et
Gérontologie Clinique, Sousse, Tunisia

Background

Poly-medication is particularly common in elderly patients because of poly-pathology, which suggests that patients should recognize the different treatments they take.

The objective of this study was to evaluate the recognition of medications by the elderly followed in an internal medicine department.

Methods

This is a cross-sectional observational study conducted in Internal Medicine Department (university Hospital Sahloul) over one-month period (March 2019) and including all patients aged 65 or older who were receiving long-term treatments. Patients were asked about the number of medications taken, the schedule and number of administrations a day, as well as the commercial names of their treatments and its therapeutic effects.

Results

Fifty three patients were included, with 24 men and 29 women (SR=0.8). The average age was 71 [65-92 years]. Twenty nine patients (54%) were hypertensive and 26 (49%) had endocrinopathy. Nineteen patients (35%) were diabetic, four (7%) had hypothyroidism and two had adrenal insufficiency. Dyslipidemia was noted in 15 patients (28%).

There were 42 illiterate patients in our population. No one had cognitive trouble according to MMS score.

The average number of drug therapy taken per day by our patients was 4.6 [1-10]. Thirteen patients (24%) were on oral antidiabetics and twelve (22%) were on insulin therapy with an average of 2 to 3 injections per day. All our patients self-injected insulin. Eight patients (15%) were on acenocoumarol (Sintom *).

Forty-one patients (7%) were autonomous according to the ADL score and eleven patients (20%) reported needing a third person to take their treatments.

Forty-six patients (86%) recognized their drugs only by their color and geometric shape. Thirty-three patients (62%) memorized their treatments by their therapeutic effects. Forty eight patients (90%) were well aware of the number and timing of catches. Seven patients (13%) were able to name their treatments by their trade names. Nineteen patients (35%) have made a mistake when we asked them to show their treatments.

Conclusion

Older people in our population face multiple challenges in recognizing their medications. According the high risk of polymedication in this age group, an appropriate and up-to-date therapeutic education of patients and their entourage seems obligatory.

FACTORS ASSOCIATED WITH 120-DAY SURVIVAL AND RECOVERY OF PRE-FRACTURE FUNCTIONAL MOBILITY AFTER MINIMAL TRAUMA HIP FRACTURE SURGERY IN OLDER PERSONS

Roshan Gunathilake^{1,2}, Susan Mcneil¹

¹ John Hunter Hospital, Newcastle, Australia

² University of Newcastle, Callaghan, Australia

Background

There is scarcity of published data about survival and functional recovery in older persons after hip fracture in the Australian context. The aim of the study was to determine patient factors associated with 120-day survival and walking recovery after orthopaedic surgery for minimal trauma hip fracture in a cohort of older persons presenting to an orthogeriatric service in a major teaching hospital in Australia.

Methods

Demographic and baseline clinical characteristics of 389 consecutive patients were extracted from the local hip fracture registry and electronic medical records. Functional ambulatory status was evaluated using an ordinal scale based on the use of an assistive device. Patients were followed up prospectively and mortality and walking recovery at 120 days after surgery was determined by telephone interviews and by review of electronic health records linked to the New South Wales birth and death registry.

Results

All-cause mortality rate was 20% at 120 days after hip surgery. Only 42% of the survivors had recovered their pre-admission walking ability within 120 days. In the Cox proportional hazards model, advanced age, male gender, living in a residential aged care facility, higher ASA grade and low serum albumin were significantly associated with 120-day mortality. In multivariate logistic regression analysis, age, pre-fracture mobility and ASA grade were significantly associated with 120-day walking recovery.

Conclusion

Minimal trauma hip fracture was associated with high mortality and the majority of patients did not recover pre-fracture mobility. Baseline patient characteristics can predict mortality and loss of walking ability in hip fracture patients receiving orthogeriatric care.

#992 - Abstract

IMPROVEMENT ON THE BARTHEL INDEX AFTER 1 YEAR OF SACUBITRIL-VALSARTAN

Raquel Rodil-Fraile¹, Gregorio Tiberio-Lopez²

¹ Clínica San Miguel, Pamplona, Spain

² Complejo Hospitalario de Navarra, Pamplona, Spain

Background

It has been reported that treatment with sacubitril-valsartan improved the performance of activities of daily living and quality of life compared to enalapril.

With the aim to provide evidences about the variation in the Barthel index after 1 year of treatment with sacubitril-valsartan, we report data about a 1-year observational pros HFrpared to enalapril.

Methods

Observational study. Multimorbidity patients with sintomathic chronic heart failure (CHF) with reduced ejection function in treatment with sacubitril-valsartan follow-up by the Internal Medicine of Complejo Hospitalario de Navarra during 1 year.

For data analysis student t-test for paired samples we were performed. All tests were performed using STATA version 9 (Texas, NC).

Results

We included 46 multimorbidity (3 or more chronic medical conditions: isquemic cardiopathy, diabetes, chronic kidney disease, HF, COPD, dementia) patients with symptomatic heart failure reduced ejection function (HFrEF) (67% males with mean age of 79±7.41 years) in follow-up in the Chronic-Multimorbidity Unit of the Complejo Hospitalario de Navarra in the period from September 2016 to February 2018. The median Charlson comorbidity index was 8 points. Chronic kidney disease was the most common co-morbidity (91%), presenting 64% of patients

with moderate/severe kidney disease. The most common etiology of HFrEF was ischemic (65%). Year follow up, the majority of patients (74%) tolerated the maximum dose of 24/26 mg BID. There is a significant improvement in the Barthel index in our patients after one year of sacubitril-valsartan treatment (77 vs 84 points, p= 0.006, 95%CI -12.34 - -2.24).

Conclusion

Sacubitril-valsartan improve the functionality of patients, measured under the Barthel index, in multimorbidity patients with HFrEF.

#1058 - Case Report

AZITHROMYCIN – A VERY RARE CAUSE OF ACUTE CONFUSIONAL SYNDROME

Alexandra Ávila¹, Vanda Conceição¹, Ricardo Filipe¹, Margarida Rosado², Nuno Vieira¹, Maria José Grade¹, Luisa Arez¹

¹ Serviço de Medicina 3, Unidade Hospitalar de Portimão do Centro Hospitalar Universitário do Algarve, Portimão, Portugal

² Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

Introduction

Drug-induced delirium is a common neuropsychiatric disorder that often affects the elderly people. Antibiotics such as azithromycin are drugs less associated with this disorder, but it can cause it too.

Case description

We present a case of a 72-year-old woman, hypertensive and diabetic, treated with oral antidiabetic and antihypertensive drugs, none of these drugs had been introduced recently. She was referred to the Emergency Room for behavioral changes, altered mental status and aphasia with 12 hours of evolution. On examination, the patient was disoriented in time and space, with global aphasia, decreased strength in the right upper limb and hemianopsia on the right. She had no fever, no respiratory, urinary, or other changes suggestive of infection. Days before admission, the patient had an upper respiratory infection, for which she was given Azithromycin 500 mg/day for 6 days.

The clinical investigation was unrevealing for a definite etiology: blood count, leukogram, ionogram, liver and renal function tests, urine type II, blood cultures, uroculture, viral serologies and research of drugs of abuse, arterial blood gases, were performed without alterations. Images studies: chest x-ray, cranioencephalic computed tomography (CT), cranio-encephalic Angio CT, and cranioencephalic magnetic resonance imaging showed no alterations, as well as electroencephalogram with aspects suggestive of metabolic/drug dysfunction.

With these results, the suspicion of delirium induced by Azithromycin arose, since this had been the only recently initiated medication. At the seventh day after the end of the drug, the patient was totally oriented, without language alterations and without focal neurological deficits. After one month of follow-up the patient was asymptomatic.

Discussion

When compared with other cases described in the literature, the symptoms of this patient had a later onset and resolution, which can be explained by the high half-life of azithromycin (68 hours), as well as by the high plasma levels observed in geriatric patients (30-50%) compared to young adults, which may potentially be a cause of delirium in this population.

#1097 - Abstract

COMPREHENSIVE GERIATRIC ASSESSMENT IN EMERGENCY DEPARTMENT

Isabel Pulido Valente, Carla Nunes, Paulo Boto, Sónia Martins, Manuel Lopes

National School of Public Health, Lisboa, Portugal

Background

Older population increases use Emergency Department (ED) adding 12% to 21% of the total. Studies suggest that even after being observed in the ED, the older persons continue to have unresolved needs. Objective: epidemiological, clinical, functional and social characterization of the older population that goes to a tertiary central hospital emergency department.

Methods

426 questionnaires during their stay in the ED. Inclusion: all patients over 65 admitted to the ED of Lisbon central hospital. Exclusion: not collaborate in the study. Variables: Age, sex, polypharmacy, comorbidities, were applied basic and instrumental evaluation tests, cognitive evaluation, humor, nutrition and social tests. Functional, social, clinical and social scores were constructed. SPSS Statistics software (v. 24). A χ^2 test was performed and a ROC curve model performed.

Results

53.6% women, mean age 79.3 (min-65, max-101) 75 to 84 years. 26.5% live alone. 97.1% take chronic medication, with 6.7 different drug qualities (min-0, Max-19). The average admissions for ED in 2017 were 2.7 admissions / year (Min-0; Max-21). 99.5% had comorbidities (min-1; max-15) had an average of 4.9 comorbidities. 70.6% were discharged. 51.2% of patients were dependent on basic life activities and 75.6% were dependent on instrumental life activities. 62.5% had gait autonomy and 11.5% had ineffective gait. 51.7% depression. 50% dementia and 63% with nutritional changes. 17% illiterate and 55% primary education. 33% social risk. The scores were adverse in 48,6% of social score, 79,6% clinical score, 54,9% of functional score and 83,1% of mental score. The social and clinical score were found to be statistically significant for the probability of admission.

Conclusion

we concluded by an older population with a predominance of polypharmacy, multimorbidity, social needs and complex clinics that, the ED, as it currently stands, is incapable of allowing

effective and timely responses, neither the necessary screening nor the referral of patients.

#1158 - Abstract

POTENTIALLY INAPPROPRIATE MEDICATION IN ELDERLY OLDER THAN 75 YEARS OLD

Maria Maia, Adriana Watts Soares, Virginia Visconti, João Espírito Santo, José Lomelino Araújo

Hospital Beatriz Ângelo, Lisboa, Portugal

Background

Ageing of the population is associated with different physiologic processes that lead to the need of adapting prescription of medication. The term "polymedication" emerged to express the abusive use of pharmacological therapy in aged people. More recently, it started to be applied when potentially inappropriate medication (PIM) is being used. PIMs are considered the main responsible for the adverse drug events observed in the older adult. There are different scales and criteria that allow an analyse of the pharmacological therapeutic and identification of the PIM. A list of PIMs was developed and published by Beers and colleagues in the 90's, in the United States of America, and subsequently expanded and revised to be used in hospitalization and ambulatory, in patients older than 65 years old.

Methods

Identification of PIMs in a small sample of patients, using Beers Criteria, in pre-hospitalization medication chart, of patients older than 75 years old, hospitalized in an Internal Medicine Ward.

Results

The sample had 34 patients, 18 with more than 75 years old, of these 72.2% were female; 61.1% were living at home. Barthel index average was 52.7 (median 52). From these sample of patients, 55.5% had 4 or more comorbidities. About the medication, each patient had in average 6.4 drugs prescribed (minimum 0, maximum 12) and 50% of the patients had in their drug chart 7 or more drugs. Applying Beers Criteria, 20.5% of the total medication were PIM, and of these 52.2% were benzodiazepines or antipsychotics.

Conclusion

These small sample reflects the importance of identifying the PIM so we can prevent and predict adverse events, that bring an elevated morbidity and mortality in this population. Concerning the criteria's that were used, adapting these to a European reality urges, so they can be applied in a transversal way. Some European criteria already exist, more studies are required in order to be used and applied or the population.

#1229 - Abstract

USE OF GABAPENTIN IN HOSPITALIZED PATIENTS

André Filipe De Jesus Teixeira, Helena Manso, Marília Fernandes, Inês Rego Figueiredo, Rita Alves, Diogo Drummond Borges, Heidi Gruner, António Panarra

Centro Hospitalar e Universitário Lisboa Central, Lisboa, Portugal

Background

Gabapentin is widely used for the control of neuropathic pain, mainly peripheral diabetic neuropathy and postherpetic neuralgia, but also in epilepsy. Studies suggest benefits for the use in visceral and bone pain and in neuropathic cancer pain in combination with opioids. Its use in medical wards have been increasing due to professional experience, proven efficacy, safety and tolerability. However some adverse effects, addiction and withdrawal have been reported.

Methods

Retrospective evaluation of the electronic records of all patients admitted to an Internal Medicine Unit in a tertiary Hospital in 2018 (January 1st to December 31st) that used gabapentin. Patients were characterized according to gender, age, average length of stay, comorbidities, therapeutic adjuvants and intrahospital mortality. Dose, length of use of gabapentin and indication for prescription were taken into account.

Results

Of the 1338 patients admitted, 41 (3.1%) were on gabapentin with an average age of 68.8 years. 21 (51.2%) were male and the average length of stay was 15.6 days. There was a "de novo" use in 4 (9.8%) patients and chronic use (>1 year) in 30 (73.2%) patients, of which the main indication was diabetes (n=13). Indication for overall prescription was diabetes (18 patients, 43.9%; average HbA1c of 6.9%), neuropathic pain (18 patients), epilepsy (1 patient) and alcohol withdrawal (1 patient). Other found comorbidities, besides diabetes, were depression in 10 (24.4%) patients.

Concerning adjuvants there were mainly benzodiazepines (19 patients, 46.3%) and analgesics including morphine (14 patients, 34.1%); previous pregabalin use was seen in 6 (14.6%) patients. Daily doses varied from 100mg to 1200mg (average was 467.7 mg) with only one patient above 900mg.

Inpatient mortality was 24.2%, slightly lower for chronic users (17.24%) and higher for diabetic patients (28.6%).

Conclusion

In our small sample the average age was lower than in the internal medicine ward (68.9 vs 78.3 years) and female gender was not favored as usual in published studies. Current doses were infra therapeutic (<900 mg) in almost all cases, considering the recommendations available. Average length of stay (15.6 vs 10.8 days) was higher than the internal medicine ward as was inpatient mortality (24.2% vs 8.9%).

There's a need for understanding the usage of infra therapeutic doses and its efficacy in pain management and control.

#1368 - Abstract

DIRECT ANTICOAGULANTS: SAFETY IN THE ELDERLY SUFFERING FROM ATRIAL FIBRILLATION

Gemma Ortiz Llauradó, Esther Llinàs Coronado, Daniel Iglesias Sáenz, Fireli Oblitas Béjar, María Victoria Pardo Ortega

Hospital de Terrassa, Terrassa, Spain

Background

Non-valvular atrial fibrillation (NVAf) is the most common cardiac arrhythmia and its incidence increases with age. Some of these patients have an indication for oral anticoagulant therapy (OA) for the prevention of systemic embolisms. The classic treatment is OA with anti-vitamin K (AVK) (acenocumarol), however in the last years several direct oral anticoagulants (DOAC) have been commercialized. The pivotal studies of DOACs include patients up to 73 y-o without comorbidity. The inclusion criteria are not a representative sample of the patients that are attended in real practice, for this reason, it is difficult to predict the complications that may occur. We want to evaluate the safety of DOACs in elderly patients (EP) with NVAf, compared to AVK in relation to hemorrhagic event, catalogued SACODA by Spanish Ministry of Health and admitted by Ethics Committee

Methods

Observational, retrospective, descriptive study. Inclusion criteria were >75 y/o patients and clinical indication of therapy with either AVK or DOAC (dabigatran, rivaroxaban or apixaban), treated from January 2012 to December 2015, and followed them for at least 2 years. Patients were selected from our data base. Exclusion criteria were mitral stenosis, mechanical prosthetic valves and treatment with other oral anticoagulants, were excluded, as well low molecular weight heparins, stage 5 chronic kidney disease, any other causes of thrombophilia and termination of AO by recovery of atrial rhythm in the last year. We included patients from January 2012 and December 2015, who were followed for at least 2 years.

Results

942 patients (59% male) between 75 and 99 y/o (mean 83,7 ± 4,8 y/o), CHA2DS2VASc and HASBLED mean scores 4.65 ± 1.35 and 2.41 ± 0,9 respectively. Most of them had polypharmacy (87%), cognitive impairment (low 17%, moderate to severe 12%) and a third of the sample had a Charlson comorbidity index >3 points. We registered 181 hemorrhagic events (1% deaths). The multivariable analysis did not show significant statistical differences in bleeding depending on the type of OA nor the basal and clinical characteristics of the patients. The digestive hemorrhage was most frequent (48%). It increases as the kidney disease worsens and it is independent of the basal characteristics of the patients.

Conclusion

Our data suggest that in real-life the bleeding rate in our EP

population has not significant differences in DOAC vs AVK. The stage of renal impairment seems to be strongest than the age as a bleeding factor.

#1379 - Abstract

AGING WITH INTERNAL MEDICINE: PORTRAIT OF A DISTRICT HOSPITAL

Joana Carneiro, Mariana Magalhães, Ana Valada Marques, Joana Louro
Western Hospital Centre, Caldas Da Rainha, Portugal

Background

Population is aging and the number of people living with multiple chronic diseases and frailty syndrome is increasing. While the characteristics of our population are changing, internists have to deal with patients who are old, polymedicated, and have more complex medical, psychiatric and social issues.

Methods

The aim of this study is to characterize the overall health status of elderly patients hospitalized in the Internal Medicine Department. For this, we conducted a retrospective and observational study using medical records of a random sample of 100 patients over 65 years of age who were hospitalized in Internal Medicine Department in 2018. Statistical analysis was made using SPSSstatistic14®.

Results

Our sample consisted of 100 patients with the age of 65 years or older, equally divided by gender. The mean age was 82.8 ± 7.37 years. 51% of the patients had some degree of dependence, 27% were bedridden and 30% had no description of the performance status. Patients had an average number of comorbidities of 4.71 ± 1.98 . 83% were polymedicated (defined as 5 or more drugs), with an average of 7.87 ± 3.65 number of medications per patient. 70% of the patients were medicated with at least one of the drugs included in the "Beer Criteria for Potentially Inappropriate Medication in Older Adults" at the admission. There was no statistically significant difference between the number of the drugs prescribed at discharge comparing with the admission, as well as between the number of patients medicated with drugs included in the Beer list before and after the hospitalization. Of the 22% of patients who died during hospitalization, 73% had a non-resuscitation order, of these, 55% did complementary diagnostic exams and 45% received antibiotics after the non-resuscitation order decision and only 61% of the patients' clinical records mentioned analgesia.

Conclusion

The world is changing and internal medicine is changing with it. The complexity of this older population adds a tremendous challenge to internal medicine not only in the diagnostic and therapeutic approach at hospitalization but also at discharge. Hierarchizing

priorities and valuing the focus of the therapeutic approach implies a profound paradigm shift in internal medicine and it is essential to ensure the best medical care to this population.

#1502 - Abstract

OBESITY IN THE ELDERLY - PROFILE OF THE ELDERLY PATIENTS FOLLOWED IN OBESITY CONSULTATIONS

Telma Alves, Joana Paixão, Leila Cardoso, Leonor Aleluia, Fátima Silva, Pedro Ribeiro
Serviço de Medicina Interna, Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal

Background

Obesity is a chronic metabolic disease whose global prevalence is estimated to have risen in the elderly population, mainly due to dietary changes and sedentary lifestyles. This fact has negative repercussions in morbidity/mortality, quality of life and comorbidities. Intentional weight loss through dietary reeducation and physical exercise, prevents the occurrence of harmful and irreversible consequences on geriatric population health, namely sarcopenic obesity, decreased bone density and metabolic syndrome.

Methods

Retrospective characterization of patients aged ≥ 65 years who attended obesity appointments between January 2017 and January 2019. The variables considered were: demographic characteristics, provenience, weight variation, body mass index, abdominal perimeter, exercise practice, and pre and post comorbidities.

Results

During this period, 59 patients were observed, of which 67.24% (n=39) were women and 32.76% (n=19) were men, with a mean age of 69 years. Regarding the origin of referrals: 29.31% (n=17) General and Family Medicine; 20.69% (n=12) of Internal Medicine; 18.97% (n=11) of Pneumology; and 29.31% (n=17) of other specialties. Considering weight profile evolution, 8 (13.79%) patients gained weight, 25 (43.10%) lost $>5\%$ and 33 (56.90%) lost $<5\%$. Of the patients with a weight loss superior to 5%, 36% had a decrease in systolic blood pressure (SBP) higher than 10 mmHg. Of the total number of patients, 26% (n=15) experience a reduction of abdominal perimeter $>5\%$ and the majority implemented physical exercise in their daily routines 70.69% (n=41). Concerning comorbidities, 91.38% (n=53) patients presented arterial hypertension, 39.66% (n=23) diabetes mellitus, 74.14% (n=43) dyslipidemia, 63.79% (n=37) osteoarticular disease, 34.48% (n=20) obesity syndrome hypoventilation/obstructive sleep apnea syndrome, and 6.90% (n=4) thyroid pathology.

Conclusion

Increasing levels of obesity may compromise future gains in

life expectancy with the desired quality. Fortunately, our work reveals the growing interest of this pathology among physicians. We concluded that the prevalence of risk factors observed in the studied population is alarming, especially considering that the majority of them is associated with higher all-cause mortality. Therefore, the reduction of the weight profile and abdominal perimeter have a positive impact on the patient's SBP profile and consequently on the metabolic syndrome, independently of the other risk factors that define it.

#1571 - Abstract

CLINICAL CHARACTERISTICS OF MUSCULOSKELETAL DISEASES FALLING PATIENTS OVER 60 YEARS

Anton Naumov¹, Viktoriya Moroz², Natalia Khovasova¹

¹ Department of deases of aging of Pirogov Russian National Research Medical University (RNRMU), Moscow, Russia

² Russian Clinical and Research Center of Gerontology of Pirogov Russian National Research Medical University (RNRMU), Moscow, Russia

Background

To study the prevalence of musculoskeletal diseases falling patients over 60 years

Methods

142 patients of the Moscow geriatric hospital have been examined. In their anamnesis have been diagnosed more than one falls during the previous year. The average age of the patients was 75.52±8.28 (120 women). The average number of falls over the past year was 2.63±2.28. Two or more falls over the past year have been detected among 61.26% patients. The risk of falls according to the Morse scale averaged 42.29±19.6; more than 51 points has been detected by 40.8%. The self-assessment risk scale of falls has shown the high risk among 87.4% of patients.

Results

Osteoarthritis has been diagnosed among 62.7% of patients, low back pain has been detected among 32.4% of patients, and foot pathology only by 2.8%. Among patients with osteoarthritis pain in large joints has been found in 60.7%, pain in small joints over 2.24%. Chronic pain syndrome has been detected among 42.25% of patients. Patients with persistent pain syndrome comprised 20.5%. Patients with chronic pain syndrome had suffered the intensity of pain (VAS) by 56.9±17.82, with intermittent pain - 36.9±25.5. Among patients with chronic pain syndrome, weak pain has been detected only by 23.3%, medium intensity - 63.3%, strong- 13.3%. Among patients with persistent pain: weak - 47.7%, medium intensity -27.3%, strong 6.8%. Over patients with chronic pain syndrome 71.7% used NSAIDs, and in the group of patients with persistent pain only 44.5%. Neuropathy has been estimated by 20% of patients with chronic pain (DN4), and by 14.7% of patients with persistent pain. Moreover, an assessment of depression development risk (PHQ-2) has been carried out:

among 35% of patients with chronic pain syndrome has been detected the risk of depression, and among 24.4% of patients with persistent pain syndrome respectively. Decrease in basic and functional activity (IADL) has been detected by 81.7% of patients with chronic pain and by 68% with persistent pain. Two or more falls occurred among 68.3% of patients with chronic pain and among 59 % with persistent pain.

Conclusion

88.73% of patients who have experienced a fall had musculoskeletal system diseases. More often there are osteoarthritis and low back pain. Every fifth patient with chronic pain syndrome, who has experienced a fall, has a neuropathic component, and 35% have a psychogenic component.

#1715 - Abstract

DEPRESCRIBING IN ADVANCED DEMENTIA AND ITS EFFECT ON SURVIVAL

Marta Briega, Noemi Gilabert, Nicolas Labrador, Jose Virgilio Torres, Enrique De Vega-Ríos, Jose Curbelo, Carmen Suarez Hospital Universitario de La Princesa, Madrid, Spain

Background

The aim of this study is to compare 12-month mortality after discharge in two cohorts of patients with advanced dementia: those in whom a deprescription strategy was undertaken (deprescription group; DG) and those in whom deprescription did not happen (control group; CG).

Methods

Retrospective cohort study of all patients with advanced dementia discharged from the Department of Internal Medicine in a hospital in Madrid, during 2016. A follow-up period of 12 months after discharge was planned. One-year mortality rates was compared between groups. A stratified analysis of 12 month mortality rates, categorizing patients into subgroups depending on the deprescribed medication (statins, antihypertensives, antiosteoporotic, antiplatelet, anticoagulant, antidementia or other cardiovascular prevention drugs), was also performed. Demographic and clinical variables were collected, including sex, age, mortality at 12 months, cause of death and hospital readmission at 3 and 12 months.

Results

133 patients were analyzed with an average age of 89,4 years of which 93 (70%) were women. Deprescription was performed in 73 (55%) cases. Overall 12-month mortality rate was 45%, ranging from 58% in the deprescription group to 41% in the control group (NS). Hospital readmission rates were 11% in the DG and 32% in the CG at 3 and 12 months respectively. The most frequent causes of death on readmission were infectious diseases in 18 cases (33%), stroke in 6 cases (11%), non-cerebral cardiovascular disease in 2 cases (3.7%), VTD in 2 cases (3.7%) and surgical reasons in 2 cases

(3.7%). Cause of death was unknown in 24 cases (44%).

We have not found statistically significant differences in the stratified, subgroup analysis of 12-month mortality rates in patients in whom statins (DG 43% v CG 26% NS), antihypertensives (37% v 44% NS), antiosteoporotic (40% v 55% NS), antiplatelets (52%-36% NS), anticoagulants (33% v 39% NS) nor other cardiovascular prevention drugs were deprescribed (47% v 35% NS). However, a statistically significant survival difference was found in patients who maintained antedementia drugs v those who did not (CG 33% v DG 63%, $p < 0.05$).

Conclusion

Deprescription of several frequent groups of medication in elderly patients with advanced dementia did not result in a statistically significant higher mortality. Infectious diseases were accountable for the most cases of death. Deprescription of anti-dementia drugs was linked to a higher mortality, this finding requires further exploration.

#1939 - Abstract

COMPARISON OF NUTRITIONAL ASSESSMENT SCORES IN DETECTING MALNUTRITION IN ELDERLY, HOSPITALIZED PATIENTS

Christos E Lampropoulos, Maria Konsta, Vicky Dradaki, Irini Dri, Afroditi Roumpou, Ioanna Papaioannou

Department of Internal Medicine, Argolidos General Hospital, Argos, Greece

Background

Malnutrition has been related to increased morbidity and mortality. Purpose of our study was to estimate the utility of various nutritional scores in detecting malnutrition in elderly, hospitalized patients and correlate them with long-term mortality and medical cost of admission.

Methods

Sample population included 183 patients (91 men, 92 women, mean age 80 ± 8.4). Mini Nutritional Assessment (MNA full, screening), Malnutrition Universal Screening Tool (MUST) and Short Nutritional Appetite Questionnaire (SNAQ) were used to estimate the nutritional status. After adjustment for the cause of current admission, a known prognostic factor according to previously applied multivariate models, sensitivity and specificity, positive and negative predictive values and ROC curves were assessed. Primary endpoints were mortality (from admission until 2 years afterwards) as well as the financial cost of current admission, compared to national guidelines for closed consolidated medical expenses.

Results

Concerning mortality, MNA (screening) and SNAQ had similar, low sensitivity (55.7% and 44% respectively) while MNA (full)

and MUST had higher one (65% and 60% respectively). All the questionnaires had relatively high specificity (80-85%). Screening MNA had the best positive predictive value (80%) whereas all questionnaires had similar negative predictive value (66-71%). They all had similar ROC curves (0.74-0.78).

With regard to additional medical cost due to extended hospitalization, all scores (MNA screening and total, MUST, SNAQ) had relatively low sensitivity (65%, 67%, 53% and 72% respectively), positive (70%, 71%, 76% and 67% respectively) and negative predictive value (61%, 62%, 58% and 64% respectively). MUST had higher specificity (79%) compared to the rest (58-67%). ROC curves were similar for all scores (0.68-0.73).

Conclusion

As far as it concerns mortality, screening MNA had higher specificity and positive predictive value than the rest. MUST questionnaire seems more advantageous in predicting additional medical cost because of extended hospitalization, due to its higher specificity.

#1947 - Abstract

EVALUATION OF DRUG-DRUG INTERACTIONS AMONG ELDERLY PEOPLE OF AN INTERNAL MEDICINE WARD: A RETROSPECTIVE STUDY

Mafalda Miranda Baleiras, Cristina Carvalho, Sofia Duque, José Guia, Luís Campos

Hospital São Francisco Xavier, Lisbon, Portugal

Background

Ageing increases multimorbidity, thus pushing drug prescription upwards. Polypharmacy increases the likelihood of drug-drug interactions (DDI). A DDI happens when two or more drugs interact in such a way that either the effectiveness or toxicity of at least one drug is changed. DDI can result in therapeutic failure, adverse drug reactions (ADR) or even death. According to literature, 17% of all preventable ADR in hospitalized patients are caused by DDI.

Methods

This is a retrospective study aiming to assess the DDI prevalence in elderly and describe the most prevalent interactions. It uses a sample of patients over 65 years-old admitted to an internal medicine ward from January to August 2018. Prescriptions at admission were checked. "Medscape Drug Interaction Checker" was used to evaluate and grade the DDI.

Results

The study included 104 patients, with a mean age of 78.5 years. Mean number of drugs prescribed to patients on admission was 8.3. Polypharmacy was identified in 78 cases (75%). A total of 398 DDI were identified, approximately 4 per patient. According to severity classification, 23 (5.8%) were serious DDI, 317

(79.6%) were significant and 58 (14.6%) were minor. 75% of the patients in the study sample had at least one clinically relevant DDI (significant or serious). Central nervous system depression (18.8%), hyperkalaemia (11.8%) and prolongation of QT interval (6.3%) were the most common potential clinical consequences of the identified DDI. Proton pump inhibitors, psychotropic and nonsteroidal anti-inflammatory drugs were the most commonly involved drug substances among the clinically relevant DDI.

Conclusion

Age-related physiologic changes and polypharmacy make elderly people susceptible to ADR from potential DDI. Personalized drug prescribing strategies and close monitoring of patients are keys to achieve optimal therapeutic results. Freely available software solutions on the Internet can help to predict clinically relevant DDI. DDI should be promptly identified in order to prevent adverse outcomes.

#1996 - Case Report

THE USE OF PROVERTINUM, A NON-ACTIVATED PLASMA-DERIVED FACTOR VII TO TREAT A SEVERE GASTRIC HEMORRHAGE OF UNKNOWN AETIOLOGY

Gabriella Oliva, Carolina Bologna, Marina Lugara, Anna Guida, Maria Gabriella Coppola, Pasquale Madonna, Paolo Tirelli, Antonietta De Sena, Nunzia Silvestri, Claudio De Luca, Ernesto Grasso

Asl Napoli 1, Ospedale del Mare, Napoli, Italy

Introduction

The hemorrhagic shock in elderly patients represents a challenge for physicians. Bleeding control is usually achieved by blood products, or by surgery when feasible. However, when bleeding is not managed only by transfusion of red blood cells, platelets or fresh frozen plasma, the use of coagulation factors is necessary.

Case description

An 87-year-old woman was admitted to the Internal medicine ward for dyspnoea, swollen limbs and mild anaemia. She was affected by colon cancer, treated with sub-total hemicolectomy, cryptogenic cirrhosis, chronic kidney disease, atrial fibrillation in direct anticoagulant therapy (rivaroxaban 15 mg/day) and is currently being treated with low-molecular-weight heparin (4000 UI twice daily), previous thyroidectomy for carcinoma, macrocytic anaemia. A colonoscopy was performed, no bleeding sources were identified. During the hospitalization, she presented melena and hemorrhagic shock. Hemoglobin (Hb) values rapidly dropped from 9.1 g/dl to 8 g/dl, coagulation tests were in normal range. Therefore, an esophagogastroduodenoscopy was performed and showed a clot in the stomach, without active bleeding. An abdominal CT scan with contrast and arteriography were performed and did not show an active bleeding source. The patient was transfused with 4 units of concentrated red blood cells, and 4 units of fresh

frozen plasma. The Hb drop continued until 4.4 g. In order to achieve the haemostasis, the patient was treated with 1800 UI of Provertinum, a non-activated Plasma-derived factor VII (posology 30 UI/kg) and transfused with a further unit of concentrated red blood cells. The hemorrhage stopped, blood pressure increased and the Hb rapidly reached the value of 8.5 g/dl and subsequently 9 g/dl (PT 80%, INR 1.10, a.PTT 40 sec). This value remained stable and no further blood transfusion or antihaemorrhagic therapy was needed until the patient was discharged. No thromboembolic complications were observed.

Discussion

Although not included in the European guidelines on the management of major bleeding, the successful use of Provertinum, non-activated plasma-derived factor VII, in this patient with hemorrhagic shock (due to a severe gastric hemorrhage of unknown aetiology), has effectively determined the recovery of the described clinical scenario, allowing the complete stabilization and safe discharge of the patient. Further investigations are needed, but we would recommend the use of Provertinum to control bleeding in this type of patient.

#2040 - Abstract

PRESCRIPTION OF PROTON PUMP INHIBITORS IN AN INTERNAL MEDICINE WARD

Cristina Carvalho Gouveia, Mafalda Miranda Baleiras, Pedro Ferreira, Sofia Duque, Luis Campos

Hospital de São Francisco Xavier, Centro Hospitalar de Lisboa Ocidental, Lisbon, Portugal

Background

The prescription of proton pump inhibitors (PPI) has significantly increased over the last few decades. When PPIs are inappropriately prescribed, they can contribute to polypharmacy and risk of nonadherence, adverse reactions, drug interactions and hospitalization. PPI can also be associated to hypomagnesemia, vitamin B12 deficiency, small intestine bacterial overgrowth and bone fractures. In this study, we aim to identify potential risk factors associated to PPI prescription and to evaluate the adequacy of their prescription in an internal medicine ward.

Methods

Retrospective study of patients admitted to an internal medicine ward between January and February 2017. The population was separated in two groups: group A – patients using PPI and B – patients not using PPI. The appropriateness of PPI prescription was evaluated by reviewing the medical records of the patients in group A.

Results

144 patients were included. 52 of them (36.1%) were using PPI (group A), 46 of which (88.5%) at hospital admission and 52

(100%) at discharge. Omeprazole was the most prescribed drug (55.8%), followed by pantoprazole (28.8%), esomeprazole (9.6%) and lansoprazole (5.8%). In group A, only 30 patients (57.7%) had appropriate indications for PPI prescription and the main one was prophylaxis of gastrointestinal bleeding in high-risk patients. The principal inappropriate indication for PPI prescription was anticoagulation alone. The mean age of patients in group A was 74.8 years-old and in group B 76.4 years-old. Patients in group A had higher Charlson index (5.5 vs B: 4.6 points) and mean number of medications at hospital admission (7.7 vs B: 5.5) and discharge (9.8 vs B: 6.1).

Conclusion

In our study, the prevalence of inappropriate PPI prescription was noteworthy. Polypharmacy and comorbidity (higher Charlson index) seemed to be associated to prescription of PPI, while higher age did not seem to be related to prescription of these medications. Since the overuse of PPI has a negative impact on healthcare costs and may lead to adverse effects, it is essential to regularly re-evaluate the patients by reassessing the need for ongoing PPI use, in order to decrease iatrogenic illness.

#2089 - Abstract

PREDICTING PERIOPERATIVE PERFORMANCE IN COMPLEX PLURIPATHOLOGICAL PATIENTS

Maria Gema Pelayo Garcia

Internal Medicine Service. Hospital Punta Europa, Algeciras, Spain

Background

Due to improvement in surgical and anesthetic procedures, older and more complex patients undergo surgical treatment. Hip fractures account for a significant disease burden in elderly population. The rise of this activity urges to identify these patients with the aim to enhance disease prevention, chronic disease management, and perioperative treatment. For that matter, orthopedic-hospitalist comanagement (OHC) service was established at our hospital to manage hip fracture patients. Our objective was to assess the most prevalent comorbidities and complexity at admission in this population with the aim to develop tailored health-care strategies.

Methods

We retrospectively identified a sample of 111 patients aged ≥ 65 years who underwent surgical repair of hip fractures in our hospital over a year period between January 2017 and December 2017. General data (age range, sex, Charlson Comorbidity Index (CCI), pluripathology and polipharmacy status) were collected from charts of every patient during the hospital stay. The study was approved by the Hospital Research Ethical committee.

Results

Age 65-74 yr: 13 (11.7%); 75-84 yr: 50 (45%); 85-94 yr: 35 (31.5%);

>95 yr: 13 (11.7%). Male accounted for 21.6 %. Pluripathology: 47.7%. The most prevalent conditions were stroke, dementia and motoneuron disease: 40, 5%, cardiovascular disease: 37.8%, moderate to severe chronic renal disease and anemia/malignancy: 20.7%. CCI <5: 26%, 5-9 > 72%, >9: 1.8%. Polipharmacy: 52.25%

Conclusion

Hip fractures are a public health problem worldwide and related to elderly suffering from chronic complex disease. The most important principle in limiting the possibility of perioperative complications is prevention by means of correct identification.

#2167 - Abstract

HOSPITALIZED ELDERLY PATIENTS: CLINICAL CHARACTERISTICS

Margarida Viana Coelho, Rui Marques Osorio, Domingos Sousa, Sergio Antunes Da Silva, Rita Martins Fernandes, Ana Isabel Rodrigues

Internal Medicine Department, Hospital de Faro, Centro Hospitalar Universitário do Algarve, Faro, Portugal

Background

Internal medicine departments of acute care hospitals admit many elderly adults who have particular characteristics, such as severe frailty and an elevated number of comorbidities. Frailty is defined by increased vulnerability, due to a cumulative decline of the homeostatic reserve. It is a problematic expression of population ageing, leading to a state where a stressor, like an acute disease, elevates the risk of adverse events.

Our objectives were to determine the frailty score of hospitalized elderly patients, the number of comorbidities in this population, the length of stay and readmission rates.

Methods

Retrospective study of all patients with 65-years or older, hospitalized in a ward of an internal medicine department of a tertiary-care teaching medical center in Portugal. We have studied electronic medical records from January 1, 2017 through December 31, 2017. For each patient we evaluated demographic characteristics, prior performance status, comorbidities, length of stay and readmission rates.

Results

We included 316 patients with an average age 76,81 years. Frailty score higher or equal to four was present in 67% of the patients. Only 33% had a Frailty score below four. The major causes of hospitalization were respiratory diseases corresponding to 40,4%, followed by circulatory diseases in 37,4% of the cases. The medium number of comorbidities was four per patient, with a predominance of diabetes, hypertension, atrial fibrillation and dyslipidemia. The length of stay was 18 days and there was an 9,8% rate of readmissions in patients with Frailty score above four versus 7,3% in patients with less severe Frailty.

Conclusion

Elderly hospitalized patients in our study had high Frailty scores and an elevated number of comorbidities. Respiratory and circulatory diseases were the most prevalent causes of hospitalization. This population has higher lengths of stay. Recurrent hospitalizations were more frequent in patients with severe Frailty score.

A STONE-AGE CONFUSIONAL SYNDROME

Margarida Lopes Madeira, Gonçalo Mendes, Mafalda Figueira, Daniela Félix Brigas, Francisca Santos, Diana Silva, Eugénio Nóbrega Dias, Clara Rosa, Ermelinda Pedroso
Centro Hospitalar de Setúbal, Setúbal, Portugal

Clinical summary

A 82 year-old female patient was admitted to hospital with confusion. Medical history included: chronic kidney disease, renal lithiasis and dementia.

In the Emergency Department, in addition to the confusion, the patient also had cough and expectoration, so she was diagnosed with pneumonia and transferred to the Internal Medicine Service. After 5 days antibiotic therapy the patient presented partial clinical improvement, maintaining the confusional syndrome. Due to the worsening of renal function, the introduction of a urinary catheter was attempted, which was made difficult by the presence of a foreign body: a stone measuring 6x3 cm. Removal the foreign body solved the confusional syndrome.

CUTANEOUS CRYPTOCOCCOSIS IN A PATIENT WITH HAIRY CELL LEUKEMIA

María Alejandra Pérez Ardila, Juan David Zuluaga, Henry Augusto Millán, Fredy Andrés Luna, Juliana Villa, Iván Enrique Noreña
Fundación Cardioinfantil, Bogotá, Colombia

Introduction

In patients with hematologic neoplasms, one of the complications is invasive fungal infection, which can occur in up to 10.2% of patients, with *Aspergillus* spp. and *Candida* spp. as the main microorganisms isolated. These infections are associated with a 40% mortality. *Cryptococcus* spp. infections may occur less frequently; in patients with hematologic neoplasms infected by this microorganism 45% are non-Hodgkin lymphomas; in this group, 10 cases have been reported in association with hairy cell leukemia.

Case description

We present the case of a 51-year-old man with a diagnosis of hairy cell leukemia who had not started chemotherapy. He presented with febrile neutropenia associated with micronodular lesions on chest tomography as well as parahilar and mediastinal adenopathies. *Mycobacterium tuberculosis* infection was established by a mediastinal lymph node biopsy. In the second phase of the tuberculosis treatment he was referred to the emergency department for a nodular lesion in the thigh which did not improve with antibiotic treatment and progressed to ulceration. Due to the suspicion of fungal infection a biopsy was performed showing structures compatible with *Cryptococcus* spp, the culture was positive for *C. Neoformans*. We did not have this isolation in bronchoalveolar lavage or in studies of cerebrospinal fluid. After receiving antifungal treatment and debridement the lesion improved.

Discussion

This corresponds to the 11 th case reported of *Cryptococcus* spp. infection in a patient with hairy cell leukemia. These patients have a higher risk of compromise in the central nervous system and disseminated forms so early detection is critical for the prognosis.

FUSARIUM INFECTION IN A PATIENT WITH LEUKEMIA: NOT ALL HYPHAE ARE ASPERGILLUS

María Alejandra Pérez Ardila, Juan David Zuluaga, Henry Augusto Millán, Fredy Andrés Luna Vela, Juliana Villa, Iván Enrique Noreña
Fundación Cardioinfantil, Bogotá, Colombia

Clinical summary

A 46 year old female patient with acute promyelocytic leukemia began chemotherapy with trans retinoic acid and idarubicin; the patient developed febrile neutropenia with erythematous lesions nodular lesions in the arms and legs thighs which were warm and indurated. The skin lesions were biopsied due to suspected disseminated fungal infection. The result of two blood galactomannan measurements was negative, with no microorganisms isolated from blood cultures. Management with amphotericin B was started without observing improvement in the lesions, with persistence of fever. The pathology showed structures compatible with *Fusarium* spp in the skin biopsy. Voriconazole was added to the treatment with which the lesions resolved. Fungal culture in the skin biopsy and blood cultures was negative.

#27 - Case Report

GENERALIZED TETANUS IN A PATIENT IN COLOMBIA: REMINISCENCE OF A FORGOTTEN DISEASE

María Alejandra Pérez Ardila, Juan David Zuluaga, María Valentina Perdomo, Henry Augusto Millán, Fredy Andrés Luna Vela, Ivan Noreña
Fundación Cardioinfantil, Bogotá, Colombia

Introduction

Clostridium tetani is an obligate anaerobic gram-positive microorganism causative of tetanus. Most cases occur in developing countries, the spores reside in the soil and can enter through skin lesions. The vaccine prevents the development of the infection and is found in Colombia's immunization plan. In 2018, 30 cases were confirmed in the country, with a rate of 0.06 per 100,000 inhabitants.

Case description

We present the case of a 39-year-old male patient from a rural area of Colombia who works in agriculture, without reliable data on the vaccination scheme. He consulted for 8 days of evolution with pain in the lower left limb, described as a sensation of weight that impeded gait, associated with paresthesias in this same location. 3 weeks earlier he had presented a wound with a wire in the left thigh. Physical examination showed episodes of contractions in the left thigh, trismus, and sardonic laugh, accompanied by episodes of tachycardia and profuse diaphoresis of short duration. Diagnosis of generalized tetanus was made so metronidazole was started. Alprazolam and magnesium sulfate were used to control the symptoms of dysautonomia and the severity of the spasms. After 2 days of treatment the patient presented progressive improvement of the symptoms until complete resolution.

Discussion

The diagnosis is based on the physical examination, history of immunization and clinical findings since laboratory tests can not confirm or exclude the disease. Mortality can reach 60%, so antibiotic treatment should be started early associated with immunization, wound management and physical therapy.

#28 - Case Report

VIBRIO CHOLERAЕ IN TRANSPLANT PATIENTS: NEW ENEMY IN SIGHT

María Alejandra Pérez Ardila, Juan David Zuluaga, Henry Augusto Millán, Fredy Andres Luna Vela, Ivan Noreña, Juliana Villa
Fundación Cardioinfantil, Bogotá, Colombia

Introduction

Diarrhea in recipients of solid organ transplants has a prevalence of 20-50%, the most common infectious causes are *C. difficile*, norovirus and CMV, other bacterial and protozoal infections are less frequent. We present two cases of infection by *Vibrio cholerae* in transplant patients.

Case description

Case 1

53-year-old male patient with a history of kidney and liver transplant 9 months ago; in ambulatory management with ciclosporin, mycophenolate sodium and prednisolone. He consulted for 1 week of evolution with liquid stools not associated with abdominal pain, without emesis, fever or chills. Filmarray was performed which detected: *Vibrio cholerae*, enterotoxigenic *E. coli* and *Shigella*. He received treatment with ceftriaxone for 7 days and a single dose of doxycycline with resolution of the gastroenteritis symptoms.

Case 2

62 years old female with a history of liver transplantation in 2007, in management with Tacrolimus and prednisolone. She consulted for 2-day diarrhea. In the Filmarray *Vibrio cholerae* was isolated, dicloxacillin was administered in a single dose with resolution of the symptoms.

Discussion

According to the WHO, in 2016, 132 121 cases of *Vibrio cholerae* were reported. In the Americas no cases reported were from Colombia. The reported cases ignite alarms about the sanitation system in the country. Taking into account the possibility of infection by this microorganism, the use of multiplex PCR is recommended as an approach in infectious gastroenteritis in this group of patients, with greater probability of detection of the causative micro-organism with respect to conventional methods (culture, EIA, single PCR).

#30 - Case Report

DISSEMINATED PARACOCIDIOIDOMYCOSIS IN AN IMMUNOCOMPETENT PATIENT

María Alejandra Pérez Ardila, Juan David Zuluaga, Henry Augusto Millán, Fredy Andrés Luna Vela, Juliana Villa, Ivan Noreña
Fundación Cardioinfantil, Bogotá, Colombia

Introduction

Paracoccidioidomycosis is a systemic disease caused by the fungus *Paracoccidioides brasiliensis* and *P. lutzii*, endemic in South America and Central America. The main risk factor is exposure in rural areas, with greater prevalence in farmers and ranchers. In Colombia, the incidence fluctuates between 0.5 -2.2 per 100 000 inhabitants.

Case description

69-year-old male patient, farmer from Bogotá. I have consulted for convulsive episodes, significant weight loss, vomiting and generalized hyperpigmentation. Hyponatremia and hyperkalemia were found. Brain MRI is performed in which focal lesions in the central nervous system are observed. On suspicion of metastatic disease, abdominal CT is performed in search of a primary focus that shows mass in the adrenal glands. Low cortisol levels associated with elevated ACTH were found, consistent with primary adrenal insufficiency. Subsequently, a biopsy of the suprarenal glands and central nervous system is performed, which confirms disseminated paracoccidioidomycosis. Antifungal therapy is started with amphotericin B in the induction phase and itraconazole in maintenance phase and treatment for adrenal insufficiency with prednisolone and fludrocortisone

Discussion

Paracoccidioidomycosis with simultaneous dissemination to the adrenal glands and central nervous system is an unusual presentation of the disease. In the chronic disseminated form, the involvement of the adrenal glands occurs in 40% of the cases, of which only 10% show clinical signs of adrenal insufficiency. The dissemination to the central nervous system has an incidence of 1.2-12.5%. This highlights the importance of making a thorough evaluation to patients this pathology to rule out infection in organs other than lung and mucous membranes.

#49 - Abstract

PERTUSSIS PREVALENCE AMONG ADULT PATIENTS WITH ACUTE COUGH ILLNESS

Ahmet Ilbay¹, Mine Durusu Tanriover¹, Pinar Zarakolu², Ezgi Çaliskan Güzelce¹, Hatice Bolek¹, Serhat Unal²

¹ Department of Internal Medicine, Hacettepe University, Faculty of Medicine, Ankara, Turkey

² Department of Infectious Diseases and Clinical Microbiology, Hacettepe University, Faculty of Medicine, Ankara, Turkey

Background

Pertussis (whooping cough) is a very contagious vaccine preventable disease that continues to persist despite high childhood vaccination rates. Pertussis in adults can be easily overlooked or misdiagnosed especially in acute cases with other probable diagnoses.

Methods

We aimed to determine the prevalence of pertussis in adult patients with acute cough illness. Secondly, we aimed to determine the clinical features of the pertussis cases. Internal Medicine and Pulmonary Medicine inpatient wards and outpatient clinics were screened between March 1 and June 22, 2018. Patients with cough duration between one week and one month were enrolled. Those who were on antibiotics for more than 5 days were excluded. Nasofaringeal swabs were taken from the patients who were eligible and who consented. Polymerase chain reaction (PCR) analyses were done to detect *B. pertussis*, *Bordetella parapertussis*, *Bordetella holmesii* and pertussis toxin genes.

Results

A total of 115 patients were enrolled and swabbed. According to CDC pertussis case definitions, 47.8% of the patients were diagnosed with probable pertussis. *Bordetella pertussis* PCR positivity was detected in four patients. We found the prevalence of pertussis as 3.5% in our cohort. All of the patients with pertussis had a history of paroxysmal cough with a mean duration of 20 days at presentation.

Conclusion

Pertussis continues to be a health problem for adults and may present with acute cough illness. The growing number of adult pertussis cases suggest that vaccination of children is inadequate to prevent pertussis and the concept of 'lifelong vaccination' should be strengthened.

#54 - Case Report

BACTEREMIA CAUSED BY MICROCOCCUS LUTEUS: A CASE REPORT

Diana Katherine Guavita Navarro, Vanessa Barbosa Prieto
University Hospital Mayor Mederi, Bogota, Colombia

Introduction

The *Micrococcus* genus, are gram positive cocci, strictly aerobic, commonly isolated in skin and nasopharynx. Usually they are not

associated to any disease, however they had been found in some literature cases of endocarditis, pneumonia and mostly in infection associated with medical devices.

Case description

We are presenting the case of a 19-year-old patient in a primary glomerulopathy study who performance of the outpatient renal biopsy. He later entered for 1 day of facial edema, fever and arthralgias. The echocardiogram is negative for endocarditis and the ultrasound of the abdomen shows a left inferior perirenal hematoma not susceptible to drainage. Extension studies document positive blood cultures for *Micrococcus luteus*. 14 days of antibiotic therapy with vancomycin are completed with resolution of bacteremia and satisfactory evolution.

Discussion

Bacteremia due to *M. luteus* is an unusual and important event given the antibiotic spectrum that should be used and the association of biomedical materials with the acquisition of the infection. This is the first case in a renal biopsy context, without permanent devices.

#56 - Case Report

NECROTIC PINNA INFECTION IN AN IMMUNOCOMPROMISED, ELDERLY PATIENT SECONDARY TO ASPERGILLUS

Andrew Groff, Chavely Valdés Sánchez, Rama Vunnam, Kaleigh Krill, Jennifer Saigal, Rohit Jain
Hershey Medical Center, Hershey, United States

Introduction

Aspergillus species is an opportunistic fungal infection that primarily affects pulmonary and central nervous system. Cutaneous infection is a rare presentation in an immunosuppressed individual. Prompt diagnosis and treatment is crucial to prevent disseminated infection.

Case description

Patient is a 76-year-old female with a history of rheumatoid arthritis on methotrexate and abatacept, who presented with a two-week history of painful papules and worsening erythema on her left ear despite one-week treatment with antibiotics and topical antifungal. Left ear was tender to palpation, edematous, and erythematous with several black eschars on the root of helix, lateral helix/antihelix, tragus, antitragus and lobule. Initial tissue biopsy showed invasive fungal infection with angioinvasion and surgical pathology revealed extensive necrosis of the skin, subcutaneous tissue, and cartilage angioinvasion. Septate fungal hyphae, most consistent with *Aspergillus* was identified. Tissue culture also grew 4+ *Stenotrophomonas maltophilia* and 2+ *Pseudomonas aeruginosa*. Immunosuppressed medications were held. Patient was treated with voriconazole, levofloxacin, and valacyclovir and wound care. Patient ultimately needed a skin graft from the left supraclavicular fossa.

Discussion

Aspergillosis is the second most common fungal infection, which often affects immunosuppressed individuals. Cutaneous presentation is rare, whereas patients presenting with pulmonary and central nervous system infections are common. Treatment for cutaneous aspergillosis involves voriconazole and surgical debridement to avoid potential disseminated disease, which is associated with high mortality. This case highlights the importance of including rare fungal infections in the differential diagnosis, when evaluating cutaneous infections in immunosuppressed patients.

#57 - Abstract

VASCULAR CATHETER-SITE CARE USING DIFFERENT SKIN ANTISEPTICS FOR PREVENTION OF CATHETER-RELATED BLOOD STREAM INFECTION: A META-ANALYSIS

Martin Kristoffer Elises Ogbac¹, Euodia Padilla Guinmapang², Frederick Elises Ogbac³

¹ C P Reyes Hospital, Tanauan, Philippines

² Perpetual Help Medical Center - Las Pinas, Las Pinas, Philippines

³ Ospital ng Makati, Makati, Philippines

Background

Infections are common complications among end-stage kidney disease (ESRD) patients undergoing hemodialysis (HD). Catheter-related blood stream infection (CRBSI) plays a significant role among ESRD patients.

CRBSI develops from bacterial colonization of the central venous catheter (CVC). Bacteria colonize the CVC with subsequent access to the blood by 3 routes – external surface of CVC through contaminated insertion site; internal surface of CVC through contaminated catheter hubs, injection ports and lines usually by the hands of healthcare workers or patients; contaminated intravenous drugs and nutritional preparations.

Several guidelines are proposed to prevent CRBSI including topical solutions to disinfect the access site. The 2 most commonly used solutions are chlorhexidine and povidone-iodine. This study aims to identify which is more effective in preventing CRBSI.

Methods

Several published randomized controlled trials about the different topical solutions in preventing CRBSI were identified using MEDLINE, COCHRANE, and EMBASE. The studies included were published from 1990 to 2018. The primary outcome was the incidence of catheter colonization and CRBSI.

Results

8 studies were included. 4902 central vascular insertions were identified. Patients enrolled in the chlorhexidine group had a catheter bacterial colonization incidence of 5.17% while those in the povidone-iodine group had 7.9%. Patients in the chlorhexidine

group had a CRBSI incidence of 2.9% while those in the povidone-iodine group had 4.6%.

Conclusion

Chlorhexidine is superior in preventing colonization of central vascular catheters compared to povidone-iodine. It is not clear, however, whether which intervention is more effective in preventing CRBSI as both groups demonstrated almost similar incidence of CRBSI.

#65 - Abstract

MANAGEMENT OF COMMUNITY ACQUIRED PNEUMONIA AT A TERTIARY-CARE TEACHING HOSPITAL

Mukhtar Alomar¹, Aseel Alsuwayegh², Nora Alkhayat², Daad Almuqbel², Ahmed Mayet²

¹ King Fahad Medical City, Riyadh, Saudi Arabia

² King Saud University Medical City, Riyadh, Saudi Arabia

Background

The implementation of community-acquired pneumonia (CAP) guidelines has led to shorten the duration of antibiotic treatment, reduce costs, and improve pneumonia-related morbidity and mortality. The adherence to CAP guidelines is varied in multiple international studies. This study aimed to evaluate the rate of adherence to Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS) guidelines 2007 for the diagnosis and treatment of CAP in hospitalized patients and to identify patient-related factors that may have influenced the adherence to treatment guidelines at our tertiary care teaching hospital.

Methods

The patients admitted with CAP; their charts were prospectively reviewed from April 1st until July 31st, 2018. The patients were eligible to participate in the study if they were >18 years of age and admitting diagnosis with CAP. Demographic data, comorbid conditions, smoking history, antibiotic culture and sensitivity, duration of antibiotic therapy, relevant laboratory data, and the diagnostic procedures were retrieved from the medical records. The proportion of patients who were treated according to CAP guidelines were recorded and compared with the most widely referenced guideline; IDSA/ATS for treatment of CAP. Descriptive statistics with frequency, percentages, mean, and standard deviation (SD) were used to illustrate the study results. Odds ratios (OR) of associated factors were also calculated.

Results

During the study period, 138 eligible patients were identified, 51.4% were female, their mean age was 59.1±20 years, and 49.3% had diabetes. Only 8% patients received a single initial empirical antibiotic whereas 92% received combination antibiotics. One hundred twenty-two patients received appropriate initial

empirical therapy on the first day of hospitalization; 9.4% patients received broad-spectrum antibiotics that were not warranted. Eighty-one 58.7% of the patients had a change in antimicrobial regimen during the hospital admission. Overall appropriateness of CAP management based on the composite of initial empirical treatment, duration of treatment, and switching antibiotics according to culture and sensitivity during the admission period was 58.0%; Severe respiratory illness was the most significant independent risk factor.

Conclusion

The study shows adherence to CAP guidelines for an initial empirical therapy on the first day of hospitalization was optimal whereas overall adherence to CAP management throughout the hospital stay was low.

#66 - Abstract

A CASE SERIES OF WEST NILE VIRUS NEUROINVASIVE DISEASE IN A TERTIARY CARE HOSPITAL IN ITALY IN 2018

Lorenzo Maria Canziani, Guendalina De Nadai, Federica Maria Pilar Tordato, Daria Pocaterra, Maddalena Casana, Paola Morelli
Istituto Clinico Humanitas, Milano, Italy

Background

In 2018, 2083 West Nile virus (WNV) infections have been reported in Europe.

Methods

In 2018, we diagnosed 4 cases of WNV neuroinvasive disease between week 33 and 36.

Case Description

Case 1

A 74-year-old man, known for epilepsy and cirrhosis, developed fever and seizures on week 33. On day 4 of hospitalization, the patient presented acute vision loss. WNV-IgM was positive on serum and CSF, WNV-RNA was present on CSF. Few days after, the patient was comatose and transferred in ICU. The patient acquired a multidrug-resistant *A. baumannii* skin colonization. The patient's mental status slowly improved, and he was rapidly discharged thereafter. The neurological sequelae at discharge included blindness (0.2/10 bilateral), left motor hemisindrome and postural instability with gait disturbances.

Case 2

A 80-year-old man presented with fever and stupor during week 34. He was known for gastric DLBCL on treatment with R-CHOP, ischemic cardiopathy, previous aortic valve substitution, and chronic HCV infection. The CSF appearance was typical for viral meningitis. A cerebral MRI revealed bilateral thalamic lesions, with hyperintensity on FLAIR. WNV-RNA was present only on serum, and WNV-IgM was negative. The patient died after few days.

Case 3

A 73-year-old man presented with fever, asthenia, diffuse aches, confusion, and hearing loss during week 36. He was known for diabetes mellitus, ischemic cardiopathy, hypertension, COPD, previous aortic valve substitution, past duodenal ulcer, chronic HCV infection. WNV-RNA was present on urine, WNV-IgM was present in serum and CSF. The mental status improved over days. One month after discharge, the patient reported persistent hearing loss and gait disturbances.

Case 4

During week 36, a 77-year-old otherwise healthy man was admitted because of persistent fever, lethargy and stupor. WNV-IgM was positive on serum and liquor. The mental status improved over days. At discharge, the patient presented gait disturbances that resolved within 3 months.

Conclusion

Between week 33 and 36 of 2018, we diagnosed 4 cases of WNV neuroinvasive disease. All patients were male, elderly, and reported multiple insect bites; significant comorbidities were present. Common traits were sudden onset of high-grade fever and stupor. One patient died, two of them partially recovered with notable disabilities, and one patient recovered completely. Our experience suggests that, as WNV disease incidence grows and the European population ages, more frail people will suffer from WNV neuroinvasive disease.

#76 - Abstract

DETERMINING THE NEUROCOGNITIVE STATUS AND THE FUNCTIONAL ABILITY OF PATIENTS TO SCREEN FOR HIV-ASSOCIATED NEUROCOGNITIVE DISORDER (HAND)

Ritika Agarwal, Ravinder Singh Aujla, Amit Gupta, Mukesh Kumar Agarwal

Chandra Laxmi Hospital, Ghaziabad, India

Background

To adequately evaluate the extent of neurocognitive impairment, a battery of neuropsychological tests is typically administered which are neither cost effective nor time efficient in the outpatient clinical setting as they often require several hours to complete and can be labor intensive requiring additional trained personnel to administer and correctly score. The aim of the study was to find a brief screening tool to identify those who would benefit from a full diagnostic evaluation.

Methods

The study enrolled 160 patients living with HIV (PLHIV) (80 pre-ART and 80 On-ART) fulfilling the inclusion and exclusion criteria. Neurocognitive assessment and an assessment of Functional ability was done by using the Montreal Cognitive Assessment (MoCA) and Lawton and Brody IADL Scale respectively.

Results

The study population consisted of 75.6% males and 24.4% females with mean age of 44±10 years. All of the subjects were literate (61.2% subjects had received up to high school level education), 76.2% were married. The mean duration of HIV infection among ART naive PLHIV and those on ART was 2±1.33 years and 3±2.10 years respectively. The mean CD4 count of the study population at study enrolment was 361.46±187.28 cells/mm³ (range 34 - 844 cells/mm³). Only 5% of subjects were found to have mild impairment in ADL with the most common affected domain being food preparation (50%). The overall prevalence of HAND in the study subjects was 52.5%. Of these, 47.5% had ANI and 5% had MND. In MoCA, the most frequently affected domains were Language (97.6%), visuospatial ability (92.9%) and memory (71.4%).

Conclusion

The prevalence of HAND is one in two PLHIV have neurocognitive dysfunction. The prevalence of HAND among Pre-ART subjects (i.e. ART naive) and those on ART is similar suggesting that neurocognitive impairment starts early in HIV infection. Older age (>40 years) and fewer years of formal education were important determinants statistically associated with the presence of HAND. HAND involves both cortical and subcortical regions of the brain with subcortical involvement being predominant. The most frequently affected neurocognitive domains were Language, Visuospatial function and Memory. Memory and Visuospatial function impairment had the most predictive potential for detecting the presence of HAND. HAND screening is recommended in all PLHIV at enrolment into care. Simple tools like MoCA can be used in busy outpatient settings by healthcare workers to screen for HAND.

WEIL SYNDROME - A CASE REPORT

Ana Beatriz Amaral, Pedro Duarte, Cláudia Rodrigues, Luís Dias
Hospital do Divino Espírito Santo de Ponta Delgada, Ponta Delgada,
Portugal

Introduction

Leptospirosis is a zoonosis caused by bacteria of the genus *Leptospira*. Clinically, it is very heterogeneous, varying from asymptomatic cases to severe and fatal forms.

Case description

A 22-year-old male farmer, went to the emergency department for a clinical presentation after 5 days with fever, associated with holocranial headache, myalgias, and dry cough with haemoptysis. On examination he was conscious, eupnoic, hypotensive and tachycardic, without other signs of relief. Chest X-ray without changes. Blood analysis with leukocytosis (12.89x10³/μL) with neutrophilia, thrombocytopenia (98x10³/μL) and CRP of 14 mg/dL. Blood samples for culture were taken and the patient was

medicated with ceftriaxone. Genetic investigation of leptospira, later confirmed the diagnosis. In a few hours there was clinical and laboratorial aggravation, with abundant haemoptysis, hemodynamic instability and respiratory difficulty. Chest x-ray showed bilateral cotton infiltrate. The patient was admitted to the Intensive Care Unit (ICU) in need of invasive mechanical ventilation, with the diagnosis of leptospirosis with septic shock and alveolar haemorrhage, requiring a blood transfusion. During ICU stay, jaundice, worsening of liver function and acute renal injury were observed. Transferred to the Internal Medicine ward after 6 days of hospitalization at the ICU. After three more days and clinical improvement, he was discharged and sent home.

Discussion

Weil Syndrome represents the most serious clinical manifestation of Leptospirosis, occurring in about 5-10% of patients. It is characterized by the appearance of jaundice, acute renal failure and haemorrhagic diathesis. The diagnosis of Leptospirosis often implies a high degree of suspicion and it is important to initiate treatment early.

ANGIOINVASIVE ASPERGILLOSIS CONFINED TO THE GASTROINTESTINAL TRACT WITH NEGATIVE GALACTOMANNANS DURING CYTARABINE TREATMENT

Julian Alberto Naranjo¹, Iván Noreña¹, Maria Cynthia Fuentes Lacouture¹, Joaquín Guerra²

¹ Fundación Cardioinfantil, Bogotá D.c, Colombia

² Fundación Cardioinfantil, Bogotá D.c, Colombia

Introduction

Angioinvasive aspergillosis in patients with febrile neutropenia is frequent. We present the case of a patient with acute myeloid leukemia (AML) who develops invasive aspergillosis confined to the gastrointestinal tract without pulmonary primary infection.

Case description

A 50-year-old patient is diagnosed with non-M3 AML. During treatment, he develops febrile neutropenia, treated with antibiotics. Because of persistent fever despite treatment, galactomannans, serum cultures and bronchoalveolar lavage were performed, which were all negative. On day 20 of chemotherapy with cytarabine and idarubicin, patient manifests abdominal pain and bloody diarrhea. Abdominal CT reveals concentric thickening of sigmoid colon, suggestive of ischemic colitis, and he is taken to surgical resection. On fifth day post-surgery, he develops bloody stools and changes in color of colostomy mucosa. On second surgery 3 wall perforations were found, intestinal pathology showed invasive aspergillosis on colonic walls. Treatment with voriconazole was given for 4 weeks, with adequate clinical and paraclinical evolution until now.

Discussion

Angioinvasive aspergillosis is a well-known complication among patients with febrile neutropenia. Nevertheless, gastrointestinal tract aspergillosis is still infrequent, and manifests usually as a dissemination from a primary pulmonary source, rarely being described as an isolated organ infection. It has also been linked to a possible mucosal damage secondary to cytarabine treatment. Opportune diagnosis is required to avoid complications and death.

#87 - Medical Image

A CASE OF INFLUENZA AND INVASIVE ASPERGILLOSIS IN A STEROID-TREATED PATIENT

Lorenzo Maria Canziani, Francesca Colapietro, Niccolò Stomeo, Luca Careno, Alberto Malesci, Maurizio Cecconi
Istituto Clinico Humanitas, Milano, Italy

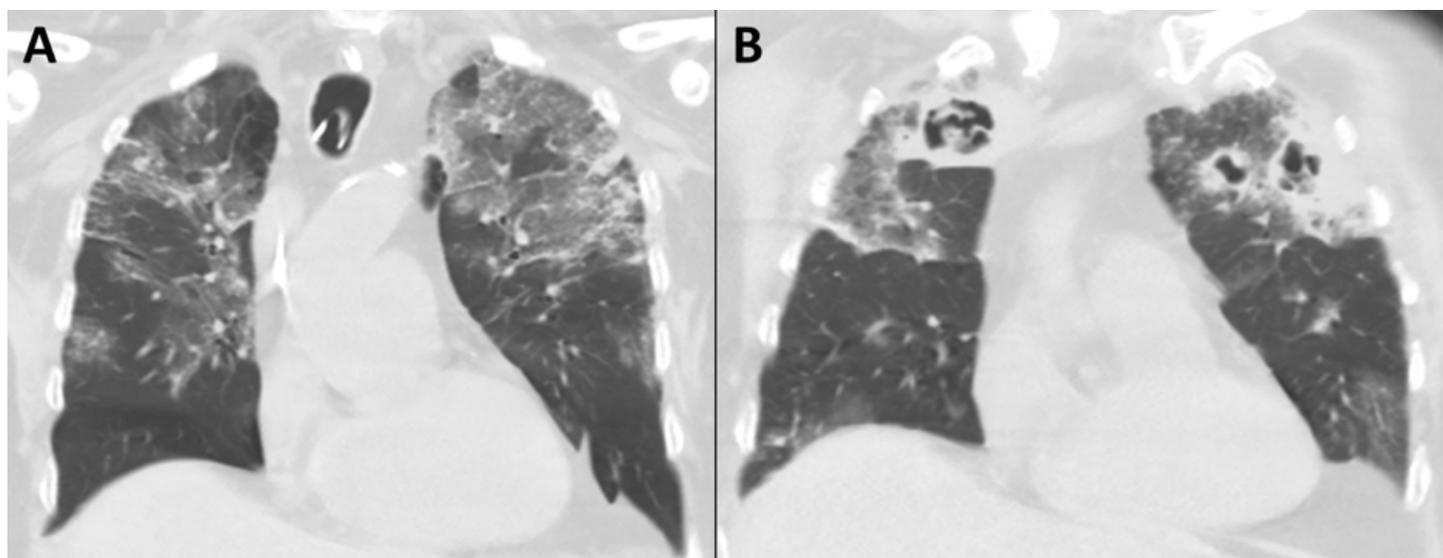

Figure #87. Panel A: Thorax CT scan at day 1 of hospitalization, with bilateral diffuse consolidation and ground-glass pattern, due to Influenza A. Chronic bullous emphysema with bronchiectasis are also present. Panel B: Thorax CT scan at day 22 of hospitalization: the ground glass opacities are reduced, but new excavated lesions with crescents were present bilaterally. Later, invasive aspergillosis is confirmed.

#120 - Case Report

ENDOBONCHIAL TUBERCULOSIS, A RARE MANIFESTATION OF TUBERCULOSIS

Ivo Cunha, Ricardo Pereira
Hospital Pedro Hispano, Matosinhos, Portugal

Introduction

Endobronchial tuberculosis (ET) is a rare manifestation of tuberculosis. The evolution and prognosis are varied from complete resolution to the formation of severe bronchial stenoses. The exact incidence of ET is not known, because bronchofibroscopy (BFC) is not performed in most cases of tuberculosis. BFC is the most important method in the early diagnosis of ET through the histological and microbiological study of biopsied material and to exclude local complications and other pathologies.

Clinical summary

A 61-year-old man presented to the ED with fever and dyspnea. His medical history included COPD and past spine surgery. For persistent back pain he received high dose steroids. Influenza A was rapidly diagnosed. The patient was not vaccinated and had a sick contact. A CT was compatible with secondary ARDS (Panel A). Despite two weeks of proper treatment, respiratory failure persisted. A CT showed multiple new excavated lesions with crescents (Panel B). Invasive aspergillosis was confirmed by Galactomannane positivity on serum. After 50 days, patient died of acute respiratory hemorrhage. Steroid use is associated with influenza and aspergillosis. Preventive measures as influenza vaccination for patients and households may help reducing complications and curbing hospitalization costs.

Case description

We report the case of a 78-year-old man with chronic obstructive pulmonary disease. He presented with 6 months of evolution of mucopurulent cough, asthenia, nocturnal hypersudoresis and weight loss of 18 kg. In this time interval he performed antibiotic therapy with temporary clinical improvement. Mycobacteria in sputum was negative. Tomography showed bronchiectasis in the right lower lobe. Analytically, only with a VS of 55 mm/1h and PCR of 47 mg/dL. Mantoux test with 20 mm induration. BFC showed a 3 cm polyp on the right main bronchus with no further changes. Histologically there was no evidence of malignancy and a lymphoplasmacytic inflammatory infiltrate without granulomas was observed. BAAR research was positive. Microbiological study of the bronchial lavage was negative. Koch bacillus by PCR was negative. Due to the degradation of the clinical status of the

patient, the presumptive diagnosis of ET was assumed and the initiation of antibiotic therapy was carried out, with a progressive improvement of the clinical status and resolution of complaints, supporting the definitive diagnosis of ET.

Discussion

In this case, the pedicled lesion manifested with cough and bronchorrhea. The location in the main right bronchus is the place most frequently involved. Bronchiectasis in the right lower lobe, ipsilateral to the pedicled lesion, is one of the reported complications of ET. BFC played a key role. In spite of the microbiological examinations of the bronchial lavage samples that this technique allowed to obtain, they did not allow the isolation of the BK, the performed biopsy was fundamental to exclude a malignant lesion and to obtain a sample where the study of BAAR by the ZN technique was positive. This last finding, plus the lymphoplasmacytic infiltrate, the constitutional syndrome and the evidence of previous contact with the Koch bacillus, ended up providing a presumptive diagnosis of TE. Tuberculosis should be considered in the differential diagnosis of endobronchial masses.

#123 - Case Report

LARGE CELL PNEUMONIA IN A IMMUNOCOMPETENT ADULT

Nuno Vieira E Brito, Ricardo Taborda, Paula Alcantara
Centro Hospitalar de Lisboa Norte, Lisboa, Portugal

Introduction

Parainfluenza virus infections are a season condition that mainly affect children with a benign course. Reinfection can occur through life causing complications in the elderly and in immunosuppressed individuals. Pneumonia due to parainfluenza 3 (HPIV3) is rare in adults with mostly severely immunosuppressed individuals afflicted

Case description

A 55 years old female with type 1 diabetes since 36, complicated multiple episodes of ketoacidosis was brought to the emergency department for nausea, vomiting and liquid diarrhoea with one week of duration progressing to altered mental status and ketoacidosis. She had no respiratory complaints or fever. She was polypneic, hypotensive, a pH of 6.9, ketonemia of 6.5 and blood sugar of 486. She had 96% saturation on ambient air. Blood work showed a leucocytosis (19,800 with 85.3% neutrophils), haemoconcentration, negative C reactive protein, chest x ray showed diffuse interstitial infiltrate with an exudative characteristic. During the following 3 days the patients condition progressed to Acute Respiratory Distress Syndrome. Blood cultures, serology and urinary test where negative for bacterial agents or atypical pneumonia agents. Autoimmunity was negative. She was transferred to the intensive care unit at day 3 of admission due to a need for non-invasive ventilation with 100% oxygen and underwent bronchoscopy showing thick secretions with bronchial

lavage with an inconclusive cytological study due to thickness and chest CT with diffuse alterations of the lung parenchyma, ground glass opacifications and crazy paving with spared zones. A second lavage showed the giant cells with foreign body aspect and a low cell count for immunotyping. Microbiology of the lavage was positive for HPIV3 in the respiratory virus screening. The patient evolved favourably with support therapy with no further need for non invasive ventilation and returned to the ward at day 10 and was discharged at day 17 undergoing respiratory therap

Discussion

HPIV3 Pneumonia is rare in immunocompetent adults. It has been described in immunosuppressed individuals and children with born immune deficiencies the mortality of large cell pneumonia induced by this virus is up to 40% and in some cases associated with a alveolar proteinosis, hypothesis that was raised in this patient by the thick lavage fluid and crazy paving. may occur related to duration and degree of hyperglycaemia as well as periods of ketosis causing alterations of lung surfactant as well as neutrophil defences.

#157 - Case Report

AUSTRIAN SYNDROME – A RARE CASE REPORT

Ana Sacchetti Corte-Real, Patrícia Vasconcelos, Daniela Madeira, Inês Bargiela
Hospital Prof. Doutor Fernando Fonseca, Amadora, Portugal

Introduction

Austrian Syndrome (AS) is the rare combination of meningitis, endocarditis and pneumonia, due to infection by Streptococcus pneumoniae (SP) and it's associated with a high death rate.

Case description

We report a 78-year-old diabetic, chronic alcoholic man who was admitted to our hospital because of 3-day history of fever and dyspnea. Physical examination revealed a GCS of 12, neck rigidity, hypotension, polypnea, fever and rales above left lower lob. Blood tests revealed leukocytosis and blood cultures were obtained. A chest x-ray revealed left consolidation, a brain CT scan was unremarkable, and cerebrospinal fluid (CSF) analysis was compatible with bacterial meningitis; Gram staining was positive. We started antibiotherapy (AB) with ceftriaxone. On the third day of hospitalization the patient developed a systolic cardiac murmur in auscultation. The echocardiography revealed aortic endocarditis. The blood and CSF cultures revealed multisensitive SP. We changed the AB to penicillin G and the patient was discharged after 6 weeks of this treatment. Vaccination for SP and alcohol abstinence was recommended.

Discussion

The predominant clinical presentation of SA is acute, with a rapid and aggressive clinical course. Alcohol consumption and

advanced age are major risk factors and the aortic valve (AoV) is predominantly affected, accordingly to our case. Pneumococcal endocarditis has become a rare disease since the introduction of penicillin but a large number of cases have been recently reported. We aim to emphasize that early diagnosis is essential for a prompt treatment and better prognosis. So, a high index of clinical suspicion is warranted.

#180 - Abstract

MULTI-RESISTANT MICROORGANISMS: CLINICAL AND EPIDEMIOLOGICAL CHARACTERISTICS OF INFECTIONS IN A DISTRICT HOSPITAL

Isabel Moreno Lucente, Vanesa Muñoz Mendoza, Francisco Javier Ramos Germán

Hospital Obispo Polanco, Teruel, Spain

Background

The indiscriminate global consumption of antibiotics has generated multiresistant microorganisms (MRM) in recent times. The infections produced by these germs are associated with an increase in mortality, as a consequence of the limitations in its treatment. The objective of this study is to know the clinical and epidemiological characteristics of patients infected or colonized by MRM.

Methods

The present is a descriptive, retrospective study based on the review of medical records. The histories were selected from the database of the Microbiology service, in relation to all MRM isolations between January 1st and December 31th, 2017.

The main MRM isolates were: *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Morganella morganii*, *Enterobacter cloacae*, *Pseudomonas aeruginosa* and *Staphylococcus aureus*. The main mechanisms of resistance observed were: beta-lactamases of extended spectrum (BLEE) production, beta-lactamases AmpC type production, carbapenemases production and resistance to methicillin.

Results

During the study period, 127 isolates of MRM belonging to 93 patients were detected. The average age was 72.7 years. In the 76.7% of the cases the isolates took place in elderly patients (over 70 years). The microorganism found most frequently was methicillin-resistant *S. aureus* (39.4% of cases), followed by *E. coli* BLEE (39.4%). Regarding the place of isolation, 28.6% occurred in the Internal Medicine and 26% in the Intensive Care Unit. As for the antimicrobial treatment, in 60.7% it was adjusted according to the isolated germ and the results of the antibiogram; in the remaining 24.4% the antibiotic regimen was not modified. The most frequently observed risk factors were: Diabetes Mellitus (34%), Chronic Kidney Disease (16%), institutionalization (16%), neoplasia (14.2%) and immunosuppression (12%).

Conclusion

In the health area of Teruel, MRM isolates are more frequent in the elderly population, probably related to comorbidity and previous hospitalizations. The main risk factors for the development of MRM infections were the existence of Diabetes Mellitus, Chronic Kidney Disease and institutionalization. The most frequently found MRM is methicillin-resistant *S. aureus*, followed by *E. coli* BLEE. Suboptimal prevention measures may encourage the dispersion of these MMRs, and improvement is imperative.

#190 - Case Report

EPIDURAL ABSCESS AS A COMPLICATION OF ACUTE OTITIS MEDIA

Vanesa Muñoz Mendoza¹, Isabel Moreno Lucente¹, Bianca Ridaura Aparisi²

¹ Obispo Polanco Hospital, Teruel, Spain

² Sagunto Hospital, Valencia, Spain

Introduction

Intracranial complications of acute otitis media (AOM) are unusual with an incidence of 0.36%, but potentially serious, with a high mortality rate. These complications occur frequently in children and young adults.

Case description

We report a case of a 21-year-old male with no history of previous disease.

He reported right otalgia in the last week, he was diagnosed of acute otitis media by his general practitioner and started antibiotic treatment with amoxicillin/clavulanate. In the last two days the patient refers severe holocranial headache and fever. He came to the emergency room, and in the physical examination was observed a bulge and translucent tympanic membrane and unilateral temporary hemianopsia. A cranial CT was performed and was found an epidural abscess in temporal lobe and right mastoiditis. It was initiated broad spectrum antibiotics (ceftriaxone- vancomycin and metronidazole) and was performed an eardrum perforation and drainage. A surgical intervention was performed with drainage of the abscess, but it was incidentally discovered a cholesteatoma.

Post-op period was positive, and antibiotics was progressively de-escalated, but some long-term damages persisted as hearing impairment.

Discussion

Epidural abscesses resulting from acute or chronic ear infections present most commonly as headache that is occasionally relieved by profuse otorrhea. Treatment requires surgical drainage after identification of the abscess on MRI or CT imaging, in addition to intravenous antibiotics.

Underlying cholesteatoma is common and is usually associated with intracranial abscess or sinus thrombosis.

#193 - Case Report

HUMAN IMMUNODEFICIENCY VIRUS PRIMAINFECTION – AN ATYPICAL PRESENTATION IN ADULT

Daniela Casanova, David Paiva, Ana Luisa Campos, Isabel Trindade, Jorge Cotter

Hospital Senhora da Oliveira, Guimarães, Portugal

Introduction

The human immunodeficiency virus (HIV) has a wide spectrum of clinical manifestations, it can present as a mononucleose-like syndrome. Given such unspecific symptoms, if the level of suspicion isn't high enough, the diagnosis may pass unknown. About 10-60% of the patients are asymptomatic during primoinfection. The remaining usually became symptomatic 2 to 4 weeks after exposition. With constitutional symptoms and lymphadenopathies being the most common manifestations, usually at the second week of disease, corresponding to the specific immune response to HIV.

Case description

A 50-year-old man, smoker of about 30 pack-year. Without other relevant clinical history. Admitted on the emergency department with cervical, axillary and inguinal lymphadenopathies detected in the previous 3 weeks. Associated with marked hypoacusia, with sudden onset, and weight loss. Blood analysis showed lymphocytosis and monocytosis. It was performed a computed tomography (CT) thoraco-abdominopelvic that showed multiple unspecific lymphadenopathies. From the virologic study performed positivity to type 1 HIV. Given the hypoacusia we performed a Cranial CT that described "extensive content with soft tissue density in the tympanic and mastoid cells, suggesting bilateral otitis media". Submitted to nasolaryngoscopy with observation of diffuse lymphoid tissue hypertrophy at the level of the pharyngeal cavum and dysfunction of the eustachian tube, compatible with bilateral effusive otitis media. It was initiated empiric antibiotherapy with amoxicillin/clavulanic acid, with gradual audition improvement. The patient had clinical discharge, referred to Infectious diseases evaluation in order to start antiretroviral therapy.

Discussion

In this case we have an atypical presentation of HIV primoinfection. Although lymphoid hypertrophy is more frequently described as manifestation in the pediatric population, where the lymphoid tissue hypertrophy of Waldeyer's ring leads to the obstruction of the eustachian tube, it is described as a rare manifestation in adults. Due to the presence of typical symptoms, such as lymphadenopathies and constitutional symptoms, the level of suspicion of acute viral infection was high enough to diagnose it on this case.

#209 - Case Report

WHEN IT'S NOT WHAT IT SEEMS... AN INSIDIOUS TB DIAGNOSIS

Valeria Giosia

University of Milan, Milano, Italy

Introduction

Extrapulmonary tuberculosis (TB) may have various clinical and radiological features.

Differential diagnosis includes neoplasia (eg: secondary lesions, lymphoma), infections, and infiltrative diseases like sarcoidosis.

Case description

A 78 year-old man with history of prostate cancer in remission after treatment with radio and chemotherapy, presented with recent onset of normocytic, normochromic anemia, mildly elevated inflammatory markers and significant weight loss.

Recent diagnosis of duodenal ulcer and suspect esophageal fistula was made. Histology was negative for cancer cells in duodenum, with evidence of erosive inflammation. The fistula was not confirmed at a following EGD.

CT-scan showed numerous necrotic-colliquating adenopathies in mediastinum, thorax, and abdomen, associated with pleural

and peritoneal effusion and different inflammatory lesions in the left lung. In addition, hypodense pancreatic lesions suspect for neoplasia were found, accompanied by findings suggestive of peritoneal carcinosis.

Given the high suspicion of lymph node and pancreatic neoplasia, an endoscopic US-guided FNAB was performed, negative for neoplastic cells but showing giant histiocytic, inflammatory cells. Serum tumor markers were negative.

The patient underwent bronchoscopy with BAL, resulted negative for cancer cells, with negative Ziehl Neelsen stain.

A thoracic wall biopsy was performed and histology revealed a granulomatous, giant-cellular, chronic inflammation. Given the granulomatous aspect of the lesion, a PCR for M. Tuberculosis was asked on the bioptic specimen, eventually resulting positive.

The patient was then promptly referred to the Infectious Disease Unit for appropriate treatment.

Discussion

Nowadays the incidence of extra-pulmonary TB is increasing in developed countries due to, among other causes, migratory flows, HIV "epidemics" and increased chemotherapy availability. Besides, signs at presentation may be similar to those of neoplastic and infiltrative diseases.

For these reasons, whenever biopsies are negative for neoplasia but signs of chronic and granulomatous inflammation are found, TB should be considered and looked for, with cultures and genome search on bioptic samples.

#231 - Case Report

OROPHARYNGEAL CANDIDIASIS (OC) IN IMMUNOCOMPETENT PATIENT

Miriam Vieitez Santiago¹, Alba María Martínez Torrón², Rita Nogueiras Álvarez², Ana Campo Ruiz¹, Raquel Jaso Tejera¹, Miguel Carrascosa Porras¹, María Elena Casuso Sáenz¹, Paloma Sánchez Junquera¹, Nuria Díez Herrán¹, Ana Isabel González-Torre González¹

¹ Hospital Comarcal de Laredo, Laredo, Spain

² Hospital Universitario Marqués de Valdecilla, Santander, Spain

Introduction

Oropharyngeal and esophageal candidiasis is an opportunistic infection that sometimes affects healthy individuals but is usually asymptomatic.

Candida albicans is the most common species that causes this type of candidiasis.

Case description

70-year-old female with a history of ex-smoking. Non-acute COPD with mild obstruction. Anxiety-depressive syndrome in treatment.

She goes to the internal medicine clinic for more than 6 months of evolution, odynophagia and oropharyngeal burning that makes it difficult to swallow. Associates weight loss of 20kg.

In the last 3 months, *Candida albicans* is isolated in the oropharynx and treated twice with fluconazole 100 mg daily for 14 days and once with itraconazole for 7 days. The patient persists symptomatically. Sampling is repeated at the end of the two antifungal guidelines with no response to treatment.

On physical examination: Weight: 53.1 kg; Size: 157 cm. IMC: 21,5. Small whitish lesion on the oral mucosa in the lateral area of the right cheek. Normohydrated. No adenopathy at any level. Rest of the exploration without significant findings.

Tests are performed for the study of general syndrome (complete analysis, chest X-ray, abdominal ultrasound, CT scan) and immunodeficiency (review of blood smears, serology, immunology) with all results being normal. Finally, gastroscopy is performed where there is no objective esophageal affection by candida.

Antifungigram is not performed in our hospital; but due to the patient's medical history, it is most probable that it was an oropharyngeal candidiasis (OC) resistant to treatment with azoles. That is why we contacted the Hospital Pharmacy service of the reference hospital for the preparation of oral amphotericin B treatment (100 mg every 6 hours for 14 days).

It is not a usual form of administration and should be done with a master formula to dose the appropriate and individualized dose into rinsing vials and swallow.

After treatment with oral amphotericin B she comes to the consultation for revision and the patient has clearly improved. Culture is taken, being this negative for fungi.

Discussion

The development of OC is almost always related to local factors, such as the use of broad-spectrum antibiotics or inhaled corticosteroids, xerostomia, or radiation treatment. But in our case there were none of these.

What has led us to consider in this case is the need to have an antifungigram. Since the patient would have been treated correctly from the beginning without presenting so much affection.

CONSTITUTIONAL SYNDROME IN SUB-SAHARAN WOMEN

Isabel Moreno Lucente¹, Jose Ignacio Mateo González², Magdalena García Rodríguez², Carlos De Andrés David², Bianca Ridaura Aparisi², Camilla Nardini²

¹ Hospital Obispo Polanco, Teruel, Spain

² Hospital General de Valencia, Valencia, Spain

Introduction

Emerging infectious diseases are those caused by an infectious agent recently identified and previously unknown, capable of causing public health problems at the local, regional or global level. The appearance of new infectious diseases is increasingly frequent. This is due to factors such as the global population increase, globalization, increasing antibiotic resistance and international travelers.

Case description

82-year-old woman from Equatorial Guinea, arrived in Spain 20 days ago, who consulted for constitutional syndrome of several months of evolution. She reports postprandial abdominal pain with sensation of abdominal distension and retrosternal burning discomfort that the patient describes as "sensation of ascending worms". It associates anorexia and denies fever or athermal sensation.

Physical examination revealed a large not painful hepatosplenomegaly. In lower extremities skin lichenified dermatitis and hypopigmented areas.

Analytics showed bicytopenia with hemoglobin <10bg/dl and thrombopenia <55000. Alterations in coagulation and high eosinophilia were also observed. The initial suspicion of malaria was not confirmed after a negative thick drop test, as well as PCR and antigen determinations for plasmodium with negative results. Determinations of retrovirus, hepatotropic viruses and mycobacterias were requested; so how serologies for schistosome, oncocerca and filaria's. Likewise, in order to rule out a possible lymphoproliferative process, a body CT was performed. The results of abdominal CT were hepatomegaly, 18 cm splenomegaly, dilation of splenic axis with collateral circulation and gastric varices. This correlated with the positivity for HCV. The patient left the hospital with an appointment in outpatient clinics to take the pending results. In external consultations, the patient was informed of the final diagnoses of hepatitis C, infestation by *Mansonella perstans* and positive serologies for oncocerca, where she received treatment with sofosbuvir/velpatasvir, ivermectin and dosicycline.

Discussion

Filariasis are parasitic diseases that mainly affect lymphatic tissue and skin, which are caused by nematodes. They need insects that act as vectors to infect humans, which are the only reservoir. They are usually neglected diseases that present high incidence and prevalence in underdeveloped and developing countries. The diagnosis is made with the detection of microfilariae blood/skin and it is important that the treatment must be individual and collective.

#246 - Case Report

MYCOPLASMA PNEUMONIAE: A CASE OF PERICARDIAL EFFUSION IN THE ABSENCE OF RESPIRATORY SYMPTOMS

Mariana Soares, Iolanda Oliveira, Margarida Massas, Sara Correia, Carmen Corzo, Conceição Barata

Hospital Espírito Santo de Évora, Évora, Portugal

Introduction

Mycoplasma pneumoniae is a common pathogen in pediatric population and young adults, mainly causing respiratory tract infection, as community acquired pneumonia. Extra respiratory involvement is rare, predominantly seen as arthralgia or myalgia, and can be explained by blood or lymphatic spread, as well as by direct invasion of structures in proximity to the lung. Cardiac

involvement is very rare, with a recognized incidence of 1-5%. We present a case of pericardial effusion, attributed to *Mycoplasma pneumoniae* infection, in a 49-years-old woman.

Case description

Patient admitted to a psychiatric ward due to nervous anorexia, observed by internal medicine owing to pancytopenia. She presented with no symptoms, other than psychiatric, namely fever, hemorrhage or respiratory manifestations. During etiologic study of pancytopenia, auto-immune and serologic testes were performed, with identification of positive IgM and IgG to *Mycoplasma pneumoniae*. Even though the low body weight could be attributed to nervous anorexia, we opted to perform CT of thorax, abdomen and pelvis, to exclude occult neoplasm. The CT showed only pericardial effusion and thickness of the left pleura, followed by an echocardiogram, confirmatory of a moderate pericardial effusion. The patient never presented respiratory symptoms, chest pain or hemodynamic compromise, reason why we didn't perform pericardiocentesis, nor started antibiotherapy, convinced of an immunologic mechanism of pericardial effusion. We started therapy with colchicine and continued to follow the patient in consult, for echocardiographic re-evaluation, keeping in mind the possible future need to start antibiotics.

Discussion

Pericarditis and pericardial effusion are rare manifestations of *Mycoplasma pneumoniae* infection, normally seen in patients with respiratory symptoms, with or without pulmonary infiltrates. In the presented case, pericardic involvement occurred in the absence of respiratory manifestations, only associated with left pleural thickness, which led us to believe in an immunological mechanism. This case elucidated us about the possible interest of including serologic testing of *Mycoplasma pneumoniae* in the routine evaluation of pericardial effusion, since treatment with non-steroid anti-inflammatories and antibiotics proved its efficacy. The implementation of this study could probably show a higher incidence of the association between these two entities.

TESTICULAR TUBERCULOSIS, REPORT OF 2 CASES

Flávio Pereira¹, André Terras Alexandre², Mariana Conceição³, Sara Raimundo², Ana Rafaela Araújo¹, Inês Ladeira⁴

¹ Centro Hospitalar do Baixo Vouga, Aveiro, Portugal

² Centro Hospitalar de Trás-os-Montes e Alto Douro, Vila Real, Portugal

³ Centro Hospitalar Centro Hospitalar Tondela, Viseu, Portugal

⁴ Centro Hospitalar Vila Nova de Gaia/Espinho, Vila Nova De Gaia, Portugal

Introduction

Tuberculosis is an infection caused by *Mycobacterium tuberculosis* that demands prolonged anti-bacillary treatment. Testicular tuberculosis is a rare presentation of genitourinary tuberculosis.

Case description

Case 1

67-year-old male presented with right-sided testicular swelling for 2,5 years. There was no history of respiratory or constitutional symptoms. He underwent left-sided orchidectomy which showed chronic granulomatous orchi-epididymitis with necrosis. Ziehl-Neelsen staining was negative. Interferon Gamma Release Assay was positive. Sputum sample mycobacterial culture was negative. Probable testicular tuberculosis was assumed and patient started rifampicin 600 mg, isoniazid 300 mg, pyrazinamide and mg ethambutol 1200 mg daily for 2 months followed by rifampicin 600 mg and isoniazid 300 mg daily for 10 months with complete response.

Case 2

48-year-old South African male presented with slight painful, right-sided testicular swelling for 2 months. There was no history of respiratory or constitutional symptoms. He was in Portugal for more than 20 years, but he had been in South Africa 2 years before the presentation for 2 weeks. Ultrasonography revealed a solid, vascularized lesion adjacent to the right epididymis. The patient underwent surgical resection which showed multiple epithelioid granulomas with central necrosis and mixed inflammatory cells. Both Ziehl-Neelsen staining and Xpert MTB-RIF Assay were negative. Sputum and urine samples were negative for alcohol acid fast bacilli. Thoracic computed tomography was normal. Probable testicular tuberculosis was diagnosed, and patient started rifampicin 600 mg, isoniazid 300 mg, pyrazinamide 1500 mg and ethambutol 1200 mg daily. Patient is currently in follow-up visits, in the intensive treatment phase.

Discussion

Although rare, testicular tuberculosis must be considered in the differential diagnosis of prolonged symptoms. Isolation of *Mycobacterium tuberculosis* is hard and most times impossible if the surgical piece is not sent to mycobacterial culture. Molecular testing improves diagnostic accuracy but is not always positive. Sometimes treatment has to be initiated when the diagnosis. Complete diagnostic confirmation is not always possible.

PRIMARY PSOAS PYOMYOSITIS WITH HIP JOINT SEPTIC ARTHRITIS AND METHICILLIN SUSCEPTIBLE STAPHYLOCOCCUS AUREUS (MSSA) BACTEREMIA

Than Zaw Oo

Singapore General Hospital, Singapore, Singapore

Introduction

Staphylococcus Aureus is a skin commensal bacteria and primary *Staphylococcus Aureus* infection without any apparent cause is uncommon. This case is reporting a case of a pre-morbidly healthy and immunocompetent patient who was diagnosed with primary psoas pyomyositis with hip joint septic arthritis and MSSA bacteremia.

Case description

A 65 years old Chinese female presented with left hip joint pain for one week and fever onset of one day duration. She was found to have MSSA bacteremia and MRI of the hip joint revealed a left psoas muscle abscess and septic arthritis. The intravenous injection of antibiotic was started and the abscess was drained under imaging guidance. Echocardiogram did not reveal any signs of infective endocarditis. She was discharged with prolonged course of intravenous antibiotic injection.

Discussion

This patient is an immunocompetent individual without any significant predisposing factors. The psoas pyomyositis was indolent and there was no other apparent cause that could be found. Pyomyositis is well known to have predilection for large muscle groups and often results in localized abscess formation as in our patient. In view of the indolent nature and insidious onset of such infection, high clinical suspicion is required to identify this disease entity.

#265 - Abstract

HOSPITALIZED Q FEVER: IMPACT ON THE SPANISH PUBLIC HEALTH SYSTEM (1998-2017)

Beatriz Rodríguez Alonso¹, Hugo Almeida², Montserrat Alonso Sardón³, Juan Miguel Manrique Pérez¹, José Luis Pérez Arellano⁴, Moncef Belhassen García¹

¹ Complejo Asistencial Universitario de Salamanca, Salamanca, Spain

² Unidade Local de Saúde da Guarda, Guarda, Portugal

³ Universidad de Salamanca, Salamanca, Spain

⁴ Hospital Universitario de Gran Canaria Doctor Negrín, Gran Canaria, Spain

Background

Q fever (QF) is a zoonosis caused by *Coxiella burnetii*. It is a "Notifiable Disease", worldwide expanded and with different clinical manifestations depending on the geographic zone. The impact of Q fever cases in-patients is not well described.

Methods

We present a retrospective descriptive study using the Minimum Basic Data Set (CMBD in Spanish) in patients admitted to hospitals of the National Health System (NHS) between 1998 and 2017 with a diagnosis of Q fever (International Classification of Diseases, ICD-9: 083.0.)

Results

We have found 4,214 hospitalized patients diagnosed with Q fever. The mean age was 50.1±19.3 years. 3,147 cases were men (74.7%). The period incidence rate was between 0.41 y 0.65 cases per 100,000 person-years, which was similar during all the period we have studied. It was a primary diagnosis in 3,071 cases (89.8%) and a second one in 1,143 (27.1%) of them. The mean hospital

stay was 22.8 ± 21.4 days. The lethality rate was 1.95 in 1998 and it was progressively increasing until 4.26 in 2015, even though the cohort of cases was stable between all these years. The states with higher incidence were Balearic Islands, Canary Islands and Cantabria, respectively. Nevertheless, the higher lethality rate took place in Asturias, Galicia and Cantabria, respectively. Each case admitted to hospitals diagnosed of Q fever had a mean health cost of $36.600.1 \pm 39.421.8$ € for the Spanish government. That means a total of 154,232,778.6 € during these twenty years.

Conclusion

Q fever is an endemic disease in our country and, though the notification is increasing, is underestimated yet. Despite of our health system has experienced an exponential development in the last twenty years; the mortality rate of this disease has been increasing progressively. Furthermore, it has a long hospital stay which implies an important economic cost to our health system.

PERITONEAL CARCINOMATOSIS OR SOMETHING ELSE?

Ana Andrade Oliveira, Joana Morais, Inês Burmester, Olga Pires, Isabel Marques, Filipa Rodrigues, Mariana Devesa, Maria João João Regadas, Paulo Gouveia

Hospital de Braga, Braga, Portugal

Introduction

Peritoneal tuberculosis is a rare entity, being the 6th most frequent location of extrapulmonary tuberculosis. Its diagnosis is difficult given the absence of specific clinical and imaging characteristics, is sometimes confused with peritoneal carcinomatosis.

Case description

A 64-year-old woman with hypothyroidism and history of nephrectomy due to recurrent pyelonephritis was referred from primary care after an abdominal CT raised the possibility of peritoneal carcinomatosis ("adenopathies at the cardiophrenic angles, peritoneal effusion with nodular densification and small peritoneal implants"). She reported peri-umbilical abdominal pain and discomfort in the last 3 months and 5 kg of weight loss in the last month. She denied fever, night sweats or other constitutional symptoms. Laboratory tests showed normocytic normochromic anemia and positive CA-125 (100 U/ml). The first paracentesis showed a predominance of neutrophils. Endoscopy, colonoscopy, pelvic-US, mammography and mammary-US all showed no abnormalities. PET-CT was consistent with carcinomatosis showing increased uptake in supra and infra-diaphragmatic adenopathies and peritoneum. Then, she underwent an exploratory laparoscopy, unmasking a peritoneum with a raspberry appearance. Samples of peritoneum were taken which revealed a necrotizing granulomatous inflammation. A new paracentesis was done that revealed a high adenosine deaminase and 56% of lymphocytes. The Interferon Gamma Release Assay to detect *Mycobacterium tuberculosis*

infection (IGRA) was also positive. Peritoneal tuberculosis was at that time assumed as the final diagnosis, and antibiotic therapy was initiated. Shortly after that, her symptoms started to improve and she regained her weight.

Discussion

Many non-neoplastic conditions can mimic peritoneal carcinomatosis, such as tuberculosis. The histology samples with necrotizing granulomatous inflammation, high adenosine deaminase, and positive IGRA confirmed the diagnosis of peritoneal tuberculosis, even though it wasn't one of our first hypothesis.

STREPTOCOCCUS GALLOLYTICUS ENDOCARDITIS IN A PATIENT WITH COLON CANCER

João Aurélio, Joana Nascimento, Tiago Vasconcelos, Pedro Rouxinol, Marta Duarte Segurado, Raquel Pinho, Helena Rita, Luisa Arez

Centro Hospitalar Universitario do Algarve, Portimão, Portugal

Introduction

Several associations between bacteria and gastrointestinal neoplasia have been reported, with the best documented relationship being streptococcus Bovis, primarily *S. Gallolyticus* subspecies, and colon cancer.

Case description

We describe the case of a 65 years old male, previously diagnosed with neoplasia of ascending colon, admitted for pre-surgical care. On admission patient presented with bad general status, weight loss (>10% in 3 months) fever, elevated inflammatory markers, Leucocyturia (initially diagnosed as urinary tract infection). Started empiric antibiotic therapy, with previous collection of blood and urine cultures.

In the fifth day of admission, the patient developed signs and symptoms of heart failure, blood cultures were positive for *Streptococcus gallolyticus* which prompted the realization of an echocardiography that showed aortic valve vegetations. Based on the diagnosis of infective endocarditis antibiotic was switched to ampicillin + gentamicin.

During therapy Patient developed acute heart failure in context of severe aortic valve insufficiency, leading to urgent valvulotomy. After surgery and resolution of acute status, patient was referred for Surgery consult for new evaluation and if possible curative surgery.

Discussion

Despite the strength of the correlation between *Streptococcus gallolyticus* infective endocarditis and colon cancer, it is source of debate whether *S. gallolyticus* bacteremia is consequence of the gastrointestinal lesion or a trigger of colorectal neoplasia.

Currently both European Society of Cardiology (ESC) and

American Heart Association (AHA) recommend rulling out gastrointestinal neoplasia in patients diagnosed with *S. bovis* infective endocarditis or bacteremia. ESC adds that in the absence of any tumour, schedulling annual colonoscopy is highly suggested.

#289 - Abstract

DO WE COMPLY WITH THE TREATMENT RECOMMENDATIONS FOR INFLUENZA?

Victoria Palomar, Sara Muñoz, Victor Madrid, Carlota Tuñón, Luis Miguel Palomar, María Montserrat Chimeno
Complejo Asistencial de Zamora, Zamora, Spain

Background

During influenza activity, influenza testing should be obtained in the following patients: immunocompromised/at high risk for complications outpatients or patients who require hospitalization with acute onset of respiratory symptoms with or without fever; patients requiring hospitalization with acute respiratory illness or with acute worsening of chronic cardiopulmonary; individuals who develop acute onset of respiratory symptoms with or without fever, after hospital admission.

IDSA's guidelines recommend prompt initiation of antiviral therapy for individuals with suspected or confirmed infection and any of the following features: patients hospitalized with influenza or outpatients with severe or progressive illness, regardless of illness duration prior to hospitalization and outpatients who are at high risk of complications.

Methods

Observational, cross-sectional and descriptive study to describe the patterns of hospitalized patients for suspected influenza in a B-level Hospital between the 2017-2018 and 2018-2019 seasons. We collect the diagnostic tests for influenza A or B by PCR for in pharyngeal swabs, between October 2017-February 2018 and October 2019-February 2019 requested at the Zamora Healthcare Complex in charge of Internal Medicine and Pulmonology.

The following variables are analyzed: sex, age, flu CPR and treatment with oseltamivir.

Results

In first season, 195 tests were requested against 268 in second season.

In season 2017-2018, 80.5% were requested in patients > 65 years. 74 were positive, of which 23% for influenza B and 14% for influenza A. 32.3% were treated with oseltamivir, 20% with negative test result, 50.5% influenza A and 28.5% influenza B.

In season 2018-2019, 79% were requested in patients > 65 years. 103 were positive exclusively for influenza A. 36% were treated, 20.6% with negative results and 79.3 % influenza A.

Conclusion

1. In season 2018-2019, 73 more tests were requested, obtaining 29 positive tests more than the previous season.

2. In season 2018-2019, 100% of the positive tests were for influenza A compared to 14% of the previous season.
3. Regarding the age and months with the highest incidence of tests requested, the findings were similar, prevailing at > 65 years and January and February.
4. In both seasons the negative results are similar as well as the percentage of treated patients.
5. All patients who require admission and suspected influenza have conditions to start treatment with Oseltamivir, however 2/3 do not receive treatment.

#290 - Abstract

ARTIFICIAL NEURAL NETWORKS APPLIED TO BODY TEMPERATURE ANALYSIS AND FEVER FORECASTING

Borja Vargas¹, Juan Carlos Colás², José Manuel Mira², Paula González¹, Manuel Varela¹, Luis Vigil¹, María José Fernández-Cotarelo¹, Óscar Vázquez¹, Ana Colás³

¹ Hospital Universitario de Móstoles, Móstoles, Spain

² Universidad Politécnica de Madrid, Madrid, Spain

³ Hospital Universitario 12 de Octubre, Madrid, Spain

Background

Artificial neural networks (ANN) are a powerful statistical tool for classification purposes. Although not common in clinical practice, body temperature monitoring provides a substantial amount of information about thermoregulation that could be used to forecast fever. ANN might be an appropriate strategy in this setting.

Methods

Body-temperature time series were obtained from 17 patients admitted to a general Internal Medicine ward because of fever, accounting for 21233 measurements. Body temperature was measured in the external auditory canal (EAC) and over the forearm skin. Several surrogate variables were obtained and included in the ANN as predictors.

Assessment of fever prediction was based on the ability of the model to classify temperature measurements as "pre-febrile" if temperature in the EAC reached 38°C sixty minutes later, and as "not pre-febrile" otherwise. The training set included 14800 measurements and the validation set, 6433.

Classification accuracy of the ANN model was evaluated with the area under the receiver-operating curve (AUC), and a confusion matrix was created for different thresholds, in order to choose the most convenient model for clinical purposes.

Results

The AUC of the model was 0.871. For a threshold of 0.3, the ANN had a sensitivity of 61.42% (269 out of 438), a specificity of 87.87% (5268 out of 5995), and a global accuracy rate of 86.07%. For a threshold of 0.6, the sensitivity was 22.15% (97 out of 438), the specificity 97.23% (5829 out of 5995) and the global accuracy rate 92.12%. On the 6433 measurements of the validation series,

there were 7 fever peaks, 5 of which were forecasted by the ANN model, with only one false positive (one peak was predicted with no fever in the following minutes).

Depending on the threshold established, anticipation to fever spikes ranged from a minimum of 14 minutes to a maximum above 90 minutes.

Conclusion

Artificial neural networks (ANN) are a powerful statistical tool for classification purposes. Although not common in clinical practice, body temperature monitoring provides a substantial amount of information about thermoregulation that could be used to forecast fever. ANN might be an appropriate strategy in this setting.

#304 - Case Report

SPONDYLODISCITIS: ABOUT A CLINICAL CASE

Margarida Melo De Morais, Maria Jesus Silva

Centro Hospitalar Lisboa Norte, Lisboa, Portugal

Introduction

Spondylodiscitis is an infectious disease of the spinal column, involving the vertebral bodies and intervertebral discs, more commonly the lumbar structures.

Fever, back pain and neurological deficits are described as frequent findings.

The diagnosis is often delayed, probably due to an indolent presentation of the disease, with unspecific symptoms, such as asthenia.

Tubercular spondylodiscitis is the most common form of musculo-skeletal tuberculosis.

Despite the aetiology, this is a potentially fatal condition, which requires a long and challenging treatment period and a long stay at the hospital.

Case description

We expose a case of a 70 years old man, who presents, 3 weeks prior to the hospital commitment, with right testicle pain, symmetric loss of strength of the lower limbs and urinary retention.

The patient also referred asthenia and anorexia, associated with a loss of 6 Kg in a period of 2 months.

Initial laboratory works showed an elevated CRP and microcytic anaemia. Spondylodiscitis involving L4-L5 and L5-S1 levels was documented in a CT scan.

The patient was submitted to multiple empirical antibiotic cycles, once we could not identify an infectious agent, with no success.

Anti-tubercular therapy was instituted, with clinical, laboratory and imagological improvement.

Discussion

Despite the lower mortality rate associated with this entity after the introduction of antibiotherapy, spondylodiscitis still presents as a significant challenge in terms of treatment and accompanying potential morbidity.

The identification of an infectious agent is very important to a better management of the patient.

Infection by *Mycobacterium tuberculosis* should be considered.

#305 - Abstract

ASSESSMENT OF CARDIOVASCULAR RISK AND ARTERIAL STIFFNESS IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS

Mariana Sousa Freitas, Clarisse Coelho Neves, Helena Jacinto Sarmento

Senhora da Oliveira Guimarães Hospital, Guimarães, Portugal

Background

Several studies suggest that patients infected with human immunodeficiency virus (HIV) under highly active antiretroviral therapy (HAART) have higher cardiovascular risk than general population. Arterial stiffness is an independent predictor of cardiovascular events and can be measured through PWV (carotid-femoral pulse wave velocity). The HIV role on arterial stiffness is a controversial issue. The objectives of this study were to characterize a sample of patients infected with HIV under HAART regarding the cardiovascular risk; to compare PWV values of this group of patients with uninfected controls; and to investigate predictors of PWV in HIV-infected group.

Methods

PWV was measured and data was collected from a sample of 125 HIV-infected patients under HAART. PWV measurements in study group were compared with those in a control group of 250 subjects similar in sex, age, prevalence of hypertension and type 2 diabetes mellitus (DM). A linear regression model was constructed to identify predictors of PWV in HIV-infected group.

Results

In the HIV-infected group, composed mostly by men, the mean age and respective standard deviation were 48.6 ± 11.6 years. In this group, 112 individuals (89.6%) presented moderate to very high cardiovascular risk. Significant differences were found in median PWV between HIV-infected and control groups (8.56 vs. 8.00 m/s, $p = .002$). Age, peripheral systolic blood pressure, presence of DM, amount of alcohol consumed and current CD4+ T cell count were independent predictors of PWV in HIV-infected group.

Conclusion

The group of HIV-infected patients showed higher cardiovascular risk and arterial stiffness measurements than general population. PWV may be an important predictor of subclinical cardiovascular disease in HIV-infected patients.

#310 - Case Report

A FATAL STRONGYLOIDES STERCORALIS HYPERINFECTIOIN SYNDROME IN A HIV-INFECTED PATIENT

Vicente David De La Rosa Valero, María Del Carmen Hernández Murciano, Elena Del Carmen Martínez Cánovas, Carlos Báguena Pérez-Crespo, Ignacio Iniesta-Pino Alcázar, Gabriel Puche Palao, Ana Martín Cascón, Mónica Martínez Martínez, Lia Ferraro, Enrique Bernal Morell

Hospital General Universitario Reina Sofía De Murcia, Murcia, Spain

Introduction

Strongyloides stercoralis is a parasite that is endemic in tropical and subtropical regions and occurs sporadically in temperate areas. The clinical presentation of strongyloidiasis varies from asymptomatic infection and mild symptomatic abdominal disease to fatal disseminated infection in immunosuppressed patients.

Case description

A 46-years-old man, originally from Dominican Republic, has lived in Murcia (Southeast of Spain) for 16 years. Doesn't refer medical history of interest. He comes to our emergency department due to a three-days history of diarrhea and vomiting, consisting of three vomits of alimentary content and eight liquid stools daily without pathological products. On physical examination, he was hypotensive (BP 100/60), tachycardic (111 rpm), with signs of muco-cutaneous dehydration, with normal cardiorespiratory auscultation and abdominal palpation. The emergency department's analysis showed severe hyponatremia (sodium 115), so admission to Internal Medicine was decided after sodium replacement. The next day in hospitalization plant, he becomes unstable with a severe respiratory distress, so he enters in ICU. There, he was found to be hypotensive (BP 78/35) and hypoxemic (PaO₂ 63.7 mmHg) with muco-cutaneous pallor and malaise, so intensive fluid therapy is initiated and is intubated. Chest X-ray showed an alveolar-interstitial pattern encompasses both lungs and analysis showed an anemia (Hb 4.9) with lymphopenia (300). Given the clinical picture of respiratory distress along with severe anemia, there was a suspicion of pulmonary hemorrhage, so transfusions of six packed red blood cells are started and after that, an emergency bronchoscopy is performed. This showed large amounts of mucus mixed with abundant red blood and *S. stercoralis* larvae could be seen microscopically. It was performed an HIV test was finally positive with CD4 lymphocyte levels of 20. Subcutaneous ivermectine and intravenous meropenem were started but without clinical improvement, so he died in a few hours due to massive pulmonary hemorrhage. No retroviral treatment was started due to the risk of immune reconstitution syndrome.

Discussion

S. stercoralis is capable of staying in same host for a long time (even several decades) due to its self-infectation cycle. If an immunosuppressive factor interferes (HIV infection, for example) favors a pattern of disseminated hyperinfection affecting several systems by invasion of them (in our case, pulmonary and digestive).

#313 - Case Report

A RARE CASE OF ACTINOMYCES EMPYEMA IN AN IMMUNOCOMPETENT YOUNG MALE

José Miguel Lessa Silva, Joana Gomes Cochicho, Sara Viana, Rita Parente, Ruben Raimundo, Adriano Pacheco Mendes, Ana Neves, André Mendes, Tamar Nunes Garcia, Isabel Soles
Hospital Doutor José Maria Grande, Portalegre, Portugal

Introduction

We present a rare clinical report of a complicated respiratory infection by an isolated *Actinomyces* bacteria.

This is a rare clinical entity, with no pathognomonic presentation, which embraces a diagnostic challenge, easily confused with other entities.

Case description

A 34-year-old male, rubber industry worker and smoker, with a clinical record of multiple pulmonary infections treated with short course oral antibiotic therapy; presents at emergency service with a 3 week's history of pleuritic chest pain and dyspnea. The patient also referred nocturnal fever, night sweats and cough with purulent sputum.

At admission, presented hemodynamically stable, with reduced breath sounds in the left lung, and type 1 respiratory insufficiency. Chest X-Ray showed lower left pulmonary hypotransparency, and CT-scan documented a massive multi-loculated left pleural effusion with condensation.

Laboratory analysis demonstrated increased inflammatory markers, with a negative serological study.

The patient was submitted for empirical antibiotic treatment with levofloxacin, but due to lack of response in the initial 48 hours Clindamycin was added with a good response.

Initially a thoracentesis was performed and the analyses of the pleural fluid obtained was suspicious of empyema, and culture in aerobic environment was negative.

Taking into account the extension of pleural effusion and its possible consequences in a young patient, a video-assisted thoracic surgery with pleural debridement was performed.

It was then that the microbiology of the pleural fluid obtained revealed the growth of *Actinomyces meyeri* and *Streptococcus intermedius*.

Discussion

Actinomyces genus are anaerobic Gram-positive bacilli that typically reside in mouth, gastrointestinal tract, and reproductive system.

The diagnosis and isolation of this pathogen is challenging, taking into account its rarity and resemblance with other chronic suppurative chest diseases and malignancy.

The nonspecific history, physical examination, radiological and laboratorial findings presented in this patient lead us to an extensive differential diagnosis.

This remarkable case shows the importance of a holistic approach to the clinical investigation of an extensive differential diagnosis, natural to an internal medicine clinician.

#317 - Case Report

A YOUNG NEUTROPENIC PATIENT WITH GLYCOGEN STORAGE DISEASE AND DIARRHEA: AN UNDERLYING INFECTION OR HER PRE-EXISTING CROHN'S LIKE DISEASE?

Chryssi Koliaki, Christos Siafarikas, Aristeidis Tsakanikas, Aggeliki Georgopoulou, Maria Mylona

1st Department of Propaedeutic & Internal Medicine, Laiko General Hospital, Athens University Medical School, Athens, Greece

Introduction

Clostridioides difficile infection (CDI) is a symptomatic infection due to the spore-forming bacterium *Clostridioides difficile*, which makes up about 20% of cases of antibiotic-associated diarrhea. Symptoms include watery diarrhea, fever, nausea and abdominal pain, while its complications may include pseudomembranous colitis, toxic megacolon with or without perforation and sepsis. Herein we present an interesting case of a neutropenic patient with prior history of glycogen storage disease-associated Crohn's like colitis, who presented with diarrhea and histologic diagnosis of CDI.

Case description
